CURRENT SURGICAL THERAPY

11th EDITION

JOHN L. CAMERON
MD, FACS, FRCS (Eng) (hon), FRCS (Ed) (hon), FRCSI (hon)
The Alfred Blalock Distinguished Service Professor
Department of Surgery
The Johns Hopkins Medical Institutions
Baltimore, Maryland

ANDREW M. CAMERON
MD, PhD, FACS
Associate Professor of Surgery
Surgical Director of Liver Transplantation
Department of Surgery
The Johns Hopkins Medical Institutions
Baltimore, Maryland

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

LIST OF CONTRIBUTORS

Herand Abcarian, MD
Professor of Surgery
University of Illinois at Chicago
Chicago, Illinois

HEMORRHOIDS

THE MANAGEMENT OF RECTOVAGINAL FISTULA

Raafat Z. Abdel-Misih, MD, FRCS Edin, FRCS Eng, FACS
Department of Surgery
Christiana Care Health System
Newark, Delaware

THE MANAGEMENT OF BENIGN GASTRIC ULCER

Sherif R. Abdel-Misih, MD
Assistant Professor of Surgery
Wexner Medical Center at The Ohio State University
Arthur G James Cancer Hospital
Columbus, Ohio

THE MANAGEMENT OF BENIGN GASTRIC ULCER

Fizan Abdullah, MD, PhD
Johns Hopkins University
Baltimore, Maryland

REPAIR OF PECTUS EXCAVATUM

Christopher J. Abularrage, MD, FACS
Director, Multidisiplinary Diabetic Foot & Wound Clinic
Assistant Professor of Surgery
Division of Vascular Surgery and Endovascular Therapy
The Johns Hopkins Hospital
Baltimore, Maryland

CAROTID ENDARTERECTOMY

David B. Adams, MD, FACS
Professor of Surgery
Head, Section of General and Gastrointestinal Surgery
Medical University of South Carolina
Charleston, South Carolina

THE MANAGEMENT OF PANCREATIC PSEUDOCYST

Reid B. Adams, MD
Claude A. Jessup Professor of Surgery
Chief, Division of Surgical Oncology
Chief, Hepatobiliary and Pancreatic Surgery
Director, Gastrointestinal Oncology Program
Department of Surgery
University of Virginia Health System
Charlottesville, Virginia

GALLBLADDER CANCER

Suresh Mitu Agarwal, MD
Associate Professor of Surgery
Section Chief, Trauma, Acute Care Surgery, Burn, and Surgical Critical Care
Department of Surgery
University of Wisconsin School of Medicine and Public Health
Madison, Wisconsin

TRACHEOSTOMY

Rizwan Ahmed, MD
Division of Surgery
Johns Hopkins Bayview Medical Center
Baltimore, Maryland

THE MANAGEMENT OF COMMON BILE DUCT STONES

Steven A. Ahrendt, MD
Associate Professor of Surgery
University of Pittsburgh
Pittsburgh, Pennsylvania

PRIMARY SCLEROSING CHOLANGITIS

Nita Ahuja, MD
The Johns Hopkins Hospital
Baltimore, Maryland

THE MANAGEMENT OF ADRENAL CORTICAL TUMORS

Gilbert Aidinian, MD, FACS, RPVI
Chief, Vascular and Endovascular Surgery
William Beaumont Army Medical Center
El Paso, Texas;
Assistant Professor of Surgery
The Norman M. Rich Department of Surgery
The Uniformed Services University of the Health Sciences
Bethesda, Maryland

THE DIABETIC FOOT

Daniel S. Alam, MD, FACS
Cleveland Clinic
Cleveland, Ohio

FACIAL TRAUMA: EVALUATION AND MANAGEMENT

Scott P. Albert, MD
Surgical Oncology Fellow
The Ohio State University
Columbus, Ohio

THE MANAGEMENT OF PANCREATIC ISLET CELL TUMORS EXCLUDING GASTRINOMAS

Marco Ettore Allaix, MD
Department of Surgery
University of Chicago Medical Center
Chicago, Illinois;
Department of Surgical Sciences
University of Torino
Torino, Italy

TUMORS OF THE ANAL CANAL

Benjamin O. Anderson, MD
Surgical Oncology Section, Division of General Surgery
Department of Surgery
University of Washington
Seattle, Washington

BREAST RECONSTRUCTION FOLLOWING MASTECTOMY: INDICATIONS, TECHNIQUES, AND RESULTS

Mark P. Androes, MD
Division of Vascular Surgery
Greenville Hospital System Clinical University
University of South Carolina School of Medicine
Greenville, South Carolina

PROFUNDA FEMORIS RECONSTRUCTION

George Apostolides, MD, FACS, FASCRS
Program Director
Greater Baltimore Medical Center
Baltimore, Maryland

HEREDITARY POLYPOSIS SYNDROMES

George J. Arnaoutakis, MD
Senior Resident, Department of Surgery
The Johns Hopkins University School of Medicine
Baltimore, Maryland

THE MANAGEMENT OF PRIMARY CHEST WALL TUMORS

Kengo Asai, MD, PhD
Hepatobiliary Surgery Fellow
Department of Surgery
Mayo Clinic
Rochester, Minnesota

THE MANAGEMENT OF ASYMPTOMATIC (SILENT) GALLSTONES

Stanley W. Ashley, MD
Chief Medical Officer
Senior Vice President for Medical Affairs
Brigham and Women's Hospital
Boston, Massachusetts

THE MANAGEMENT OF GALLSTONE PANCREATITIS

Malachy E. Asuku, MBBS, FWACS
Johns Hopkins Burn Center
Michael D. Hendrix Burn Research Center
The Johns Hopkins University School of Medicine
Baltimore, Maryland

BURN WOUND MANAGEMENT

Hugh G. Auchincloss, MD, MPH
Massachusetts General Hospital
Boston, Massachusetts

COMPARATIVE EFFECTIVENESS RESEARCH IN SURGERY

Edward D. Auyang, MD, MS
Assistant Professor
Department of Surgery
University of New Mexico
Albuquerque, New Mexico

LAPAROSCOPIC TREATMENT OF ESOPHAGEAL MOTILITY DISORDERS

Oluwafunmi O. Awonuga, MD
General Surgery Resident
University of Alabama Birmingham
Birmingham, Alabama

MOLECULAR TARGETS IN BREAST CANCER

Ezana M. Azene, MD, PhD
Vascular and Interventional Radiologist
Gundersen Health System
La Crosse, Wisconsin

TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT

Ellen Hunter Bailey, MD
Resident in General Surgery
Department of Surgery
Vanderbilt University Medical Center
Nashville, Tennessee

GALLSTONE ILEUS

Matthew J. Bak, MD
Department of Otolaryngology-Head and Neck Surgery
Eastern Virginia Medical School
Norfolk, Virginia

THE MANAGEMENT OF THYROID NODULES

Megan K. Baker, MD
Department of Surgery
Medical University of South Carolina
Charleston, South Carolina

BREAST CANCER: SURGICAL MANAGEMENT

Anthony J. Baldea, Jr., MD
University of California Davis Medical Center
Sacramento, California

CENTRAL LINE–ASSOCIATED BLOODSTREAM INFECTIONS

Douglas Ball, MD
The Johns Hopkins Hospital
Baltimore, Maryland

THE MANAGEMENT OF ADRENAL CORTICAL TUMORS

Keki R. Balsara, MD
Resident
Division of Cardiac Surgery
The Johns Hopkins Hospital
Baltimore, Maryland

BLUNT CARDIAC INJURY

Pablo A. Baltodano, MD
Postdoctoral Research Fellow, Department of Plastic and Reconstructive Surgery
The Johns Hopkins Hospital
Baltimore, Maryland

NERVE INJURY AND REPAIR

Adrian Barbul, MD, FACS
Vice-Chair, Department of Surgery
Surgical Director, Operating Rooms
Washington Hospital Center
Washington, DC

IS A NASOGASTRIC TUBE NECESSARY AFTER ALIMENTARY TRACT SURGERY?

Philip S. Barie, MD, MBA, FIDSA, FCCM, FACS
Departments of Surgery and Public Health
Weill Cornell Medical College
NewYork-Presbyterian Hospital/Weill Cornell Medical Center
New York, New York

ANTIBIOTICS FOR CRITICALLY ILL PATIENTS

Neal R. Barshes, MD, MPH
Assistant Professor of Surgery
Division of Vascular Surgery and Endovascular Therapy
Baylor College of Medicine
Operative Care Line, Michael E. DeBakey Veterans Affairs Medical Center
Houston, Texas

THE TREATMENT OF CLAUDICATION

Rolf N. Barth, MD
University of Maryland Medical Ceneter
Baltimore, Maryland

LAPAROENDOSCOPIC SINGLE-SITE SURGERY AS AN EVOLVING SURGICAL APPROACH

John G. Bartlett, MD
The Johns Hopkins Hospital
Baltimore, Maryland

OCCUPATIONAL EXPOSURE TO HUMAN IMMUNODEFICIENCY VIRUS AND OTHER BLOODBORNE PATHOGENS

Todd W. Bauer, MD
Associate Professor of Surgery
Director, High Risk Pancreatic Cancer Program
Department of Surgery
University of Virginia Health System
Charlottesville, Virginia

GALLBLADDER CANCER

Robert J. Beaulieu, MD
Resident
The Johns Hopkins School of Medicine
Baltimore, Maryland

THE MANAGEMENT OF DUODENAL ULCERS

CAROTID ENDARTERECTOMY

David E. Beck, MD, FACS, FASCRS
Professor and Chairman
Department of Colon and Rectal Surgery
Ochsner Clinic Foundation
New Orleans, Louisiana

LAPAROSCOPIC REPAIR OF PARISTOMAL HERNIAS

Matthew V. Benns, MD
University of Louisville
Louisville, Kentucky

EMERGENCY DEPARTMENT THORACOTOMY

David L. Berger, MD
Director, Colo-Rectal Group
Visiting Surgeon
Massachusetts General Hospital
Associate Professor
Harvard Medical School
Boston, Massachusetts

LARGE BOWEL OBSTRUCTION

Nikhil Bhagat, MD
Assistant Professor of Radiology and Surgery
The Johns Hopkins University School of Medicine
Baltimore, Maryland

TRANSARTERIAL CHEMOEMBOLIZATION FOR LIVER METASTASES

Anton J. Bilchik, MD, PhD
Gastrointestinal Research Program
John Wayne Cancer Institute at Saint John's Health Center
Santa Monica, California;
California Oncology Research Institute
Los Angeles, California

RADIOFREQUENCY ABLATION OF HEPATIC METASTASES FROM COLORECTAL CANCER

Danielle A. Bischof, MD
Clinical Fellow
Surgical Oncology
The Johns Hopkins Hospital
Baltimore, Maryland

THE MANAGEMENT OF ADRENAL CORTICAL TUMORS

James H. Black III, MD
The Bertram M. Bernheim MD Associate Professor of Surgery
Division of Vascular and Endovasular Surgery
Johns Hopkins University
Baltimore, Maryland

OPEN REPAIR OF ABDOMINAL AORTIC ANEURYSMS

Kirby Bland, MD
University of Alabama at Birmingham
Birmingham, Alabama

MOLECULAR TARGETS IN BREAST CANCER

Mark Bloomston, MD
Associate Professor of Surgery
Division of Surgical Oncology
The Ohio State University
Columbus, Ohio

THE MANAGEMENT OF PANCREATIC ISLET CELL TUMORS EXCLUDING GASTRINOMAS

Jennifer Blumetti, MD, FACS
Attending Surgeon
Division of Colon and Rectal Surgery
Stroger Hospital of Cook County
Clinical Assistant Professor
Division of Colon and Rectal Surgery
University of Illinois at Chicago
Chicago, Illinois

ANORECTAL ABSCESS AND FISTULA

Liliana Bordeianou, MD, MPH
Department of Surgery
Massachusetts General Hospital Digestive Healthcare Center
Harvard Medical School
Boston, Massachusetts

SURGICAL TREATMENT OF FECAL INCONTINENCE

Joseph E. Bornstein, MD, MBA
Resident
Department of Surgery
Massachusetts General Hospital
Boston, Massachusetts

LARGE BOWEL OBSTRUCTION

Judy C. Boughey, MD
Department of Surgery
Mayo Clinic
Rochester, Minnesota

THE MANAGEMENT OF RECURRENT AND DISSEMINATED BREAST CANCER

Mantaj S. Brar, MD, FRCSC
Colorectal Surgery Fellow
University of Calgary
Calgary, Alberta, Canada

THE MANAGEMENT OF PRURITUS ANI

Stacy A. Brethauer, MD
Cleveland Clinic Foundation
Cleveland, Ohio

GLYCEMIC CONTROL AND CARDIOVASCULAR DISEASE RISK REDUCTION AFTER BARIATRIC SURGERY

Benjamin N. Breyer, MD, MAS
Assistant Professor
Department of Urology
University of California, San Francisco
Interim Chief of Urology, San Francisco General Hospital
Director, UCSF Male Genitourinary Recronstruction and Trama Surgery Fellowship
San Francisco, California

RETROPERITONEAL INJURIES: KIDNEY AND URETER

Kristine E. W. Breyer, MD
University of California, San Francisco
San Francisco, California

PREOPERATIVE PREPARATION OF THE SURGICAL PATIENT

Alexandra Briggs, MD
Clinical Fellow in Surgery
Department of Surgery
Brigham and Women's Hospital
Boston, Massachusetts

THE MANAGEMENT OF GALLSTONE PANCREATITIS

Nelya Brindzei, MD
Memorial Sloan-Kettering Cancer Center
New York, New York

THE USE OF POSITRON EMISSION TOMOGRAPHIC SCANNING IN THE MANAGEMENT OF COLORECTAL CANCER

LD Britt, MD, MPH, D.Sc (Hon), FACS, FCCM, FRCSEng (Hon), FRCSEd (Hon), FWACS (Hon), FRCSI (Hon), FCS(SA) (Hon)
Brickhouse Professor and Chairman
Department of Surgery
Eastern Virginia Medical School
Norfolk, Virginia

ABDOMINAL TRAUMA

Malcolm V. Brock, MD
Associate Professor of Surgery
Associate Professor of Oncology
Director of Clinical and Translational Research in Thoracic Surgery
Department of Surgery
The Johns Hopkins Hospital
Baltimore, Maryland

THE MANAGEMENT OF BARRETT'S ESOPHAGUS

PARAESOPHAGEAL HERNIA

L. Michael Brunt, MD
Professor of Surgery
Section of Minimally Invasive Surgery
Washington University School of Medicine
St. Louis, Missouri

LAPAROSCOPIC CHOLECYSTECTOMY

Timothy G. Buchman, PhD, MD, FACS, FCCP, MCCM
Director, Emory Center for Critical Care
Professor of Surgery and of Anesthesiology
Emory University
Atlanta, Georgia

INITIAL ASSESSMENT AND RESUSCITATION OF THE TRAUMA PATIENT

Ronald W. Busuttil, MD, PhD
Professor and Executive Chairman
Department of Surgery
University of California, Los Angeles
Los Angeles, California

PORTAL HYPERTENSION: THE ROLE OF SHUNTING PROCEDURES

Richard P. Cambria, MD
Massachusetts General Hospital
Boston, Massachusetts

THE MANAGEMENT OF THORACIC AND THORACOABDOMINAL AORTIC ANEURYSMS

Andrew M. Cameron, MD, PhD, FACS
Associate Professor of Surgery
Surgical Director of Liver Transplantation
The Johns Hopkins Hospital
Baltimore, Maryland

TREATMENT FOR HEPATOCELLULAR CARCINOMA: RESECTION VERSUS TRANSPLANTATION

VASCULAR RECONSTRUCTION DURING THE WHIPPLE OPERATION

Melissa S. Camp, MD, MPH
The Johns Hopkins Hospital
Baltimore, Maryland

LYMPHATIC MAPPING AND SENTINEL LYMPHADENECTOMY

Kurtis A. Campbell, MD, FACS
Associate Professor of Surgery
The Johns Hopkins University School of Medicine
Attending Surgeon
Mercy Medical Center and The Johns Hopkins Hospital
Baltimore, Maryland

ABDOMINAL WALL RECONSTRUCTION

Michael J. Campbell, MD
Assistant Professor of Surgery
University of California, Davis
Sacramento, California

PERSISTENT AND RECURRENT HYPERPARATHYROIDISM

Rebecca R. Cannom, MD, MS
Clinical Assistant Professor of Surgery, University of Southern California
Attending Surgeon, Kaiser Permanente
Los Angeles, California

THE MANAGEMENT OF COLORECTAL POLYPS

Francis J. Caputo, MD
Cooper University Physician
Department of Vascular and Endovascular Surgery
Cooper University Health Care
Camden, New Jersey

ATHEROSCLEROTIC RENAL ARTERY DISEASE

Diana Caragacianu, MD
Department of Neurosurgery
Brigham and Women's Hospital
Harvard Medical School
Boston, Massachusetts

SURGICAL APPROACH TO THYROID CANCER

Philip W. Carrott, Jr., MD
Division of Thoracic and Cardiovascular Surgery
University of Virginia Health System
Charlottesville, Virginia

ESOPHAGEAL FUNCTION TESTING

Joseph Caruso, MD
Department of General Surgery
Walter Reed National Military Medical Center
Bethesda, Maryland

GANGRENE OF THE FOOT

John Y. Cha, MD
Assistant Professor of Surgery
Division of Acute Care Surgery
University of South Florida
Tampa, Florida

THE MANAGEMENT OF RECTAL INJURIES

Elliot L. Chaikof, MD, PhD
Johnson and Johnson Professor of Surgery
Harvard Medical School
Surgeon-in-Chief
Beth Israel Deaconess Medical Center
Boston, Massachusetts

RAYNAUD'S SYNDROME

Bipan Chand, MD, FACS, FASMBS, FASGE
Associate Professor of Surgery
Chief, Division of GI/Minimally Invasive Surgery
Loyola University Medical Center
Stritch School of Medicine
Maywood, Illinois

LAPAROSCOPIC COMMON BILE DUCT EXPLORATION

Michael C. Chang, MD, FACS
Professor of Surgery
Department of Surgery
Wake Forest University School of Medicine
Winston-Salem, North Carolina

ABDOMINAL COMPARTMENT SYNDROME AND MANAGEMENT OF THE OPEN ABDOMEN

Philip H. Chang, MD
Instructor in Surgery
Harvard Medical School
Sumner Redstone Burn Center
Massachusetts General Hospital
Shriners Hospital for Children-Boston
Boston, Massachusetts

COLD INJURY, FROSTBITE, AND HYPOTHERMIA

Vivek Chaudhry, MD, FACS, FASCRS
Section Head, Surgical Endoscopy
Director, Research Division of Colon and Rectal Surgery
John H. Stroger Hospital of Cook County
Interim Chief, Colon And Rectal Surgery
Clinical Assistant Professor, University of Illinois at Chicago
Instructor, Rush University
Chicago, Illinois

HEMORRHOIDS

Zulfiqar Cheema, MD
Department of Surgery
University of Texas Medical Branch at Galveston
Galveston, Texas

ACUTE MESENTERIC ISCHEMIA

Herbert Chen, MD, FACS
Chairman, General Surgery
Layton F. Rikkers, M.D. Chair in Surgical Leadership
Vice-Chair for Research
Professor of Surgery
Department of Surgery
University of Wisconsin
Madison, Wisconsin

ZOLLINGER-ELLISON SYNDROME

Charlie C. Cheng, MD
Department of Surgery
University of Texas Medical Branch at Galveston
Galveston, Texas

ACUTE MESENTERIC ISCHEMIA

Elaine Y. Cheng, MD
Fellow in Abdominal Transplant Surgery
Department of Surgery
University of California–Los Angeles
Los Angeles, California

PORTAL HYPERTENSION: THE ROLE OF SHUNTING PROCEDURES

Albert Chi, MD
The Johns Hopkins Hospital
Baltimore, Maryland

FLUIDS AND ELECTROLYTES

John J. Chi, MD
Washington University School of Medicine
St. Louis, Missouri

FACIAL TRAUMA: EVALUATION AND MANAGEMENT

Lorraine Choi, MD
Department of Surgery
University of Texas Medical Branch at Galveston
Galveston, Texas

ACUTE MESENTERIC ISCHEMIA

Michael A. Choti, MD, MBA, FACS
The Hall and Mary Lucille Shannon Distinguished Professor of Surgery
Chair of the Department of Surgery and Surgeon-in-Chief
University of Texas Southwestern Medical Center
Dallas, Texas

CAVERNOUS HEPATIC HEMANGIOMA

David P. Ciceri, MD
Assistant Professor of Anesthesiology
Director, Cardiovascular Anesthesiology
Director, Surgical Trauma Intensive Care Unit
Scott and White Memorial Hospital
Department of Anesthesiology
Texas A & M Health Science Center, College of Medicine
Temple, Texas

CARDIOVASCULAR PHARMACOLOGY

David J. Ciesla, MD
Professor of Surgery
Division of Acute Care Surgery
University of South Florida;
Director
Regional Trauma Program
Tampa General Hospital
Tampa, Florida

THE MANAGEMENT OF RECTAL INJURIES

Jose R. Cintron, MD, FACS
Attending Surgeon
Division of Colon and Rectal Surgery
Stroger Hospital of Cook County;
Associate Professor
Division of Colon and Rectal Surgery
University of Illinois at Chicago
Chicago, Illinois

ANORECTAL ABSCESS AND FISTULA

William G. Cioffi, Jr., MD
Professor and Chair
Department of Surgery
Brown Medical School
Providence, Rhode Island

THE SEPTIC RESPONSE

John Clarke, MD
Assistant Professor of Medicine
Director of Esophageal Motility
The Johns Hopkins Hospital
Baltimore, Maryland

MOTILITY DISORDERS OF THE STOMACH AND SMALL BOWEL

Christine S. Cocanour, MD, FACS, FCCM
University of California Davis Medical Center
Sacramento, California

INJURY TO THE SPLEEN

CENTRAL LINE–ASSOCIATED BLOODSTREAM INFECTIONS

Raul Coimbra, MD, PhD, FACS
The Monroe E. Trout Professor of Surgery
Executive Vice-Chairman Department of Surgery
Chief, Division of Trauma, Surgical Critical Care, and Burns
University of California San Diego Health Sciences
San Diego, California

ISCHEMIC COLITIS

CHEST WALL TRAUMA, HEMOTHORAX, AND PNEUMOTHORAX

Shannon Colohan, MD
Division of Plastic Surgery, Department of Surgery
University of Washington
Seattle, Washington

BREAST RECONSTRUCTION FOLLOWING MASTECTOMY: INDICATIONS, TECHNIQUES, AND RESULTS

Paul Colombani, MD, MBA, FACS, FAAP
Professor of Surgery
Pediatrics and Oncology
Vice-Chairman
Department of Surgery
Chief
Division of Pediatric Surgery
The Johns Hopkins Hospital
Baltimore, Maryland

REPAIR OF PECTUS EXCAVATUM

Michael D. Connolly, MD
Assistant Professor
Department of Surgery
Brown Medical School
Providence, Rhode Island

THE SEPTIC RESPONSE

Claudius Conrad, MD, PhD
Assistant in Surgery, Massachusetts General Hospital
Instructor, Harvard Medical School
Boston, Massachusetts

PALLIATIVE THERAPY FOR PANCREATIC CANCER

Michael S. Conte, MD
Division of Vascular and Endovascular Surgery
University of California
San Francisco, California

AORTOILIAC OCCLUSIVE DISEASE

Patrick R. Cook, DO, FACS, RPVI
Chief, Department of Anesthesia and Operative Services
William Beaumont Army Medical Center
El Paso, Texas;
Vascular Surgery Consultant to the Office of the Surgeon General
Assistant Professor of Surgery
The Norman M. Rich Department of Surgery
The Uniformed Services University of the Health Sciences
Bethesda, Maryland

THE DIABETIC FOOT

Robert N. Cooney, MD
Department of Surgery
SUNY Upstate Medical Center
Syracuse, New York

METABOLIC CHANGES FOLLOWING BARIATRIC SURGERY

Edward E. Cornwell, III, MD, FACS, FCCM
LaSalle D. Leffall, Jr., MD Professor and Chairman of Surgery
Howard University College of Medicine
Surgeon-in-Chief
Howard University Hospital
Washington, DC

INJURIES TO THE SMALL AND LARGE BOWEL

David Cosgrove, MBBCh
Assistant Professor of Oncology
Johns Hopkins Sidney Kimmel Comprehensive Cancer Center
Baltimore, Maryland

THE USE OF NEOADJUVANT AND ADJUVANT TREATMENT FOR COLORECTAL CANCER

Bard C. Cosman, MD, MPH
Halasz General Surgery Section, Surgical Service
VA San Diego Healthcare System
Department of Surgery
University of California San Diego School of Medicine
San Diego, California

ANORECTAL STRICTURE

Todd W. Costantini, MD
Assistant Professor of Surgery
Division of Trauma, Surgical Critical Care, and Burns
Department of Surgery
University of California San Diego Health Sciences
San Diego, California

ISCHEMIC COLITIS

Charles Cox, MD
Tampa Bay Breast Care Specialists
Department of Surgery
University of South Florida, Morsani College of Medicine
Tampa, Florida

ABLATIVE THERAPIES IN BENIGN AND MALIGNANT BREAST DISEASE

John Cox, MD
Tampa Bay Breast Care Specialists
Tampa, Florida

ABLATIVE THERAPIES IN BENIGN AND MALIGNANT BREAST DISEASE

Martin A. Croce, MD, FACS
Professor of Surgery
University of Tennessee Health Science Center
Memphis, Tennessee

THE MANAGEMENT OF LIVER INJURIES

David M. Cromwell, MD
Assistant Professor of Medicine
Johns Hopkins University
Baltimore, Maryland

ACUTE COLONIC PSEUDO-OBSTRUCTION (OGILVIE'S SYNDROME)

Paul G. Curcillo II, MD, FACS
Associate Professor, Surgical Oncology
Section Chief, Minimally Invasive Surgery
Director, Minimally Invasive Surgical Initiatives and Development
Fox Chase Cancer Center
Philadelphia, Pennsylvania

INCISIONAL, EPIGASTRIC, AND UMBILICAL HERNIAS

James C. Cusack, Jr., MD
Associate Professor of Surgery
Division of Surgical Oncology
Harvard Medical School
Department of Surgery
Massachusetts General Hospital
Boston, Massachusetts

THE MANAGEMENT OF PHEOCHROMOCYTOMA

Alan P. B. Dackiw, MD, PhD
Department of Surgery
The Johns Hopkins Hospital
The Johns Hopkins University School of Medicine
Baltimore, Maryland

ADRENAL INCIDENTALOMA

Phong T. Dargon, MD
Oregon Health & Science University
Portland, Oregon

PSEUDOANEURYSMS AND ARTERIOVENOUS FISTULAS

Benjamin W. Dart IV, MD, FACS
Associate Professor of Surgery
Department of Surgery
University of Tennessee College of Medicine
Chattanooga, Tennessee

THE MANAGEMENT OF CLOSTRIDIUM DIFFICILE COLITIS

S. Scott Davis, Jr., MD, FACS
Associate Professor of Surgery
Associate Program Director, Emory Endosurgery Fellowship
Division of General and GI Surgery
Department of Surgery
Emory University School of Medicine
Atlanta, Georgia

LAPAROSCOPIC 360-DEGREE FUNDOPLICATION

Ana De Jesus-Acosta, MD
Gastrointestinal Medical Oncology
Sidney Kimmel Comprehensive Cancer Center at Johns Hopkins
Baltimore, Maryland

NEOADJUVANT AND ADJUVANT THERAPY OF PANCREATIC CANCER

Christopher J. Dente, MD
Department of Surgery
Emory University School of Medicine
Atlanta, Georgia

THE SURGEON'S USE OF ULTRASOUND IN THORACOABDOMINAL TRAUMA

Marcello Deraco, MD
Surgical Oncologist
Department of Surgery
National Cancer Institute
Milan, Italy

THE MANAGEMENT OF PERITONEAL SURFACE MALIGNANCY

Niraj M. Desai, MD
Director of the Kidney and Pancreas Transplant Program
The Johns Hopkins Hospital
Transplant Surgery Division, Department of Surgery
Johns Hopkins University
Baltimore, Maryland

TRANSPLANTATION OF THE PANCREAS

Ashwin L. deSouza, MS, MRCSEd, DNB, FCPS, MNAMS
Fellow, Minimally Invasive and Laparoscopic Colon and Rectal Surgery
University of Illinois at Chicago
Chicago, Illinois

THE MANAGEMENT OF RECTOVAGINAL FISTULA

Karen Deveney, MD
Professor of Surgery
Vice Chair of Education and Program Director
Department of Surgery
Oregon Health & Science University
Portland, Oregon

THE MANAGEMENT OF COLONIC VOLVULUS

Gerard M. Doherty, MD, FACS
Utley Professor and Chair of Surgery
Professor of Medicine
Boston University
Surgeon-in-Chief
Boston Medical Center
Boston, Massachusetts

NONTOXIC GOITER

Timothy R. Donahue, MD
Assistant Professor of Surgery, and Molecular and Medical Pharmacology
University of California, Los Angeles
Los Angeles, California

THE MANAGEMENT OF CHRONIC PANCREATITIS

Graham W. Donald, MD
Department of Surgery
David Geffen School of Medicine at UCLA
Los Angeles, California

PANCREATIC DUCTAL DISRUPTIONS LEADING TO PANCREATIC FISTULA, PANCREATIC ASCITES, OR PANCREATIC PLEURAL EFFUSION

Juan Carlos Duchesne, MD, FACS, FCCP, FCCM
Trauma Medical Director
North Oaks Shock/Trauma Center
Hammond, Louisiana;
Associate Professor of Surgery
Tulane University
Chairman
Louisiana Committee of Trauma
New Orleans, Louisiana

PANCREATIC AND DUODENAL INJURIES AND CURRENT SURGICAL THERAPIES

Quan-Yang Duh, MD
Professor of Surgery
University of California, San Francisco
San Francisco, California

PERSISTENT AND RECURRENT HYPERPARATHYROIDISM

William S. Duke, MD
Assistant Professor
Department of Otolaryngology-Head and Neck Surgery
Georgia Regents University
Augusta, Georgia

HYPERTHYROIDISM

Casey Boyd Duncan, MD, MS
Department of Surgery
The University of Texas Medical Branch
Galveston, Texas

UNUSUAL PANCREATIC TUMORS

Mark D. Duncan, MD
Associate Professor, Surgery
Chief, Surgical Oncology
Johns Hopkins Bayview Medical Center, Division of Surgery
Baltimore, Maryland

THE MANAGEMENT OF COMMON BILE DUCT STONES

Geoffrey P. Dunn, MD, FACS
Department of Surgery and Palliative Care Consultation Service
UPMC Hamot Medical Center
Erie, Pennsylvania

SURGICAL PALLIATIVE CARE

Francisco Antonio Durazo, MD, FACP
Associate Professor of Medicine and Surgery
David Geffen UCLA School of Medicine
Division of Gastrointestinal and Liver Diseases
Medical Director, Dumont-UCLA Liver Transplant Center
Los Angeles, CA

ENDOSCOPIC THERAPY FOR ESOPHAGEAL VARICEAL HEMORRHAGE

Frederic E. Eckhauser, MD, FACS
Professor of Surgery
Director of Clinical Operation
The Johns Hopkins Hospital
Baltimore, Maryland

THE MANAGEMENT OF DUODENAL ULCERS

Barish H. Edil, MD
Associate Professor of Surgery
University of Colorado
Denver, Colorado

CYSTIC DISORDERS OF THE BILE DUCTS

PERIAMPULLARY CARCINOMA

Jonathan E. Efron, MD
Associate Professor of Surgery
Chief of Ravitch Service
The Mark M. Ravitch, MD Endowed Professorship in Gastrointestinal Surgery
Johns Hopkins University
Baltimore, Maryland

THE MANAGEMENT OF CHRONIC ULCERATIVE COLITIS

Dominique Elias, MD, PhD
Department of Surgical Oncology
Gustave Roussy Institute
Villejuif, Paris, France

THE MANAGEMENT OF PERITONEAL SURFACE MALIGNANCY

E. Christopher Ellison, MD
Professor of Surgery
The Ohio State University
Columbus, Ohio

THE MANAGEMENT OF PANCREATIC ISLET CELL TUMORS EXCLUDING GASTRINOMAS

Nassrene Elmadhun, MD
PGY 3 Resident, Department of Surgery
Beth Israel Deaconess Medical Center
Boston, Massachusetts

ENDOSCOPIC TREATMENT OF BARRETT'S ESOPHAGUS

James K. Elsey, MD, FACS
Gwinnett Surgical Associates
Lawrenceville, Georgia

ACUTE CHOLECYSTITIS

Timothy C. Fabian, MD
Harwell Wilson Alumni Professor & Chairman, Department of Surgery
University of Tennessee Health Science Center
Memphis, Tennessee

THE ABDOMEN THAT WILL NOT CLOSE

Sandy H. Fang, MD
Assistant Professor of Surgery
Department of Surgery
Johns Hopkins University
Baltimore, Maryland

THE MANAGEMENT OF CHRONIC ULCERATIVE COLITIS

Alik Farber, MD, FACS
Chief of Vascular and Endovascular Surgery
Boston University Medical Center
Associate Professor of Surgery and Radiology
Boston University School of Medicine
Boston, Massachusetts

THE MANAGEMENT OF PERIPHERAL ARTERIAL EMBOLI

Mark B. Faries, MD
Melanoma Research Program, John Wayne Cancer Institute at Saint John's Health Center
Santa Monica, California

THE MANAGEMENT OF CUTANEOUS MELANOMA

Russell Farmer, MD
Fellow, Colorectal Surgery
PGY5, General Surgery
Department of Surgery
School of Medicine
University of Louisville
Louisville, Kentucky

CROHN'S COLITIS

Amir H. Fathi, MD
Case Comprehensive Hernia Center
Department of Surgery
University Hospitals Case Medical Center
Cleveland, Ohio

LAPAROSCOPIC REPAIR OF RECURRENT INGUINAL HERNIAS

David V. Feliciano, MD
Battersby Professor and Chief, Division of General Surgery
Attending Surgeon, Indiana University and IU Methodist Hospitals
Indiana University Medical Center
Indianapolis, Indiana

DIAPHRAGMATIC INJURIES

Charles M. Ferguson, MD
Surgeon/Clinical Medical Staff
Emory Clark-Holder Clinic
LaGrange, Georgia

ESOPHAGEAL PERFORATION

Carlos Fernandez-del Castillo, MD
Department of Surgery
Massachusetts General Hospital
Harvard Medical School
Boston, Massachusetts

INTRADUCTAL PAPILLARY MUCINOUS NEOPLASMS OF THE PANCREAS

Paula Ferrada, MD, FACS
Division of Trauma, Critical Care & Emergency Surgery
Department of Surgery
Virginia Commonwealth University
Richmond, Virginia

THE MANAGEMENT OF DIVERTICULAR DISEASE OF THE COLON

Cristina R. Ferrone, MD
Surgeon, General and Gastrointestinal Surgery
Department of Surgery
Massachusetts General Hospital
Assistant Professor, Department of Surgery
Harvard Medical School
Dana-Farber/Harvard Cancer Center
Boston, Massachusetts

CYSTIC DISEASE OF THE LIVER

Alessandro Fichera, MD, FACS, FASCRS
Professor
Department of Surgery
University of Washington
Seattle, Washington

TUMORS OF THE ANAL CANAL

LAPAROSCOPIC MANAGEMENT OF CROHN'S DISEASE

Christina Finlayson, MD
Professor, Surgery
Director, Diane O'Connor Thompson Breast Center
University of Colorado School of Medicine
Aurora, Colorado

ADVANCES IN NEOADJUVANT AND ADJUVANT THERAPY FOR BREAST CANCER

Jordan E. Fishman, MD, MPH
Surgical House Officer
New Jersey Medical School—Rutgers University
Newark, New Jersey

IS A NASOGASTRIC TUBE NECESSARY AFTER ALIMENTARY TRACT SURGERY?

Mark E. Fleming, DO, MC(FS/FMF), USN
Orthopedic Trauma Surgeon
Assistant Deputy Commander for Surgery
Walter Reed National Military Medical Center
Assistant Professor of Surgery
Uniformed Services University of the Health Sciences
Bethesda, Maryland

GANGRENE OF THE FOOT

James W. Fleshman, MD, FACS, FASCRS
Chief of Surgery
Baylor University Medical Center
Dallas, Texas

THE MANAGEMENT OF TOXIC MEGACOLON

LAPAROSCOPIC COLON AND RECTAL SURGERY

Yuman Fong, MD
Murray F. Brennan Chair in Surgery
Memorial Sloan-Kettering Cancer Center
New York, New York

THE MANAGEMENT OF MALIGNANT LIVER TUMORS

Christopher L. Forthman, MD
Consultant, Curtis National Hand Center
Union Memorial Hospital
Baltimore, Maryland

HAND INFECTIONS

Adam D. Fox, DPM, DO, FACS
Assistant Professor of Surgery
Division of Trauma Surgery and Critical Care
Rutgers—New Jersey Medical School
Newark, New Jersey

THE MANAGEMENT OF INTRAABDOMINAL INFECTIONS

Julie A. Freischlag, MD
The William Stewart Halsted Professor
Chair, Department of Surgery
Surgeon-in-Chief
The Johns Hopkins Hospital
Baltimore, Maryland

THORACIC OUTLET SYNDROMES

Randall S. Friese, MD
Division of Trauma and Critical Care
University of Arizona
Tucson, Arizona

ELECTROLYTE DISORDERS

Robert Gabordi, MD
Department of Surgery
University of South Florida
Morsani College of Medicine
Tampa, Florida

ABLATIVE THERAPIES IN BENIGN AND MALIGNANT BREAST DISEASE

Michele A. Gadd, MD
Massachusetts General Hospital
Division of Surgical Oncology
Boston, Massachusetts

SCREENING FOR BREAST CANCER

Csaba Gajdos, MD
Assistant Professor of Surgery
University of Colorado
Aurora, Colorado

PERIAMPULLARY CARCIMOMA

Susan Galandiuk, MD
Professor of Surgery
Section of Colon and Rectal Surgery
Director, Price Institute of Surgical Research
Department of Surgery
University of Louisville
Louisville, Kentucky

CROHN'S COLITIS

Samuel M. Galvagno, Jr., DO, PhD
Assistant Professor
Divisions of Trauma, Anesthesiology, and Critical Care Medicine
Department of Anesthesiology and the Program in Trauma
Shock Trauma Center
University of Maryland School of Medicine
Baltimore, Maryland

AIRWAY MANAGEMENT IN THE TRAUMA PATIENT

Julio Garcia-Aguilar, MD, PhD
Chief, Colorectal Service
Department of Surgery
Memorial Sloan-Kettering Cancer Center
New York, New York

THE USE OF POSITRON EMISSION TOMOGRAPHIC SCANNING IN THE MANAGEMENT OF COLORECTAL CANCER

Alan D. Garely, MD, FACOG, FACS
Chair of Obstetrics and Gynecology
Director of Urogynecology and Pelvic Reconstructive Surgery
South Nassau Communities Hospital
Clinical Associate Professor
Mount Sinai School of Medicine
New York, New York

RECTAL PROLAPSE

Susan L. Gearhart, MD, FACS, FASCAS
Assistant Professor of Colorectal Surgery
Johns Hopkins University
Baltimore, Maryland

THE MANAGEMENT OF CROHN'S DISEASE OF THE SMALL BOWEL

ANAL FISSURES

Christos S. Georgiades, MD, PhD, FSIR
Director
Vascular and Interventional Radiology
American Medical Center
Nicosia, Cyprus

VENA CAVA FILTERS

Jean-Francois H. (Jeff) Geschwind, MD
Professor of Radiology, Surgery and Oncology
The Johns Hopkins University School of Medicine
Baltimore, Maryland

THE TRANSARTERIAL CHEMOEMBOLIZATION FOR LIVER METASTASES

Bruce L. Gewertz, MD
Department of Surgery
Cedars-Sinai Medical Center
Los Angeles, California

BUERGER'S DISEASE (THROMBOANGIITIS OBLITERANS)

Armando E. Giuliano, MD, FACS, FRCSEd
Executive Vice Chair, Surgery
Chief, Surgical Oncology
Cedars-Sinai Medical Center
Los Angeles, California

THE MANAGEMENT OF THE AXILLA IN BREAST CANCER

Natalia O. Glebova, MD, PhD
Fellow in Vascular Surgery
Johns Hopkins Medicical Institutions
Baltimore, Maryland

THE MANAGEMENT OF RUPTURED ABDOMINAL AORTIC ANEURYSM

FEMOROPOPLITEAL OCCLUSIVE DISEASE

LYMPHEDEMA

Olivier Glehen, MD, PhD
Professor of Surgery
Surgical Oncology Department
Centre Hospitalo-Universitaire Lyon Sud
Pierre Benite, France

THE MANAGEMENT OF PERITONEAL SURFACE MALIGNANCY

Catherine Go
Fourth Year Medical Student
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

ESOPHAGEAL STENTS

Jason S. Gold, MD
Departments of Surgery
VA Boston Healthcare System
Brigham and Women's Hospital
Harvard Medical School
Boston, Massachusetts

ACUTE CHOLANGITIS

Steven B. Goldin, MD, PhD
Professor of Surgery
Chief of Hepatobiliary and Pancreatic Surgery
Vice Chairman of Surgical Education
Medical Student Clerkship Director
University of South Florida
Tampa, Florida

PANCREAS DIVISUM AND OTHER VARIANTS OF DOMINANT DORSAL DUCT ANATOMY

Seth Goldstein, MD
Johns Hopkins University
Baltimore, Maryland

CYSTIC DISORDERS OF THE BILE DUCTS

FLUIDS AND ELECTROLYTES

Jerry Goldstone, MD, FACS, FRCSEd (Hon)
Division of Vascular Surgery and Endovascular Therapy
University Hospital Case Medical Center
Case Western Reserve University School of Medicine
Cleveland, Ohio

THE MANAGEMENT OF ANEURYSMS OF THE EXTRACRANIAL CAROTID AND VERTEBRAL ARTERIES

Alexandra June Gordon
Medical Student
University of Illinois, College of Medicine
Chicago, Illinois

THE ROLE OF STEREOTACTIC BREAST BIOPSY IN THE MANAGEMENT OF BREAST DISEASE

Jay A. Graham, MD
Department of Surgery
Georgetown University Hospital
Washington, DC

LAPAROSCOPIC LIVER RESECTION

Caprice C. Greenberg, MD, MPH
Associate Professor of Surgery
WARF Professor of Surgical Research
Director, Wisconsin Surgical Outcomes Research (WiSOR)
Department of Surgery
University of Wisconsin
Madison, Wisconsin

MEASURING OUTCOMES IN SURGERY

Alessandro Gronchi, MD
Department of Surgery, Sarcoma Service
Fondazione IRCCS Istituto Nazionale dei Tumori
Milan, Italy

THE MANAGEMENT OF SOFT TISSUE SARCOMA

Michael A. Gropper, MD, PhD
Professor and Executive Vice Chair
Department of Anesthesia and Perioperative Care
Director, Critical Care Medicine
Investigator, Cardiovascular Research Institute
University of California, San Francisco
San Francisco, California

PREOPERATIVE PREPARATION OF THE SURGICAL PATIENT

Ahmet Gurakar, MD
Associate Professor of Medicine
Section of Gastroenterology and Hepatology
Medical Director, Liver Transplantation
The Johns Hopkins Hospital
Baltimore, Maryland

THE MANAGEMENT OF REFRACTORY ASCITES

James L. Guzzo, MD
Division of Vascular & Endovascular Surgery
Department of Surgery
Lehigh Valley Hospital
Allentown, Pennsylvania

FEMORAL AND POPLITEAL ARTERY ANEURYSMS

Adil Haider, MD, MPH, FACS
Department of Surgery
The Johns Hopkins Hospital
Baltimore, Maryland

DAMAGE CONTROL OPERATION

Yarah M. Haidar, MD
Department of Surgery
University of California, San Diego School of Medicine
San Diego, California

ANORECTAL STRICTURE

James P. Hamilton, MD
Assistant Professor of Medicine
The Johns Hopkins Hospital
Baltimore, Maryland

THE MANAGEMENT OF BUDD-CHIARI SYNDROME

John B. Hanks, MD
C. Bruce Morton Professor and Chief
Division of General Surgery
Department of Surgery
University of Virginia
Charlottesville, Virginia

EVALUATION OF THE ISOLATED NECK MASS

Tod M. Hanover, MD
Division of Vascular Surgery
Greenville Hospital System Clinical University
University of South Carolina School of Medicine
Greenville, South Carolina

PROFUNDA FEMORIS RECONSTRUCTION

Nora Hansen, MD
Feinberg School of Medicine
Northwestern University
Chicago, Illinois

THE ROLE OF STEREOTACTIC BREAST BIOPSY IN THE MANAGEMENT OF BREAST DISEASE

Rosemarie Hardin, MD
Wheeling Hospital
Wheeling, West Virginia

THE MANAGEMENT OF BENIGN BREAST DISEASE

INFLAMMATORY BREAST CARCINOMA

MALE BREAST CANCER

Elliott R. Haut, MD, FACS
Associate Professor of Surgery, Anesthesiology / Critical Care Medicine (ACCM) and Emergency Medicine
Division of Acute Care Surgery, Department of Surgery
The Johns Hopkins University School of Medicine
Core faculty, The Armstrong Institute for Patient Safety & Quality, John Hopkins Medicine
Director, Trama/Acute Care Surgery Fellowship, The John Hopkins Hospital
Baltimore, Maryland

VENOUS THROMBOEMBOLISM: PREVENTION, DIAGNOSIS, AND TREATMENT

William G. Hawkins, MD
Section of Hepatobiliary-Pancreatic Surgery, Department of Surgery
Washington University
St. Louis, Missouri

BENIGN BILIARY STRICTURES

Elizabeth Hechenbleikner, MD
Research: Colorectal
The John Hopkins Hospital
Baltimore, Maryland;
Research Resident, MedStar Georgetown University Hospital
Washington, DC

COLON CANCER

Robert Evans Heithaus, Jr., MD
Baylor University Medical Center
Dallas, Texas

PANCREAS DIVISUM AND OTHER VARIANTS OF DOMINANT DORSAL DUCT ANATOMY

Richard F. Heitmiller, MD, FACS
J.M.T. Finney Chairman of Surgery
Union Memorial Hospital
Baltimore, Maryland

THE MANAGEMENT OF PHARYNGEAL ESOPHAGEAL (ZENKER'S) DIVERTICULA

Jennifer Heller, MD
Department of Surgery
Bayview Medical Center
Baltimore, Maryland

LYMPHEDEMA

C. William Helm, MB.BChir
Department of Obstetrics, Gynecology and Women's Health
Saint Louis University
St. Louis, Missouri

THE MANAGEMENT OF PERITONEAL SURFACE MALIGNANCY

Sharon Henry, MD
Professor of Surgery
Anne Scalea Professor in Trauma
Director, Division of Wound Healing and Metabolism
R Adams Cowley Shock Trauma Center
University of Maryland School of Medicine
Baltimore, Maryland

EXTREMITY GAS GANGRENE

Joseph M. Herman, MD, MS
Associate Professor, Radiation Oncology
The Johns Hopkins Kimmel Cancer Center
Baltimore, Maryland

RADIATION INJURY TO THE SMALL AND LARGE BOWEL

Jonathan R. Hiatt, MD
Professor of Surgery
Vice Dean for Faculty
Department of Surgery
University of California–Los Angeles
Los Angeles, California

PORTAL HYPERTENSION: THE ROLE OF SHUNTING PROCEDURES

Caitlin W. Hicks, MD, MS
Department of Surgery
The Johns Hopkins Hospital
Baltimore, Maryland

DAMAGE CONTROL OPERATION

Department of Surgery
David Geffen School of Medicine at UCLA
Los Angeles, California

PANCREATIC DUCTAL DISRUPTIONS LEADING TO PANCREATIC FISTULA, PANCREATIC ASCITES, OR PANCREATIC PLEURAL EFFUSION

Kenzo Hirose, MD
Assistant Professor
Department of Surgery
Division of Surgical Oncology
Johns Hopkins University
Baltimore, Maryland

THE MANAGEMENT OF BENIGN LIVER LESIONS

Vanessa P. Ho, MD, MPH
Department of Surgery
University of Medicine and Dentistry of New Jersey-New Jersey Medical School
Newark, New Jersey

ANTIBIOTICS FOR CRITICALLY ILL PATIENTS

Richard Hodin, MD
Chief, Endocrine Surgery
Surgical Director, MGH Center for Inflammatory Bowel Disease
Massachusetts General Hospital
Boston, Massachusetts

THE MANAGEMENT OF SMALL BOWEL TUMORS

Tammy M. Holm, MD, PhD
Department of General Surgery
Brigham and Women's Hospital
Harvard Medical School
Boston, Massachusetts

SURGICAL APPROACH TO THYROID CANCER

Johnny C. Hong, MD, FACS
Associate Professor of Surgery
The Mark B. Adams Chair in Surgery
Division of Transplant Surgery, Department of Surgery
Medical College of Wisconsin
Director, Solid Organ Transplantation Joint Program
Medical College of Wisconsin-Froedtert Health-Children's Hospital of Wisconsin-Blood Center of Wisconsin
Milwaukee, Wisconsin

THE MANAGEMENT OF HEPATIC ABSCESS

Kelvin Hong, MD
Clinical Director
Fellowship Program Director
Vascular and Interventional Radiology
Johns Hopkins Medical Institutions
Baltimore, Maryland

TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT

Karen D. Horvath, MD, FACS
Professor of Surgery
Director, Residency Program in General Surgery
Associate Chair for Education
Department of Surgery
University of Washington
Seattle, Washington

LAPAROSCOPIC MANAGEMENT OF PANCREATIC PSEUDOCYST

Isaac Howley, MD
Department of Surgery
The Johns Hopkins Hospital
Baltimore, Maryland

THE MANAGEMENT OF CROHN'S DISEASE OF THE SMALL BOWEL

David B. Hoyt, MD, FACS
Executive Director
American College of Surgeons
Chicago, Illinois;
Professor of Surgery—Emeritus
Department of Surgery
University of California, Irvine
Irvine, California

CHEST WALL TRAUMA, HEMOTHORAX, AND PNEUMOTHORAX

Michal Hubka, MD
Department of General and Thoracic Surgery
Virginia Mason Medical Center
Seattle, Washington

PRIMARY TUMORS OF THE THYMUS

Matthew M. Hutter, MD, MPH
Massachusetts General Hospital
Boston, Massachusetts

COMPARATIVE EFFECTIVENESS RESEARCH IN SURGERY

Andre Ilbawi, MD
Department of Surgery
University of Washington Medical Center
Seattle, Washington

LAPAROSCOPIC MANAGEMENT OF PANCREATIC PSEUDOCYST

Kamal M.F. Itani, MD, FACS
Department of Surgery
Boston Veteran's Administration Health Care System

RETROPERITONEAL INJURIES: KIDNEY AND URETER

Martin McCarter, MD
Professor and Director of Endocrine Surgery
University of Colorado
Aurora, Colorado

PERIAMPULLARY CARCINOMA

David W. McFadden, MD
Professor and Chairman
Department of Surgery
University of Connecticut School of Medicine
Farmington, Connecticut

MALLORY-WEISS SYNDROME

Thomas McIntyre, MD
Assistant Professor of Surgery
SUNY Downstate School of Medicine
Brooklyn, New York

CYSTS, TUMORS, AND ABSCESSES OF THE SPLEEN

Elisabeth C. McLemore, MD, FACS, FASCRS
Associate Professor of Surgery
University of California, San Diego Health System
San Diego, California

STAGING LAPAROSCROPY FOR GASTROINTESTINAL CANCER

Norman McSwain, Jr., MD, FACS
Professor of Surgery, Tulane University School of Medicine
Trauma Director, Charity Hospital
Police Surgeon, NOPD
New Orleans, Louisiana

PANCREATIC AND DUODENAL INJURIES AND CURRENT SURGICAL THERAPIES

Rachel L. Medbery, MD
General Surgery Resident
Department of Surgery
Emory University School of Medicine
Atlanta, Georgia

LAPAROSCOPIC 360-DEGREE FUNDOPLICATION

Laleh G. Melstrom, MD, MS
Assistant Professor of Surgery
Rutgers Cancer Institute of New Jersey
New Brunswick, New Jersey

THE MANAGEMENT OF MALIGNANT LIVER TUMORS

Genevieve B. Melton, MD, MA
Associate Professor, Department of Surgery
Faculty Fellow, Institute for Health Informatics
University of Minnesota
Minneapolis, Minnesota

THE MANAGEMENT OF COLORECTAL POLYPS

W. Scott Melvin, MD
Department of Surgery
The Ohio State University Wexner Medical Center
Columbus, Ohio

ENDOLUMINAL APPROACHES TO GASTROESOPHAGEAL REFLUX DISEASE

Avedis Meneshian, MD
Assistant Professor, Department of Surgery
The Johns Hopkins University School of Medicine
Baltimore, Maryland;
Division of Thoracic Surgery
Anne Arundel Medical Center
Annapolis, Maryland

THE MANAGEMENT OF PRIMARY CHEST WALL TUMORS

J. Wayne Meredith, MD, FACS
Professor and Chair
Department of Surgery
Wake Forest University School of Medicine
Winston-Salem, North Carolina

ABDOMINAL COMPARTMENT SYNDROME AND MANAGEMENT OF THE OPEN ABDOMEN

Fabrizio Michelassi, MD
Department of Surgery
New York-Presbyterian Hospital
Weill Cornell Medical College
New York, New York

STRICTUREPLASTY IN CROHN'S DISEASE

Kresimira Milas, MD, FACS
Professor and Director of Endocrine Surgery
Department of Surgery and the Thyroid and Parathyroid Center
Oregon Health & Sciences University
Portland, Oregon

ENDOCRINE CHANGES IN CRITICAL ILLNESS

Zvonimir Milas, MD, FACS
Associate Professor of Surgery
Department of Surgical Oncology and the Levine Cancer Institute
Carolinas Medical Center
Charlotte, North Carolina

ENDOCRINE CHANGES IN CRITICAL ILLNESS

Preston R. Miller, MD, FACS
Associate Professor of Surgery
Department of Surgery
Wake Forest University School of Medicine
Winston-Salem, North Carolina

ABDOMINAL COMPARTMENT SYNDROME AND MANAGEMENT OF THE OPEN ABDOMEN

Stephen M. Milner, MBBS, BDS, DSc (Hon), FRCS (Ed), FACS
Professor of Plastic Surgery
Director, Johns Hopkins Burn Center
Surgical Director, Johns Hopkins Wound Healing Center
Director, Michael D. Hendrix Burn Research Center
The Johns Hopkins University School of Medicine
Baltimore, Maryland

BURN WOUND MANAGEMENT

Issa Mirmehdi, MD
Halifax Health-Hernia Institute
Daytona Beach, Florida

ATHLETIC PUBALGIA: THE "SPORTS HERNIA"

Erica L. Mitchell, MD
Associate Professor of Surgery
Division of Vascular Surgery
Oregon Health & Science University
Portland, Oregon

PSEUDOANEURYSMS AND ARTERIOVENOUS FISTULAS

Robert Moesinger, MD
Intermountain Healthcare
Adjunct Assistant Professor
Department of Surgery
Director Rural Surgery Fellowship
University of Utah
Ogden, Utah

RECURRENT INGUINAL HERNIA

Jahan Mohebali, MD
Cardiac Surgery Research Fellow
Brigham and Women's Hospital
General Surgery Resident
Massachusetts General Hospital
Boston, Massachusetts

THE MANAGEMENT OF ACQUIRED ESOPHAGEAL RESPIRATORY TRACT FISTULA

Daniela Molena, MD
Department of Surgery
Assistant Professor of Surgery
Director, Robotic and Minimally Invasive Thoracic Surgery
Director of Thoracic Surgery, Johns Hopkins Bayview Medical Center
The Johns Hopkins Hospital
Baltimore, Maryland

PARAESOPHAGEAL HERNIA

VIDEO-ASSISTED THORACIC SURGERY

Robert J. Moraca, MD
Assistant Professor of Surgery
Chief, Section of Arrhythmia and Thoracic Aortic Surgery
Department of Thoracic and Cardiovascular Surgery
Allegheny General Hospital
Pittsburgh, Pennsylvania

EXTRACORPOREAL MEMBRANE OXYGENATION FOR RESPIRATORY FAILURE IN ADULTS

Katherine A. Morgan, MD
Medical University of South Carolina
Charleston, South Carolina

THE MANAGEMENT OF PANCREATIC PSEUDOCYST

Christopher R. Morse, MD
Department of Surgery
Massachusetts General Hospital
Boston, Massachusetts

THE MANAGEMENT OF ACQUIRED ESOPHAGEAL RESPIRATORY TRACT FISTULA

MINIMALLY INVASIVE ESOPHAGECTOMY

Donald L. Morton, MD
Melanoma Research Program
John Wayne Cancer Institute at Saint John's Health Center
Santa Monica, California

THE MANAGEMENT OF CUTANEOUS MELANOMA

Anne C. Mosenthal, MD, FACS
Professor and Chair
Department of Surgery
Rutgers New Jersey Medical School
Newark, New Jersey

THE MULTIPLE ORGAN DYSFUNCTION AND FAILURE

Raghu Motaganahalli, MD, FACS
Associate Professor of Surgery
Residency Program Director, Vascular and Endovascular Surgery
Indiana University School of Medicine
Indianapolis, Indiana

TIBIOPERONEAL ARTERIAL OCCLUSIVE DISEASE

Fady Moustarah, MD, MPH, FRCS(C) General Surgery
Associate Professor, Department of Surgery
Laval University
Institut Universitaire de Cardiologie et de Pneumologie de Québec (IUCPQ)
Research Co-Chair in Bariatric & Metabolic Surgery
Centre de Recherche de l'IUCPQ, Université Laval
Québec, QC, Canada

GLYCEMIC CONTROL AND CARDIOVASCULAR DISEASE RISK REDUCTION AFTER BARIATRIC SURGERY

Nathan T. Mowery, MD, FACS
Assistant Professor
Department of Surgery
Wake Forest University School of Medicine
Winston-Salem, North Carolina

ABDOMINAL COMPARTMENT SYNDROME AND MANAGEMENT OF THE OPEN ABDOMEN

Benedetto Mungo, MD
Post Doctoral Fellow
Department of Surgery
The Johns Hopkins Hospital
Baltimore, Maryland

PARAESOPHAGEAL HERNIA

VIDEO-ASSISTED THORACIC SURGERY

Ashok Muniappan, MD
Division of Thoracic Surgery
Department of Surgery
Massachusetts General Hospital
Boston, Massachusetts

MEDIASTINAL MASSES

Michael Patrick Murphy, MD
Associate Professor of Surgery and Cellular & Integrative Physiology
Chief, Vascular and Endovascular Surgery
Richard Roudebush VAMC
Indiana University School of Medicine
Indianapolis, Indiana

TIBIOPERONEAL ARTERIAL OCCLUSIVE DISEASE

Peter Muscarella, MD
Department of Surgery
Ohio State University
Columbus, Ohio

LAPAROSCOPIC BYPASS FOR PANCREATIC CANCER

Lena M. Napolitano, MD, FACS, FCCP, FCCM
Professor of Surgery
University of Michigan School of Medicine
Division Chief, Acute Care Surgery
[Trauma, Burn, Surgical Critical Care, Emergency Surgery]
Associate Chair, Department of Surgery
Director, Trauma and Surgical Critical Care
University of Michigan Medical System
Ann Arbor, Michigan

POSTOPERATIVE RESPIRATORY FAILURE

Peter Nau, MD, MS
Department of Surgery
The University of Iowa
Iowa City, Iowa

LAPAROSCOPIC BYPASS FOR PANCREATIC CANCER

Douglas F. Naylor, Jr., MD, FACS, FCCM
Departments of General Anesthesia/Critical Care Medicine and General Surgery
Cleveland Clinic
Cleveland, Ohio

ENDOCRINE CHANGES IN CRITICAL ILLNESS

Susanna Nazarian, MD, PhD
Department of Surgery
The Johns Hopkins Hospital
Baltimore, Maryland

THE ROLE OF LIVER TRANSPLANTATION IN PORTAL HYPERTENSION

Matthew D. Neal, MD
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

NUTRITIONAL SUPPORT IN THE CRITICALLY ILL

Peter C. Neligan, MD
Division of Plastic Surgery, Department of Surgery
University of Washington
Seattle, Washington

BREAST RECONSTRUCTION FOLLOWING MASTECTOMY: INDICATIONS, TECHNIQUES, AND RESULTS

Leigh Neumayer, MD, MS
Huntsman Cancer Hospital
University of Utah
Salt Lake City, Utah

INGUINAL HERNIA

Hien T. Nguyen, MD, FACS
Director, Comprehensive Hernia Center
Assistant Professor of Surgery, School of Medicine
Associate Medical Director, Center for Bioengineering Innovation and Design (CBID) School of Engineering
Johns Hopkins University
Baltimore, Maryland

LAPAROSCOPIC INGUINAL HERNIORRHAPHY

Ninh T. Nguyen, MD, FACS
Department of Surgery
University of California, Irvine Medical Center
Orange, California

LAPAROSCOPIC APPENDECTOMY

Raminder Nirula, MD
Surgical Critical Care Fellowship Director
Co-Director, Surgical ICU
Trauma Medical Director, University of Utah
Salt Lake City, Utah

GLUCOSE CONTROL IN THE POSTOPERATIVE PERIOD

Yuri W. Novitsky, MD
Associate Professor of Surgery
Case Western Reserve University
Co-Director, Case Comprehensive Hernia Center
Director, Surgical Research
Department of Surgery
University Hospitals Case Medical Center
Cleveland, Ohio

LAPAROSCOPIC REPAIR OF RECURRENT INGUINAL HERNIAS

Terence O'Keeffe, MD, FACS
University of Arizona
Tucson, Arizona

BLOOD TRANSFUSION THERAPY IN TRAUMA

Patrick I. Okolo III, MD, MPH, FASGE
Chief, Gastrointestinal Endoscopy
Associate Professor of Medicine
Johns Hopkins University
Baltimore, Maryland

COLONIC STENTING

Charles S. O'Mara, MD, MBA
Professor of Surgery
University of Mississippi Medical Center
Jackson, Mississippi

BALLOON ANGIOPLASTY AND STENTS IN CAROTID ARTERY OCCLUSIVE DISEASE

Patrick B. O'Neal, MD
Department of Surgery
Boston Veteran's Administration Health Care System
Boston University School of Medicine
Boston, Massachusetts

NECROTIZING SKIN AND SOFT TISSUE INFECTIONS

Edwin O. Onkendi, MB, ChB
Department of Surgery
Mayo Clinic
Rochester, Minnesota

THE MANAGEMENT OF RECURRENT AND DISSEMINATED BREAST CANCER

Babak J. Orandi, MD, MSc
The Johns Hopkins Hospital
Baltimore, Maryland

OPEN REPAIR OF ABDOMINAL AORTIC ANEURYSMS

C. Keith Ozaki, MD, FACS
Vascular and Endovascular Surgery
Brigham and Women's Hospital
Boston, Massachusetts

THE TREATMENT OF CLAUDICATION

John Paige, MD, FACS
Associate Professor of Clinical Surgery
Department of Surgery
LSU Health New Orleans School of Medicine
New Orleans, Louisiana

THE MANAGEMENT OF SEMILUNAR LINE, LUMBAR, AND OBTURATOR HERNIATION

Theodore N. Pappas, MD
Distinguished Professor of Surgical Innovation
Interim Chair, Department of Surgery
Chief, General and Advanced Gastrointestinal Surgery
Vice Dean for Medical Affairs
Duke University Medical Center
Durham, North Carolina

MANAGEMENT OF CHOLANGIOCARCINOMA

Adrian Park, MD, FRCSC, FACS, FCS (ECSA)
Chair, Department of Surgery
Anne Arundel Medical Center
Annapolis, Maryland

HEMATOLOGIC INDICATIONS FOR SPLENECTOMY

Do Joong Park, MD, PhD
Department of Surgery
Seoul National University College of Medicine
Seoul, Korea

GASTRIC ADENOCARCINOMA

Charles Parker, MD
University of Cincinnati
Cincinnati, Ohio

THE MANAGEMENT OF THYROIDITIS

Nishant D. Patel, MD
Resident, Department of Surgery
The Johns Hopkins Hospital
Baltimore, Maryland

PRIMARY HYPERPARATHYROIDISM

Supriya S. Patel, MD
Resident in Surgery
Department of General Surgery
University of Southern California Medical Center
Los Angeles, California

SURGICAL MANAGEMENT OF CONSTIPATION

Timothy M. Pawlik, MD, MPH, PhD
Professor of Surgery and Oncology
Chief, Division of Surgical Oncology
John L. Cameron M.D. Professor of Alimentary Tract Diseases
The Johns Hopkins Hospital
Baltimore, MD

GASTROINTESTINAL STROMAL TUMORS

Gregory J. Pearl, MD
Professor of Surgery
Texas A & M Health Sciences Center
Chief, Division of Vascular Surgery
Baylor University Medical Center
Dallas, Texas

BRACHIOCEPHALIC RECONSTRUCTION

Gregory Peck, DO
Trauma and Critical Care Fellow
Emory University
Atlanta, Georgia

INITIAL ASSESSMENT AND RESUSCITATION OF THE TRAUMA PATIENT

Carlos A. Pellegrini, MD, FACS, FRCSI (Hon)
Henry N. Harkins Professor and Chair
Department of Surgery
University of Washington
Seattle, Washington

LAPAROSCOPIC TREATMENT OF ESOPHAGEAL MOTILITY DISORDERS

Peter D. Peng, MD
Department of Surgery
Kaiser Foundation Hospital
Oakland, California

THE MANAGEMENT OF ADRENAL CORTICAL TUMORS

Bruce A. Perler, MD, MBA
Julius H. Jacobson, II Professor of Surgery
The Johns Hopkins University School of Medicine
Chief, Division of Vascular Surgery and Endovascular Therpay
The John Hopkins Hospital
Baltimore, Maryland

THE MANAGEMENT OF RECURRENT CAROTID ARTERY STENOSIS

Jeffrey H. Peters, MD
Professor of Surgery
Chair of the Department of Surgery
University of Rochester Medical Center
Rochester, New York

THE MANAGEMENT OF ESOPHAGEAL CARCINOMA

Ho Phan, MD
UC Davis Medical Center
Sacramento, California

INJURY TO THE SPLEEN

K. Shad Pharaon, MD
Department of Surgery
Oregon Health & Science University
Portland, Oregon

THE MANAGEMENT OF VASCULAR INJURIES

Edward H. Phillips, MD, FACS
Department of Surgery
Cedars-Sinai Medical Center
Los Angeles, California

LAPAROSCOPIC SPLENECTOMY

Roy Phitayakorn, MD, MHPE (MEd)
Instructor of Surgery
Harvard Medical School
General and Endocrine Surgery
Director of Surgical Education Research
Boston, Massachusetts

THE MANAGEMENT OF PHEOCHROMOCYTOMA

Fredric M. Pieracci, MD, MPH
Staff Surgeon
Denver Health Medical Center
Assistant Professor of Surgery
University of Colorado School of Medicine
Denver, Colorado

PENETRATING ABDOMINAL TRAUMA

Henry A. Pitt, MD
Chief Quality Officer
Temple University Health System
Philadelphia, Pennsylvania

THE MANAGEMENT OF ECHINOCOCCAL CYST DISEASE OF THE LIVER

Susan C. Pitt, MD
Department of Surgery
Washington University
St. Louis, Missouri

THE MANAGEMENT OF ECHINOCOCCAL CYST DISEASE OF THE LIVER

Mun Jye Poi, MD
Assistant Professor of Surgery, Division of Vascular Surgery & Endovascular Therapy
Michael E. DeBakey Department of Surgery
Baylor College of Medicine
Houston, Texas

DEEP VENOUS THROMBOSIS

Jason D. Prescott, MD, PhD
Massachusetts General Hospital
Boston, Massachusetts

SECONDARY AND TERTIARY HYPERPARATHYROIDISM

Jennifer C. Price, MD
Fellow in Advanced Hepatology
The Johns Hopkins Hospital
Baltimore, Maryland

THE MANAGEMENT OF BUDD-CHIARI SYNDROME

Leigh Ann Price, MD
Assistant Professor of Plastic and Reconstructive Surgery
Director, Burn Fellowship Program
The Johns Hopkins University School of Medicine
Baltimore, Maryland

ELECTRICAL AND LIGHTNING INJURY

Brandon W. Propper, MD
The Johns Hopkins Hospital
Baltimore, Maryland

THORACIC OUTLET SYNDROMES

Reuven Rabinovici, MD, FACS
Professor of Surgery
Tufts University School of Medicine
Chief
Division of Trauma and Acute Care Surgery
Tufts Medical Center
Boston, Massachusetts

COAGULATION ISSUES AND THE TRAUMA PATIENT

Philip T. Ramsay, MD
Attending Surgeon and Director of General Surgery Residency
Atlanta Medical Center
Atlanta, Georgia

DIAPHRAGMATIC INJURIES

Bruce Ramshaw, MD, FACS
Halifax Health-Hernia Institute
Daytona Beach, Florida

ATHLETIC PUBALGIA: THE "SPORTS HERNIA"

Gregory W. Randolph, MD
Department of Otolaryngology—Head and Neck Surgery
Massachusetts Eye and Ear Infirmary
Department of Otology and Laryngology
Harvard Medical School
Boston, Massachusetts

SURGICAL APPROACH TO THYROID CANCER

Todd E. Rasmussen, MD, FACS
Deputy Commander
The U.S. Army Institute of Surgical Research
Fort Sam Houston, Texas;
Professor of Surgery
The Norman M. Rich Department of Surgery
The Uniformed Services University of the Health Sciences
Bethesda, Maryland

THE DIABETIC FOOT

David W. Rattner, MD
Chief, Division of Gastrointestinal and General Surgery
Massachusetts General Hospital
Professor of Surgery
Harvard Medical School
Boston, Massachusetts

GASTROESOPHAGEAL REFLUX DISEASE

Chandrajit P. Raut, MS, MSc
Associate Professor
Department of Surgery
Brigham & Women's Hospital
Center for Sarcoma and Bone Oncology
Dana-Farber Cancer Institute
Harvard Medical School
Boston, Massachusetts

GASTROINTESTINAL STROMAL TUMORS

THE MANAGEMENT OF SOFT TISSUE SARCOMA

Howard A. Reber, MD
Professor and Chief
Division of Gastrointestinal Surgery
Director, UCLA Center for Pancreatic Diseases
Department of Surgery
David Geffen School of Medicine at UCLA
Los Angeles, California

THE MANAGEMENT OF CHRONIC PANCREATITIS

Thomas Reifsnyder, MD, FACS
Department of Surgery
Bayview Medical Center
The Johns Hopkins University School of Medicine
Baltimore, Maryland

FEMOROPOPLITEAL OCCLUSIVE DISEASE

HEMODIALYSIS ACCESS SURGERY

Linda M. Reilly, MD
Professor of Surgery
University of California, San Francisco
San Francisco, California

THE MANAGEMENT OF CHRONIC MESENTERIC ISCHEMIA

Justin A. Reynolds, MD
Division of Digestive Diseases
Department of Medicine
David Geffen School of Medicine at UCLA
Los Angeles, California

ENDOSCOPIC THERAPY FOR ESOPHAGEAL VARICEAL HEMORRHAGE

Peter Rhee, MD, MPH, FACS, FCCM
Chief, Division of Trauma, Critical Care and Emergency Surgery
Professor of Surgery
Medical Director, UMC Trauma Center
Co-Medical Director, Pediatric ICU
Program Director, Acute Care Surgery Fellowship
Program Director, Critical Care Fellowship
Vice Chair, Clinical Affairs
Martin Gluck Endowed Chair in Trauma, Critical Care and Emergency Surgery
The University of Arizona
Tucson, Arizona

BLOOD TRANSFUSION THERAPY IN TRAUMA

Taylor S. Riall, MD, PhD
Associate Professor
John Sealy Distinguished Chair in Clinical Research
Department of Surgery
University of Texas Medical Branch
Galveston, Texas

UNUSUAL PANCREATIC TUMORS

J. David Richardson, MD
University of Louisville
Louisville, Kentucky

EMERGENCY DEPARTMENT THORACOTOMY

Nabil P. Rizk, MD
General Thoracic Surgeon
Memorial Sloan-Kettering Cancer Center
New York, New York

NEOADJUVANT AND ADJUVANT THERAPY OF ESOPHAGEAL CANCER

Miguel A. Rodriguez-Bigas, MD, FACS, FASCRS
Professor, Department of Surgical Oncology
Division of Surgery
The University of Texas MD Anderson Cancer Center
Houston, Texas

THE MANAGEMENT OF RECTAL CANCER

Michael J. Rosen, MD, FACS
Professor of Surgery
Chief, Division of GI and General Surgery
Director, Case Comprehensive Hernia Center
Co-Director, Case Acute Intestinal Failure Unit
University Hospitals Case Medical Center
Cleveland, Ohio

LAPAROSCOPIC VENTRAL HERNIA REPAIR

Laura H. Rosenberger, MD, MS
Resident, Department of Surgery
University of Virginia School of Medicine
Charlottesville, Virginia

SURGICAL SITE INFECTIONS

Robert E. Roses, MD
Assistant Professor
Department of Surgery
Hospital of the University of Pennsylvania
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

THE MANAGEMENT OF RECTAL CANCER

Gedge D. Rosson, MD
Associate Professor, Department of Plastic and Reconstructive Surgery
The Johns Hopkins Hospital
Baltimore, Maryland

NERVE INJURY AND REPAIR

Grace S. Rozycki, MD, MBA
Willis D. Gatch Professor of Surgery
Executive Vice-Chair
Department of Surgery
Director, Indiana Injury Institute
Indiana University
Indianapolis, Indiana

THE SURGEON'S USE OF ULTRASOUND IN THORACOABDOMINAL TRAUMA

Amy Rushing, MD
Assistant Professor of Surgery
Division of Acute Care Surgery, Trauma, and Surgical Critical Care
The Johns Hopkins Hospital
Baltimore, Maryland

VENTILATOR-ASSOCIATED PNEUMONIA

Colleen M. Ryan, MD
Associate Professor of Surgery
Harvard Medical School
Sumner Redstone Burn Center
Massachusetts General Hospital
Shriners Hospital for Children-Boston
Boston, Massachusetts

COLD INJURY, FROSTBITE, AND HYPOTHERMIA

Shirin Sabbaghian, MD
Fellow, Surgical Oncology
University of Pittsburgh
Pittsburgh, Pennsylvania

PRIMARY SCLEROSING CHOLANGITIS

Teviah E. Sachs, MD, MPH
Department of Surgery
The Johns Hopkins School of Medicine
Baltimore, Maryland

CAVERNOUS HEPATIC HEMANGIOMA

Bashar Safar, MBBS
Department of Surgery
The Johns Hopkins School of Medicine
Baltimore, Maryland

THE MANAGEMENT OF TOXIC MEGACOLON

Klaus Sahora, MD
Department of Surgery
Massachusetts General Hospital
Harvard Medical School
Boston, Massachusetts

INTRADUCTAL PAPILLARY MUCINOUS NEOPLASMS OF THE PANCREAS

Hakim K. Said, MD, FACS
Director, Microvascular Reconstructive Surgery Fellowship
Associate Professor, Surgery
Division of Plastic Surgery
University of Washington
Seattle, Washington

BREAST RECONSTRUCTION FOLLOWING MASTECTOMY: INDICATIONS, TECHNIQUES, AND RESULTS

Bulent Salman, MD
Associate Professor of Surgery
Gazi University School of Medicine
Ankara, Turkey

CYSTIC DISORDERS OF THE BILE DUCTS

Michael G. Sarr, MD
James C. Mason Professor of Surgery
Mayo Clinic
Rochester, Minnesota

THE MANAGEMENT OF ASYMPTOMATIC (SILENT) GALLSTONES

Stephanie A. Savage, MD, MS, FACS
Assistant Professor of Surgery
University of Tennessee Health Science Center
Memphis, Tennessee

THE MANAGEMENT OF LIVER INJURIES

Robert G. Sawyer, MD
University of Virginia
Charlottesville, Virginia

SURGICAL SITE INFECTIONS

Thomas M. Scalea, MD
Francis X. Kelly Professorship in Trauma Surgery
Director, Program in Trauma
Physician-in-Chief, R Adams Cowley Shock Trauma Center
University of Maryland School of Medicine
Baltimore, Maryland

AIRWAY MANAGEMENT IN THE TRAUMA PATIENT

Philip R. Schauer, MD
Cleveland Clinic Foundation
Cleveland, Ohio

GLYCEMIC CONTROL AND CARDIOVASCULAR DISEASE RISK REDUCTION AFTER BARIATRIC SURGERY

Todd Schlachter, MD
Vascular & Interventional Radiology
Johns Hopkins University
Baltimore, Maryland

VENA CAVA FILTERS

David R. Schmidt, MD, FACS
Gwinnett Surgical Associates
Lawrenceville, Georgia

ACUTE CHOLECYSTITIS

Matthew J. Schuchert, MD
Assistant Professor of Surgery
Department of Cardiothoracic Surgery
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

ESOPHAGEAL STENTS

Richard D. Schulick, MD
The Aragon/Gonzalez-Giusti Professor and Chair of Surgery
University of Colorado
Aurora, Colorado

PERIAMPULLARY CARCINOMA

Michael A. Schweitzer, MD
Assistant Professor of Surgery
The Johns Hopkins University School of Medicine
Director of Minimally Invasive Bariatric Surgery
Department of Surgery
Johns Hopkins Bayview Medical Center
Baltimore, Maryland

LAPAROSCOPIC SURGERY FOR MORBID OBESITY

Christopher M. Sciortino, MD, PhD
Assistant Professor of Surgery
Division of Cardiac Surgery
The Johns Hopkins Hospital
Baltimore, Maryland

DISORDERS OF ESOPHAGEAL MOTILITY

VIDEO-ASSISTED THORACIC SURGERY

Dorry Segev, MD, PhD
Associate Professor of Surgery and Epidemiology
Johns Hopkins University
Johns Hopkins Bloomberg School of Public Health
Baltimore, Maryland

PREOPERATIVE ASSESSMENT OF THE OLDER PATIENT: FRAILTY

LAPAROSCOPIC DONOR NEPHRECTOMY

Anthony J. Senagore, MD, MS, MBA, FACS, FASCRS
Professor and Division Chief
Charles W. and Carolyn Costello Chair for Colorectal Diseases
Department of Surgery
Division of Colorectal Surgery
Keck School of Medicine of University of Southern California
Los Angeles, California

SURGICAL MANAGEMENT OF CONSTIPATION

Ashish Shah, MD
Associate Professor of Surgery
Division of Cardiac Surgery
The Johns Hopkins Hospital
Baltimore, Maryland

BLUNT CARDIAC INJURY

Jay G. Shake, MD, MS, FACS
Division of Cardiothoracic Surgery
Assistant Professor of Surgery
Director, Cardiothoracic Intensive Care Unit
Scott and White Memorial Hospital
Texas A & M Health Science Center, College of Medicine
Temple, Texas

CARDIOVASCULAR PHARMACOLOGY

Brian D. Shames, MD
Associate Professor of Surgery, Department of Surgery
Chief, Division of General Surgery
University of Connecticut School of Medicine
Farmington, Connecticut

MALLORY-WEISS SYNDROME

Skandan Shanmugan, MD
Resident in Colon and Rectal Surgery
University Hospitals, Case Medical Center
Cleveland, Ohio

LOWER GASTROINTESTINAL BLEEDING

Reem Zeyad Sharaiha, MD, MSc
Weill Cornell Medical Center
New York, New York

OBSTRUCTIVE JAUNDICE: ENDOSCOPIC THERAPY

Gaurav Sharma, MD, MS
Surgical Resident
Brigham and Women's Hospital
Boston, Massachusetts

ACUTE CHOLANGITIS

Kenneth W. Sharp, MD
Professor of Surgery
Vice-Chair, Department of General Surgery
Vanderbilt University Medical Center
Nashville, Tennessee

GALLSTONE ILEUS

Robert Sheridan, MD
Massachusetts General Hospital
Shriners Hospital for Children
Boston, Massachusetts

PRACTICAL MANAGEMENT OF THE BURN PATIENT

Shmuel Shoham, MD
The Johns Hopkins Hospital
Baltimore, Maryland

ANTIFUNGAL THERAPY IN THE SURGICAL PATIENT

Fahad Shuja, MD
Department of Surgery
Massachusetts General Hospital
Boston, Massachusetts

ENDOVASCULAR TREATMENT OF ABDOMINAL AORTIC ANEURYSM

Gregorio A. Sicard, MD
Vice-Chairman
Eugene M. Bricker Professor of Surgery
Section of Vascular Surgery
Department of Surgery
Washington University, School of Medicine
St. Louis, Missouri

ATHEROSCLEROTIC RENAL ARTERY DISEASE

Michael B. Silva, Jr., MD
Department of Surgery
University of Texas Medical Branch at Galveston
Galveston, Texas

ACUTE MESENTERIC ISCHEMIA

Eric R. Simms, MD
Resident, Department of Surgery
Tulane University School of Medicine
New Orleans, Louisiana

PANCREATIC AND DUODENAL INJURIES AND CURRENT SURGICAL THERAPIES

Andrew Singer, MD, PhD
Assistant Professor of Surgery
Surgical Director of Kidney Transplantation
The Johns Hopkins Hospital
Baltimore, Maryland

THE ROLE OF LIVER TRANSPLANTATION IN PORTAL HYPERTENSION

Smrita Sinha, MD
Gastroenterology Fellow
Johns Hopkins University
Baltimore, Maryland

ACUTE COLONIC PSEUDO-OBSTRUCTION (OGILVIE'S SYNDROME)

Barbara L. Smith, MD, PhD
Massachusetts General Hospital
Boston, Massachusetts

LYMPHATIC MAPPING AND SENTINEL LYMPHADENECTOMY

Brian R. Smith, MD, FACS
Department of Surgery
University of California, Irvine Medical Center
Orange, California

LAPAROSCOPIC APPENDECTOMY

Lee E. Smith, MD
Emeritus Faculty, Section of Colon and Rectal Surgery
Department of Surgery
MedStar Washington Hospital Center
Professor of Surgery, Georgetown University
Washington, DC

THE MANAGEMENT OF SOLITARY RECTAL ULCER SYNDROME

Philip W. Smith, MD
Assistant Professor of Surgery
University of Virginia
Charlottesville, Virginia

EVALUATION OF THE ISOLATED NECK MASS

Julie Ann Sosa, MD, MA, FACS
Professor of Surgery and Medicine
Chief, Section of Endocrine Surgery
Director of Health Services Research
Department of Surgery
Duke University School of Medicine
Leader, Endocrine Neoplasia Diseases Group
Duke Cancer Institute and Duke Clinical Research Institute
Durham, North Carolina

MINIMALLY INVASIVE PARATHYROIDECTOMY

Jason L. Sperry, MD
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

NUTRITIONAL SUPPORT IN THE CRITICALLY ILL

Jennifer A. Stableford, MD
Assistant Professor of Surgery
Montefiore Medical Center and the Albert Einstein College of Medicine
Bronx, New York

AXILLOFEMORAL BYPASS

J. Daniel Stanley, MD, FACS, FASCRS
Associate Professor of Surgery
Department of Surgery
University of Tennessee College of Medicine
Chattanooga, Tennessee

THE MANAGEMENT OF CLOSTRIDIUM DIFFICILE COLITIS

Sharon L. Stein, MD
Assistant Professor of Surgery
University Hospitals, Case Medical Center
Cleveland, Ohio

LOWER GASTROINTESTINAL BLEEDING

Antonia Stephen, MD
Assistant Professor of Surgery
Massachusetts General Hospital
Boston, Massachusetts

SECONDARY AND TERTIARY HYPERPARATHYROIDISM

Jordan R. Stern, MD
Senior Resident in Surgery
The University of Chicago
Chicago, Illinois

PANCREATIC NECROSIS

Jeffrey A. Sternberg, MD, FACS, FASCRS
Surgical Director, Center For Inflammatory Diseases
California Pacific Medical Center
Clinical Assistant Professor of Surgery
University of California San Francisco
San Francisco, California

THE MANAGEMENT OF PILONIDAL DISEASE

Kent A. Stevens, MD, MPH
Assistant Professor of Surgery
Department of Surgery
Johns Hopkins Medical Institutions
Baltimore, Maryland

SPLENIC SALVAGE PROCEDURES: THERAPEUTIC OPTIONS

David Steward, MD
University of Cincinnati
Cincinnati, Ohio

THE MANAGEMENT OF THYROIDITIS

Dylan Stewart, MD
Assistant Professor of Surgery
Director of Pediatric Trauma Program
Division of Pediatric Surgery
Johns Hopkins Children Center
The Johns Hopkins Hospital
Baltimore, Maryland

THE MANAGEMENT OF ACUTE APPENDICITIS

Tiffany Stoddard, MD
Department of Surgery
Anne Arundel Medical Center
Annapolis, Maryland

HEMATOLOGIC INDICATIONS FOR SPLENECTOMY

Steven M. Strasberg, MD
Section of Hepatobiliary-Pancreatic Surgery
Department of Surgery
Washington University
St. Louis, Missouri

BENIGN BILIARY STRICTURES

Michael B. Streiff, MD
Associate Professor of Medicine and Pathology
Johns Hopkins Medical Institutions
Baltimore, Maryland

COAGULOPATHY IN THE CRITICALLY ILL PATIENT

Paul H. Sugarbaker, MD, FACS, FRCS
Medical Director, Center for Gastrointestinal Malignancies
MedStar Washington Hospital Center
Washington, DC

THE MANAGEMENT OF PERITONEAL SURFACE MALIGNANCY

Lee L. Swanstrom, MD, FACS
Clinical Professor of Surgery
Oregon Health & Sciences University
Division of GI and MIS Surgery
The Oregon Clinic
Portland, Oregon;
Chief Innovations Officer, Institute l'Hopital Univeritaire
Strasbourg, Strasbourg, France

LAPAROSCOPIC ADRENALECTOMY

Tze-Woei Tan, MD
Smithwick Vascular Surgery Fellow
Boston University Medical Center
Boston University School of Medicine
Boston, Massachusetts

THE MANAGEMENT OF PERIPHERAL ARTERIAL EMBOLI

Luis F. Tapias, MD
Department of Surgery
Massachusetts General Hospital
Boston, Massachusetts

MINIMALLY INVASIVE ESOPHAGECTOMY

John L. Tarpley, MD
Professor of Surgery and Anesthesiology
Department of Surgery
Vanderbilt University School of Medicine
Associate Chief, Surgical Service
Nashville VA
Nashville, Tennessee

THE MANAGEMENT OF DIVERTICULOSIS OF THE SMALL BOWEL

Ali Tavakkoli, MD
Department of Surgery
Brigham and Women's Hospital
Boston, Massachusetts

METABOLIC CHANGES FOLLOWING BARIATRIC SURGERY

Nyali Taylor, MD
Albert Einstein Medical Center
Philadelphia, Pennsylvania

ENDOVASCULAR MANAGEMENT OF ARTERIAL INJURY

Spence M. Taylor, MD
Division of Vascular Surgery
Greenville Hospital System Clinical University
University of South Carolina School of Medicine
Greenville, South Carolina

PROFUNDA FEMORIS RECONSTRUCTION

Dana A. Telem, MD
Assistant Professor of Surgery
Department of General Surgery
Stony Brook University Medical Center
Stony Brook, New York

GASTROESOPHAGEAL REFLUX DISEASE

Mario D. Terán, MD
Division of Thoracic Surgery
Johns Hopkins University
Baltimore, Maryland

THE MANAGEMENT OF BARRETT'S ESOPHAGUS

Kyla P. Terhune, MD
Assistant Professor of Surgery and Anesthesiology
Department of Surgery
Vanderbilt University School of Medicine
Nashville, Tennessee

THE MANAGEMENT OF DIVERTICULOSIS OF THE SMALL BOWEL

David J. Terris, MD
Surgical Director, GRU Thyroid and Parathyroid Center
Porubsky Professor and Chairman
Department of Otolaryngology-Head and Neck Surgery
Georgia Regents University
Augusta, Georgia

HYPERTHYROIDISM

Sarah P. Thayer, MD, PhD
Associate Professor
Department of Surgery
Andrew L. Warshaw, MD, Institute for Pancreatic Cancer Research
W. Gerald Austen Scholar in Academic Surgery
Masachusetts General Hospital and Harvard Medical School
Boston, Massachusetts

THE MANAGEMENT OF ACUTE PANCREATITIS

William D. Tobler, Jr., MD
Neurological Surgeon
The Mayfield Clinic
Cincinnati, Ohio

TRACHEOSTOMY

Paul Toomey, MD

LAPAROSCOPIC SURGERY FOR MORBID OBESITY

This page intentionally left blank

PREFACE

The first edition of *Current Surgical Therapy* was published in 1984. The text has thus been in existence for 30 years, and this represents the eleventh edition. We have updated the material to reflect the continuing evolution of minimally invasive surgery, critical care, and vascular surgery. The text continues to be perhaps the most popular surgical book in the country, and as long as it fulfills a need, we plan to continue the publication every three years. In addition, it is a special privilege and honor for the two editors to be able to review contributions from surgeons around the country, and indeed from around the world, on what they believe is current surgical therapy for virtually all general surgical topics. It is an enjoyable task and keeps two surgeons, who care for surgical patients and operate daily, current on all general surgical topics.

The eleventh edition contains more than 270 chapters. This is twice the number of chapters in the first edition of *Current Surgical Therapy*. The length, however, has been held constant through the last few editions in an effort to keep the text at a manageable size. As with prior editions, nearly every chapter is new, and has been written by a new author. All authors have contributed their specific and personal thoughts on the current surgical therapy of the disease about which they are experts. Thus, to obtain a broad view of the topic, the reader should review the contributions of other experts in the last two or three editions of *Current Surgical Therapy.*

As with the past editions, disease presentation, pathophysiology, and diagnosis are discussed only briefly, with the emphasis being on current surgical therapy. When an operative procedure is discussed, an effort has been made to contain brief and concise descriptions, with figures and diagrams when possible. *Current Surgical Therapy* is written for surgical residents, fellows, and fully trained surgeons in private practice or an academic setting. Many have told us that it is an excellent text to review prior to taking the general surgical boards or recertifying. In addition, medical students have given us feedback that they believe the text is of value to them. However, *Current Surgical Therapy* is not written principally for medical students. We believe a more classic surgical textbook with substantial sections on disease presentation, diagnosis, and pathophysiology is more appropriate for medical students.

We remain grateful to the many surgeons throughout the country, as well as the international surgeons, who participated in creating this textbook. Most of the potential authors that we solicit respond enthusiastically to the opportunity to present their expert views. Their efforts obviously are what make this textbook a success. In addition, Andrew and I could not have compiled this textbook without the herculean efforts of Ms. Irma Silkworth, who has been involved with virtually all of these editions.

Both editors continue to enjoy and thrive in our chosen profession of general surgery. In recruiting medical students into our specialty over the last 40 years, I have used the statement, "If you pick a profession you love, you never have to work the rest of your life." In our view, that profession is surgery.

Finally, we would like to dedicate this edition, as with the others, to the surgical house staff at The Johns Hopkins Hospital, who are "the best of the best."

Andrew M. Cameron, MD

CONTENTS

The Esophagus

Esophageal Function Testing 1
Philip W. Carrott, Jr., MD, James A. Mann, MD, and Benjamin D. Kozower, MD, MPH, FACS

Gastroesophageal Reflux Disease 9
Dana A. Telem, MD, and David W. Rattner, MD

Endoluminal Approaches to Gastroesophageal Reflux Disease 14
Mark R. Wendling, MD, and W. Scott Melvin, MD

The Management of Barrett's Esophagus 19
Mario D. Terán, MD, and Malcolm V. Brock, MD

Endoscopic Treatment of Barrett's Esophagus 23
Nassrene Elmadhun, MD, and Michael Kent, MD

Paraesophageal Hernia 27
Benedetto Mungo, MD, Daniela Molena, MD, and Malcolm V. Brock, MD

The Management of Pharyngeal Esophageal (Zenker's) Diverticula 36
Richard F. Heitmiller, MD, FACS

The Management of Achalasia of the Esophagus 39
Sheraz R. Markar, MD, and Donald E. Low, MD

Disorders of Esophageal Motility 44
Christopher M. Sciortino, MD, PhD, and Stephen C. Yang, MD

The Management of Esophageal Carcinoma 47
Michal J. Lada, MD, and Jeffrey H. Peters, MD

Neoadjuvant and Adjuvant Therapy of Esophageal Cancer 54
Nabil P. Rizk, MD

Esophageal Stents 58
Matthew J. Schuchert, MD, Catherine Go, and James D. Luketich, MD

Esophageal Perforation 64
Charles M. Ferguson, MD

The Stomach

The Management of Benign Gastric Ulcer 69
Raafat Z. Abdel-Misih, MD, FRCS Edin, FRCS Eng, FACS, James D. Larson, MD, and Sherif R. Abdel-Misih, MD

The Management of Duodenal Ulcers 76
Robert J. Beaulieu, MD, and Frederic E. Eckhauser, MD, FACS

Zollinger-Ellison Syndrome 80
Haggi Mazeh, MD, and Herbert Chen, MD, FACS

Mallory-Weiss Syndrome 84
Brian D. Shames, MD, and David W. McFadden, MD

Gastric Adenocarcinoma 87
Sam S. Yoon, MD, and Do Joong Park, MD, PhD

Gastrointestinal Stromal Tumors 96
Chandrajit P. Raut, MS, MSc, and Timothy M. Pawlik, MD, MPH, PhD

Morbid Obesity 103
Katherine Graw Lamond, MD, MS, and Anne O. Lidor, MD, MPH

Small Bowel

Small Bowel Obstruction 109
Lisa M. Kodadek, MD, and Martin A. Makary, MD, MPH

The Management of Crohn's Disease of the Small Bowel 113
Isaac Howley, MD, and Susan L. Gearhart, MD, FACS, FASCAS

Strictureplasty in Crohn's Disease 118
Leon Maggiori, MD, and Fabrizio Michelassi, MD

The Management of Small Bowel Tumors 122
Hiroko Kunitake, MD, and Richard Hodin, MD

The Management of Diverticulosis of the Small Bowel 128
Kyla P. Terhune, MD, and John L. Tarpley, MD

Motility Disorders of the Stomach and Small Bowel 132

The Esophagus

Esophageal Function Testing

Philip W. Carrott, Jr., MD, James A. Mann, MD, and Benjamin D. Kozower, MD, MPH, FACS

The function of the esophagus is to facilitate the passage of food and drink to the stomach and to ensure that they stay there. Disorders of this function are complex and are caused by a variety of anatomic or intrinsic issues that can be measured and diagnosed with esophageal function tests. Esophageal dysfunction can be present at any level of the esophagus, although most patients evaluated by surgeons have issues with lower esophageal sphincter (LES) function. Common symptoms such as dysphagia, regurgitation, reflux, and pain prompt a diagnostic work up workup, and esophageal function tests are essential for optimal surgical intervention. A detailed history from patients with dysphagia is imperative; many patients suffer unnecessarily because physicians are unfamiliar with this topic.

This chapter provides a brief overview of commonly encountered esophageal function disorders and a review of the primary esophageal function tests used in their diagnosis.

DISORDERS OF ESOPHAGEAL FUNCTION

Gastroesophageal Reflux

Gastroesophageal reflux disease (GERD) is a common disorder that often brings patients to medical attention for acid-suppressing medication. Chronic reflux, Barrett's esophagus, stricture and regurgitation of stomach contents into the mouth or pharynx are common symptoms that lead to surgical referral. The etiology with aspiration of the reflux or regurgitation can be complex and may be related to the amount and type of dietary consumption or to an anatomic problem, usually a hiatal hernia that alters the geometry of the gastroesophageal junction (GEJ). A mechanically defective LES is diagnosed when one of the anatomic components is abnormal (pressure, <6 mm Hg; total length, <2 cm; abdominal length, <1 cm). As one expects, the chance of GERD increases with the increasing number of defective components and is more than 90% when all three LES components are abnormal. The etiology and severity of reflux varies with every patient and can be investigated with pH studies, impedance testing, and motility or manometry studies. Newer technologies can combine these tests into one catheter.

Achalasia

Achalasia is the most common esophageal motility disorder and is defined as relaxation failure or incomplete relaxation of the LES accompanied by an absence of peristalsis in the esophageal body. The LES is hypertensive in about 50% and almost always shows a failure of normal relaxation of patients with achalasia. Patients need to know that although swallowing is improved after surgery or pneumatic dilation of the LES, it is never normal because of the abnormal peristalsis. The cause of achalasia remains unknown, but a decreased number of inhibitory ganglion cells is seen on pathologic review. An esophagram is a good screening test for a patient with dysphagia; the classic findings are a dilated esophagus with smooth tapering at the GEJ, to the classic "bird's beak" appearance (Figure 1). The diagnosis of achalasia should always rule out pseudoachalasia, any condition that can masquerade as achalasia, such as a malignant disease. Endoscopic examination is an imperative part of this evaluation and usually shows some resistance at the GEJ, with a classic "popping" feeling as the scope passes into the stomach. Endoscopy can also include the placement of a wire to facilitate the passage of a manometric catheter, where blind passage proves difficult. Manometry is the gold standard for confirmation of the diagnosis and classically shows aperistalsis and incomplete relaxation of the LES after a swallow (Figure 2). Medical therapy can include calcium channel blockers, nitrates, and sildenafil. However, these are minimally effective. Endoscopic therapies include botulinum toxin and pneumatic dilation. Botulinum toxin is effective but only works for 3 to 6 months. Pneumatic dilation is slightly less effective than surgery, and many radiologists and gastroenterologists no longer are comfortable performing this procedure. Importantly, pneumatic dilation makes surgery considerably more difficult. Surgery involves a myotomy of the LES, which can usually be performed laparoscopically, from the stomach, across the LES, and well on to the esophagus. Some patients with end-stage achalasia and a dilated nonfunctional esophagus may need an esophagectomy.

Hypertensive Lower Esophageal Sphincter

Hypertensive LES is diagnosed when a patient has an LES pressure above the 95th percentile of normal and has symptoms of dysphagia or noncardiac chest pain. The exact value differs according to the method used for measurement, but this condition can only be diagnosed with manometry. In hypertensive LES, relaxation of the LES and peristalsis are present, unlike in achalasia.

Diffuse Esophageal Spasm

Diffuse esophageal spasm (DES) is an uncommon condition that accounts for less than 10% of esophageal motility abnormalities. DES is characterized by uncoordinated contractions of the esophagus that

FIGURE 1 Classic bird's-beak appearance of achalasia on upper gastrointestinal series.

typically result in symptoms of chest pain, dysphagia, or both. The esophagram may be abnormal, but manometry is usually necessary for the diagnosis. Manometric findings, however, may not correlate with symptoms. DES is usually characterized by disordered rather than high pressure esophageal contractions.

Medical treatment options include nitrates and sildenafil and tricyclic antidepressants, which help with noncardiac chest pain. Valium and Ativan are also frequently effective if both the drugs fail to control symptoms. Use of proton pump inhibitors (PPIs) for treatment of concomitant GERD may also be helpful. A long myotomy can be effective in many patients with refractory DES but has a very high morbidity rate.

Hypercontractile "Nutcracker" Esophagus

Hypercontractile, or "nutcracker," esophagus is a manometric diagnosis defined by high pressure (>180 mm Hg) or long duration of swallow responses (>7 seconds) in patients who have either chest pain or dysphagia (Figures 3 and 4). The peristaltic contractions propagate normally, and the LES relaxes appropriately. Diltiazem has been shown to lower distal peristaltic pressures and may reduce chest pain; however, these results are not reliably reproducible. As in DES, nitrates, sildenafil, PPIs, and tricyclic antidepressants may be useful in the treatment of noncardiac chest pain.

Ineffective Esophageal Motility

Ineffective esophageal motility is characterized by decreased distal esophageal peristaltic wave pressures (amplitudes <30 mm Hg) or an absence of esophageal contractions in more than 30% of wet swallows. A distinguishing feature between ineffective esophageal motility and achalasia is that resting LES pressure is typically decreased in ineffective esophageal motility. Systemic conditions, such as scleroderma, can be associated with ineffective esophageal motility. Unfortunately, no standard treatment options exist, besides PPIs and lifestyle modifications. Patients are advised to eat small meals, remain upright after eating, chew food well, and take acid-suppressing medication.

Nonspecific Esophageal Motility

Nonspecific esophageal motility disorder refers to an esophageal motility disorder that does not have features of a named motility disorder. These abnormalities are often not associated with dysphagia and are nonspecific. Examples of frequently encountered nonspecific esophageal motility disorders are triple-peaked and retrograde contractions. Systemic diseases such as diabetes mellitus, hypothyroidism, eosinophilic esophagitis, and amyloidosis can be associated with nonspecific esophageal motor abnormalities. These abnormalities may also be seen in patients with paraesophageal hernia who have a shortened esophagus.

Hiatal Hernia

The presence of a hiatal hernia alters the usual location and structure of the LES, displacing it into the negatively pressured thorax and disrupting the reinforcement offered by the diaphragmatic crura. The manometric profile often shows the LES and the crura and intra-abdominal stomach as having increased pressure, a "double hump." High resolution manometry makes the diagnosis of hiatal hernia by manometry relatively easy. Manometry in paraesophageal hernias can be unpredictable depending on the anatomy of the hernia and the stomach because the esophagus may be shortened or of normal length. Manometry guides surgeons in repair of the hiatal hernia and helps them to choose the type of fundoplication to perform. Although a paucity of evidence is found, most esophageal surgeons avoid a complete wrap for patients with abnormal peristalsis and perform a partial, 180-degree or 270-degree, fundoplication to prevent postoperative dysphagia.

DIAGNOSTIC TESTS FOR ESOPHAGEAL DISEASES

Radiographic Imaging

Radiographic tests of the esophagus include the fluoroscopic esophagram and cross-sectional imaging. An esophagram, or barium swallow, is often performed as a biphasic examination in which double or single contrast techniques are used and should always have a solid bolus administered as a 13 mm barium tablet. Liquid and solid contrast agents are used in most diagnostic tests for dysphagia. Because the act of swallowing is a dynamic process, the inclusion of video or cine recording is imperative for better assessment of oropharyngeal function and esophageal motility.

A properly conducted videoesophagram allows the physician to comment on oropharyngeal function, morphology of the esophagus, esophageal motility, appearance of the mucosal surface, evaluation of the GEJ, presence and degree of reflux, and efficiency of secondary wave clearance. A videoesophagram is sensitive for detection of certain motility disorders, such as achalasia (94%) and scleroderma (100%); however, it is relatively insensitive for detection of most other motility disorders. The decision of whether to obtain radiographic imaging before endoscopic examination or to proceed directly to esophagogastroduodenoscopy (EGD) can be difficult. The authors recommend a videoesophagram as the initial diagnostic test in conditions such as a suspected cricopharyngeal bar, esophageal

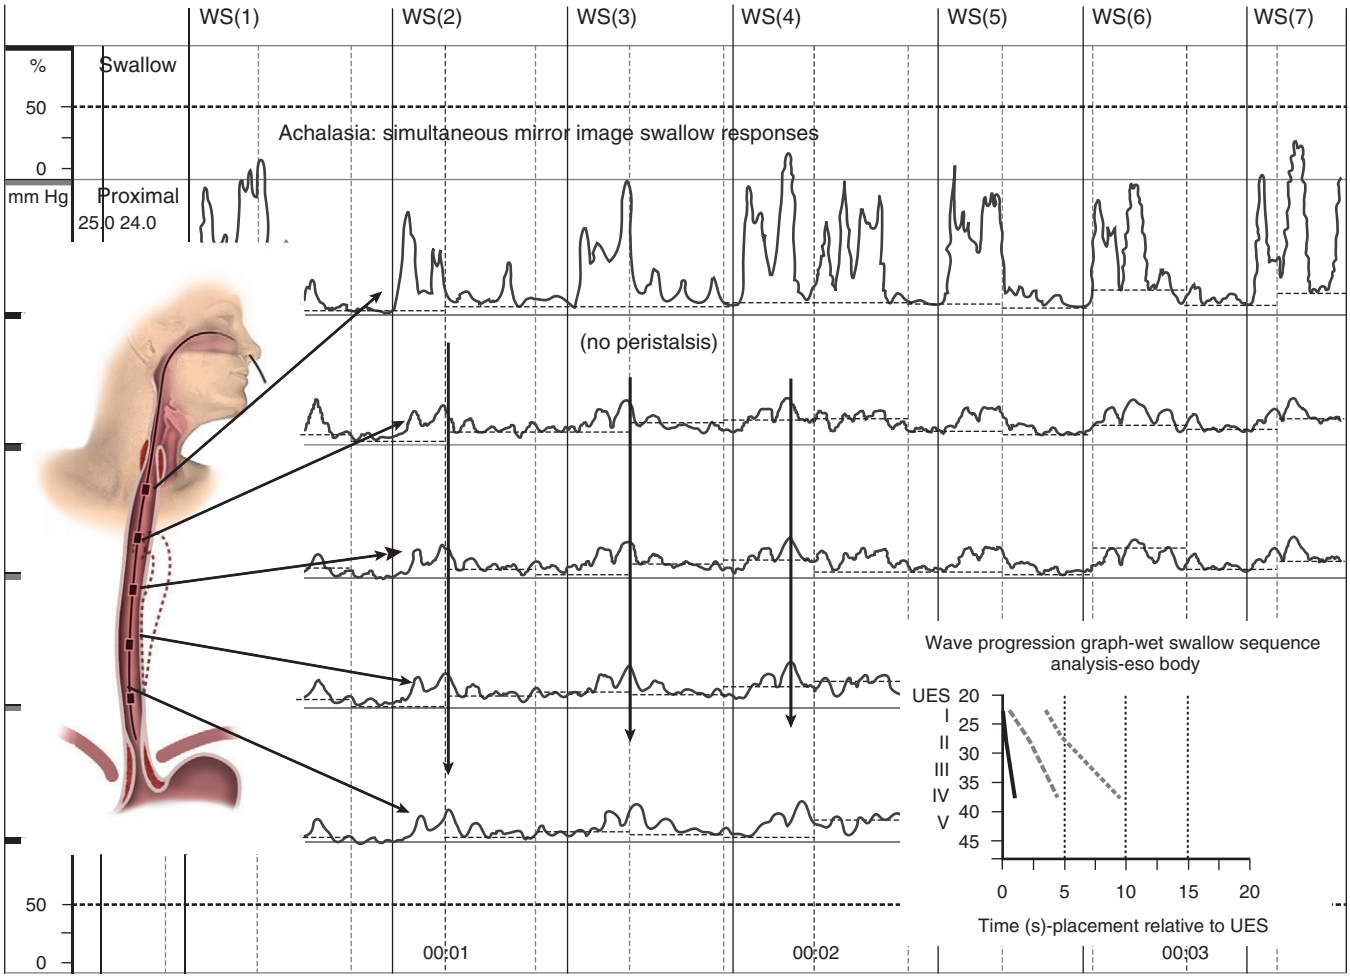

FIGURE 2 Manometry tracing of achalasia. The swallow study shows mirror-image swallow responses in the esophageal body.

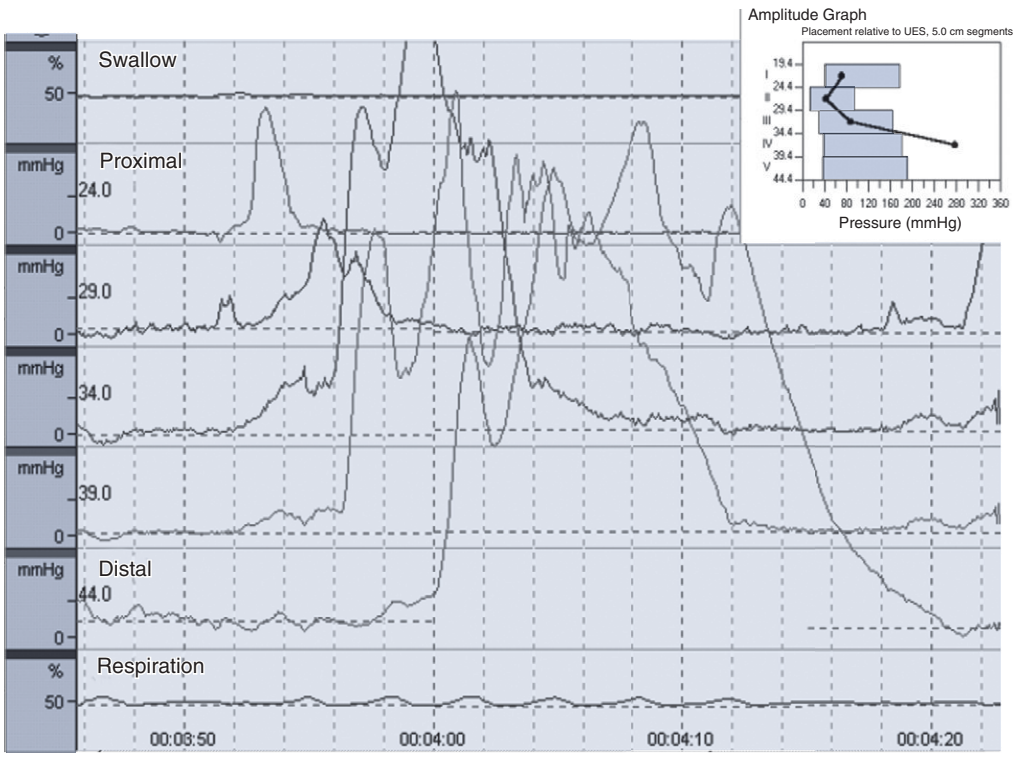

FIGURE 3 Manometry showing hypercontractile esophageal body with pressures more than 180 mm Hg, which is designated as a "nutcracker" esophagus with these high pressures and symptoms of chest pain or dysphagia.

web, diverticulum, Schatzki's ring, early achalasia, or complex stricture, where an esophagram may provide the endoscopist a "road map."

Cross-sectional imaging with computed tomographic (CT) scan is helpful for evaluation of extraluminal esophageal disease, including staging for esophageal cancer and evaluation of esophageal trauma. However, the videoesophagram is still the gold standard in evaluation for esophageal leak. CT scan is used in evaluation of esophageal changes of the wall, such as thickening, but is not accurate in the evaluation of esophageal mucosal disease or motility disorders. Magnetic resonance imaging can produce high-quality multiplanar images without use of ionizing radiation but has limited utility for most esophageal diseases because of motion artifact and long imaging times.

Endoscopy

Although not strictly an esophageal function test, endoscopic examination is often necessary for evaluation or treatment for esophageal disorders. The authors routinely perform an on-table endoscopy before esophageal surgery because the surgeon is ultimately responsible for the diagnosis and treatment option selected. For example, endoscopic evaluation in achalasia rules out pseudoachalasia and can confirm the diagnosis with the characteristic "pop" on passing through the LES. For hiatal hernia surgery, it can identify Barrett's esophagus, rule out early malignant disease of the stomach or esophagus that has been missed, and help identify the presence of a short esophagus that may need an esophageal lengthening procedure as part of the hernia repair.

Endoscopic evaluation for esophageal disorders begins with a good view of the vocal cords and aryepiglottic folds, which can appear inflamed in patients with chronic GERD. The upper esophageal sphincter (UES) consists of the cricopharyngeal muscle and is best seen on the final withdrawal of the endoscope. As the esophagus is entered, the mucosa can be carefully inspected for signs of mucosal inflammation or luminal irregularities, such as esophageal webs, rings, strictures, or esophagitis. Evaluation of the esophagus for distension or tonicity is also important because an atonic or patulous appearance may indicate the presence of a motility disorder.

At the level of the aortic arch, the striated muscle of the upper esophagus transitions to smooth muscle in the distal half of the esophagus. Patients with dysphagia should have random biopsies sampled from the distal and proximal esophagus for evaluation for eosinophilic esophagitis, particularly if the endoscopic examination shows the corrugated "feline" esophagus, with multiple concentric rings and linear furrows (Figure 5). In patients with longstanding GERD, the squamocolumnar junction proximal to the LES should be carefully inspected for signs of Barrett's esophagus (Figure 6), which appears as intestinal mucosa, with a pinker or salmon-colored appearance. The length of the Barrett's mucosa should be quantified, and multiple biopsies should be taken for assessment for dysplasia or malignancy.

The LES should really be called the LES complex because it is not one discrete muscle but rather a combination of esophageal muscle, phrenoesophageal ligament, and diaphragm. On endoscopy, it appears as a flap valve. Once the endoscope has entered the stomach, the endoscopist notes whether the gastric wall is poorly distensible and uses retroflex to examine the cardia and GEJ. The flap valve of the GEJ may be seen and assessed for competence under air pressure or for whether a hiatal hernia has expanded this area and allowed reflux and regurgitation.

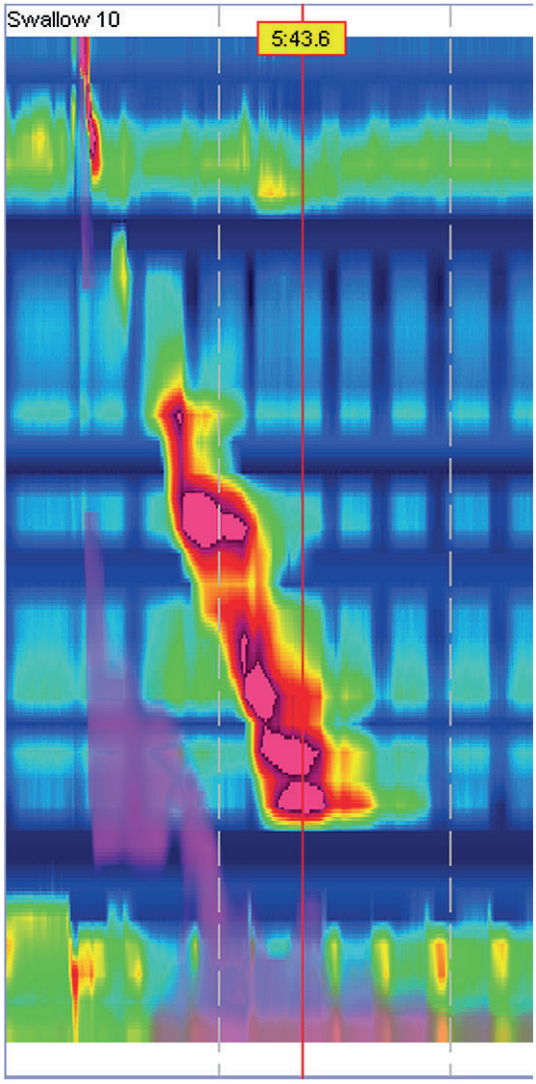

FIGURE 4 High-resolution manometry showing "nutcracker" esophagus and relaxation after the swallow.

FIGURE 5 Eosinophilic esophagitis. Mucosal rings consistent with "trachealization" of the esophagus.

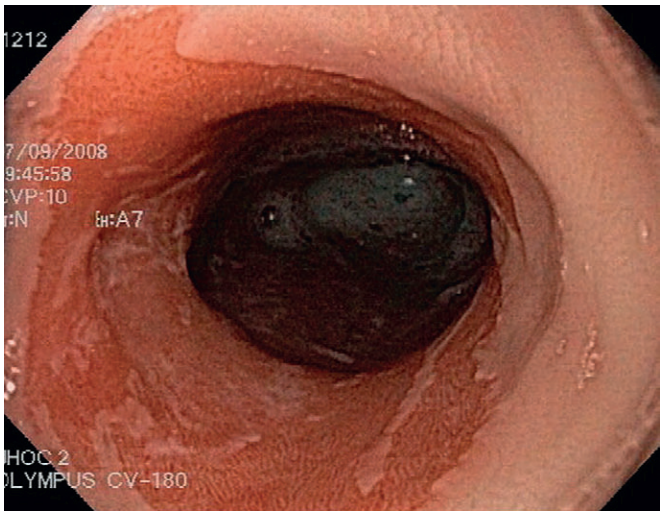

FIGURE 6 Salmon-colored mucosal changes seen in Barrett's esophagus.

BOX 1: Indications for esophageal manometry

1. Dysphagia: For the assessment of functional disorders after structural causes have been ruled out.
2. Noncardiac chest pain: For assessment for esophageal dysmotility as a cause of symptoms.
3. Diagnosis or confirmation of a suspected motility disorder.
4. Preoperative assessment of esophageal motility before planned esophageal surgery.
5. Postoperative assessment: For detection of response to surgery or confirmation of response to treatment or for assessment of the cause of persistent symptoms after surgery.

Endoscopy offers multiple therapeutic maneuvers, from dilation to biopsy to botulinum toxin injection. Mucosal ablative techniques are also used for Barrett's esophagus, and endoscopic ultrasound scan (EUS) has become the gold standard for the local and regional lymph node staging of esophageal cancer.

Esophageal Manometry

Esophageal manometry is the gold standard for assessment of esophageal motor function. It is the only modality that can define the pressure profile of peristalsis and measure LES pressure. Conventional manometry uses eight sensors, placed at various points of the esophagus, typically four in the esophageal body and four at the level of the GEJ. High-resolution manometry, specifically the Manoscan (Sierra Scientific Instruments, LLC, Los Angeles, Calif), is vastly superior and will replace older manometry equipment. High-resolution manometry provides a much clearer picture of esophageal pressure changes during swallowing and includes pressure monitors every centimeter along the catheter. This new technology offers the ability to simplify the procedural setup, eliminate motion artifact, simplify the ability to interpret data, and allow for a more sophisticated interpretation of esophageal motility. Indications for esophageal manometry are summarized in Box 1.

Technical Considerations

For conventional manometry, a solid-state or water-perfused catheter is used. The manometry catheter is swallowed until all of the sensors are in the stomach, and the catheter is then pulled back in increments of 0.5 to 1 cm for measurement of the resting pressure of the LES, esophageal body, and UES (Figure 7). Once the resting pressures have been calibrated, the catheter is positioned across the entire esophagus for recording of pressure changes during swallowing. The contraction and relaxation of the UES, the body of the esophagus, and the LES are recorded with 10 consecutive swallows of a 5-mL bolus of water. These pressure values are compared with standardized normal values (Figure 8; Table 1). Plotting of the pressure values with the passage of the water bolus down the esophagus allows for the detection of abnormal peristalsis and sphincter dysfunction. These patterns form the basis of esophageal dysmotility conditions.

The high-resolution manometry catheters have sensors every 1 cm. These catheters are able to span from the pharynx to the stomach, which obviates the need to retract the catheter to measure resting pressures. Pressure measurements are recorded both in the resting phase and for 10 swallows in a similar fashion to the older equipment. However, these pressure measurements are displayed as a topographic pressure reading over time. A typical scan of a high-resolution swallow in achalasia is shown in Figure 9. This figure also shows impedance in magenta, as the catheter used included impedance monitoring. Figures 4 and 9 are also examples of high-resolution manometry.

Diagnostic Tests for Gastroesophageal Reflux

A surgeon performing a procedure for GERD should order four principal tests before performing a fundoplication or hiatal hernia repair. First, an acid exposure test is used to document the presence of reflux because many patients with heartburn do not actually have GERD. Second, manometry is essential to ensure that esophageal dysmotility is not contributing to reflux as patients with dysmotility may not be able to clear physiologic reflux. Surgeons need to be careful when operating on patients with documented GERD and impaired motility because postoperative dysphagia can be a significant problem. A partial fundoplication or a floppy complete fundoplication may prevent dysphagia in these patients. Third, a barium swallow helps with identification of the presence and size of a hiatal hernia and may alert the surgeon to the presence of a short esophagus. A tension-free intra-abdominal GEJ at the end of the procedure is imperative, and a variety of esophageal lengthening procedures can be used if necessary. Finally, an EGD should be performed to rule out malignant disease and to identify Barrett's esophagus in patients with severe GERD. The authors typically perform the EGD in the operating room at the same setting as the procedure.

Acid exposure in the esophagus is measured with an intraluminal pH probe with one of two methods: either an intraluminal tube with a nasopharyngeal catheter or a wireless Bravo pH probe (Medtronic, Minneapolis, Minn). Both methods provide the physician with similar data, particularly relating to the amount of time the esophagus is exposed to acid reflux. When the information is correlated with a symptom log, determination is possible of whether the patient's symptoms are related to acid exposure within the esophagus. This information is commonly expressed with use of six standard parameters (Box 2) to calculate a DeMeester score, or a composite pH score. A score of less than 14.72 (95th percentile of normal) is considered physiologic reflux, whereas a score greater than 14.72 is considered abnormal. Acid exposure in the esophagus may be physiologic, and it is recorded according to the position of the patient (supine or upright) and the relation of acid exposure to meals. pH monitoring may also be used while the patient is on acid-suppressing therapy to determine whether there is adequate acid suppression with the current medication regimen. The data collected from each

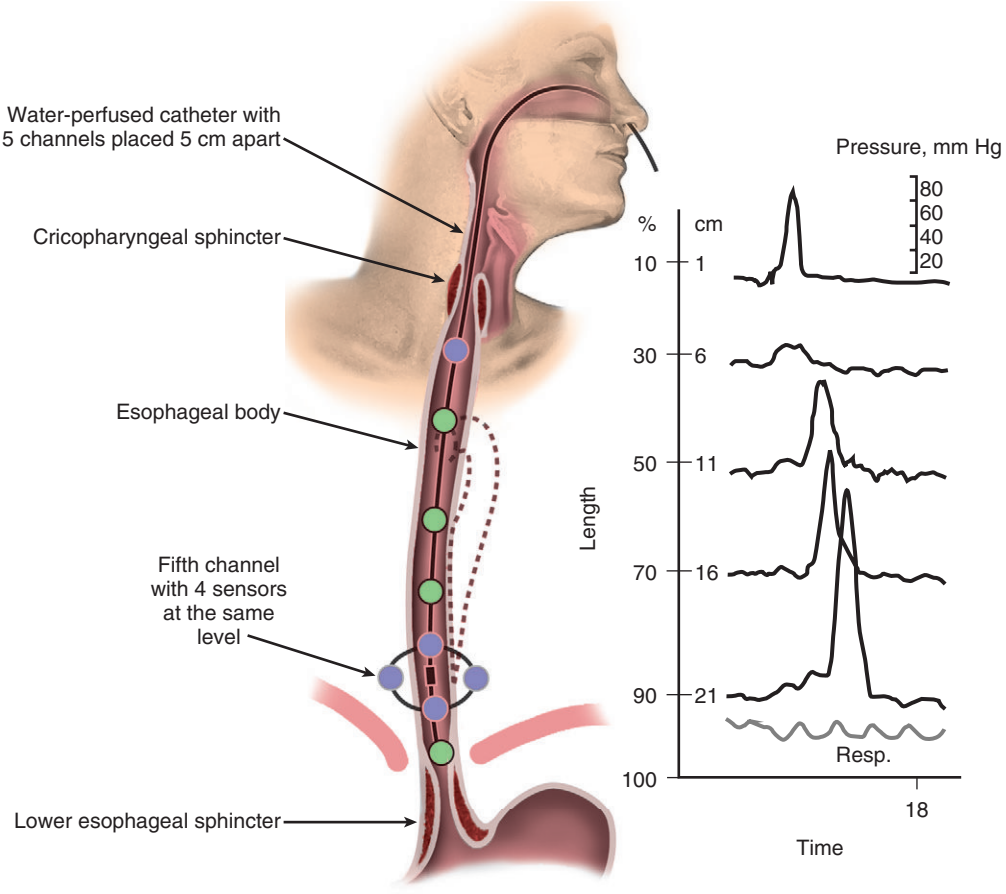

FIGURE 7 Esophageal manometry. A water-perfused or solid-state catheter is positioned in the esophagus. The sensors here are 5 cm apart, and the manometry shows normal wave propagation. Newer catheters that have sensors every 1 cm are termed high-resolution manometry.

TABLE 1: Normal LES parameters in 50 healthy volunteers

LES measurements	Mean	SD	Median	Maximum	Minimum	Percentile	
						2.5	*5*
Pressure (mm Hg)	14.87	5.14	13.8	25.6	5.2	6.1	8
Abdominal length (cm)	2.18	0.72	2.2	5	0.8	0.89	1.1
Overall length (cm)	3.65	0.68	3.5	5.5	2.4	2.4	2.6

individual's tests are compared with normal values derived from data from healthy volunteers. The Bravo probe is often preferred by patients for pH monitoring because it is placed at the time of upper endoscopy and does not require an extended time with a nasopharyngeal catheter. The Bravo probe is placed 5 cm above the LES and wirelessly transmits data to a recorder worn by the patient. It measures ph for 48 hours while a wired probe is worn for 24 hours which gives a larger sampling of ph changes in the esophagus and is more accurate.

Esophageal Impedance

Impedance monitoring measures bolus transport by measuring the resistance to electrical conductivity of the esophagus and its contents. Impedance testing is an important adjunct to traditional pH testing because it can be useful for patients taking PPIs and for evaluation of bile (nonacid) reflux. Impedance measurement works by using low AC voltage to apply an electrical potential between two electrodes on a catheter separated by an isolator. The circuit is then closed by the surrounding material spanning the electrodes. Because air, liquid, and esophageal mucosa have unique impedance characteristics, identification of the material that is bridging the electrodes is easy. Air is resistant to current flow and has a high impedance; liquid has a low impedance value. Esophageal tissue has an indeterminate range and is used as a baseline during monitoring. With multiple electrodes along a catheter system, identification of changes in impedance makes possible determination of the direction of bolus transport within the esophagus and identification of reflux of a bolus that has cleared the esophagus but comes back up from the stomach (Figure 10).

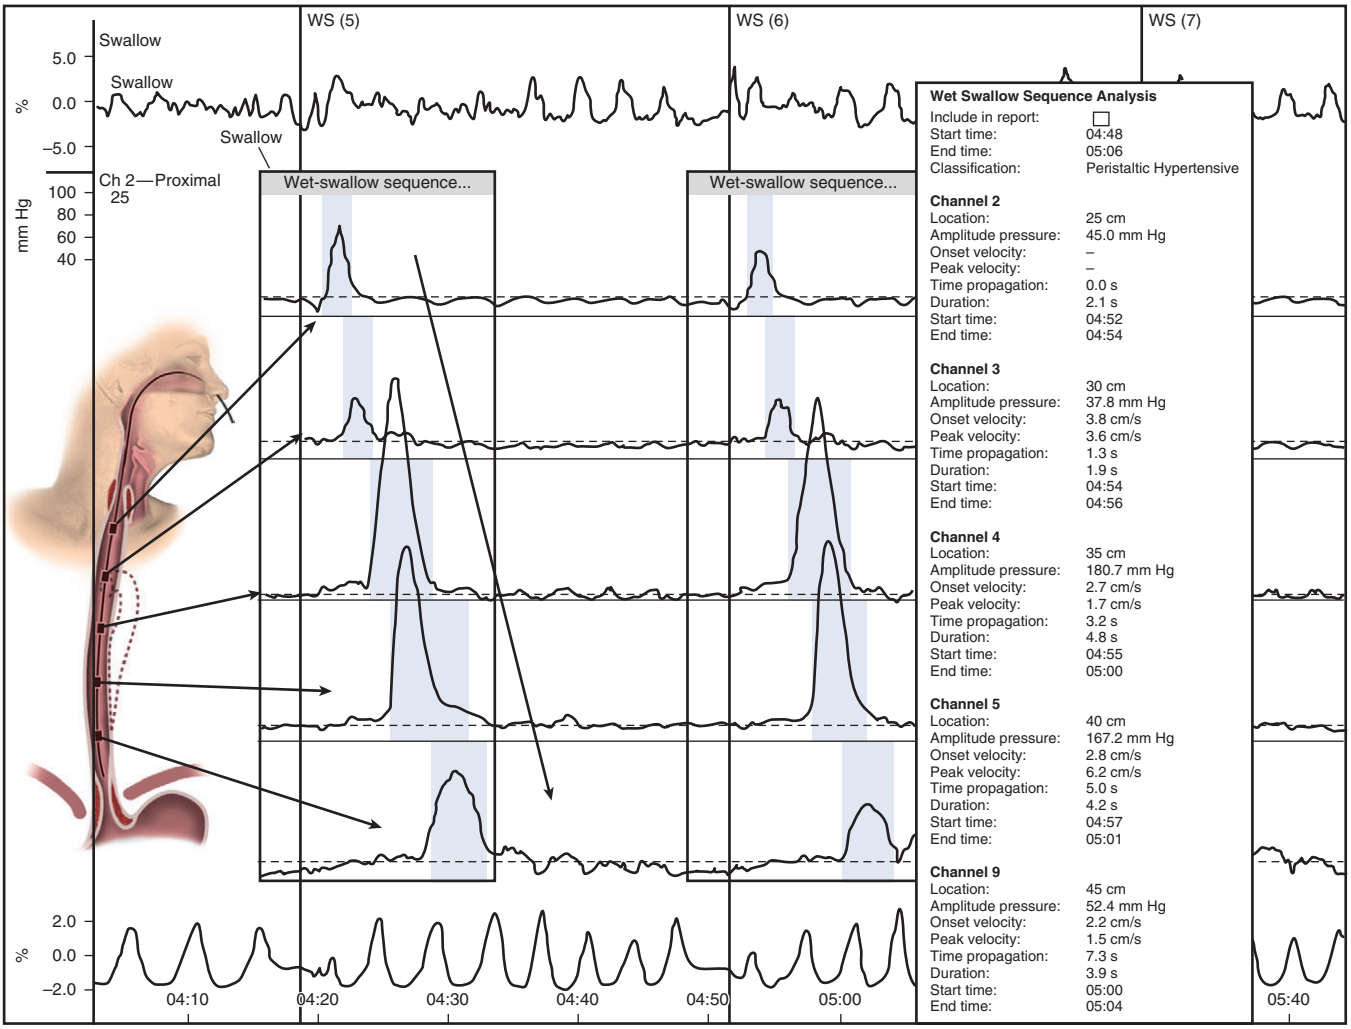

FIGURE 8 Normal esophageal body study. The channels are positioned at 5-cm intervals. The values shown are calculated for each wet swallow.

Multichannel intraluminal impedance (MII) is a new technology that incorporates impedance transducers for pressure measurement and a pH probe in one catheter. As a result, MII is used for the same indications as esophageal manometry and for detection and measurement of acid and nonacid reflux.

SUMMARY

The diagnosis of esophageal function disorders can be made from a careful history and the use of appropriate diagnostic testing. Several tests are frequently needed for the thorough evaluation of these disorders. Surgeons must understand the utility of these tests to evaluate whether a patient is a good surgical candidate for intervention and to determine the best treatment for a particular patient. A surgeon who is not familiar with these tests is not able to achieve optimal outcomes in the management of complex esophageal disorders. The authors also stress the importance of close collaboration between the radiologist, gastroenterologist, and surgeon in evaluating and treating this complicated group of patients.

BOX 2: Measured parameters during 24-hour esophageal pH monitoring

1. Percent total time pH <4
2. Percent upright time pH <4
3. Percent supine time pH <4
4. Number of reflux episodes
5. Number of reflux episodes ≥5 minutes
6. Longest reflux episode (in minutes)

Gastroesophageal Reflux Disease

Dana A. Telem, MD, and David W. Rattner, MD

INTRODUCTION

Gastroesophageal reflux disease (GERD) is caused by incompetence of antireflux barriers at the gastroesophageal junction (GEJ) that results in acid or alkaline substances refluxing into the esophagus. In the past decade, the prevalence of GERD has steadily increased. Although most patients with GERD experience intermittent symptoms, an estimated 20% of adults experience symptoms weekly and 7% to 10% have daily symptoms. Treatment of GERD involves a stepwise approach. Initial treatment focuses on lifestyle modifications and medical therapy directed at neutralizing acid. Goals of treatment center on symptom control, resolution of esophagitis when present, and prevention of disease complications. Surgical therapy for GERD has evolved a great deal since the first antireflux procedures were described more than half a century ago. Despite improved surgical techniques, debate comparing the benefit of surgical intervention with optimal medical therapy continues. The outcome of surgical treatment for gastroesophageal reflux depends on key preoperative patient factors and adherence to proper surgical technique. Thus, surgeons who treat GERD must be familiar with the tenets of proper patient selection and with the principles of operative therapy.

OPERATIVE INDICATIONS

Proper patient selection is essential both to obtain optimal surgical outcomes and to manage postoperative patient expectations. The most frequent indication for surgery has traditionally been reflux symptoms refractory to pharmacologic therapy. However, in the era of powerful acid suppressive medications (i.e., proton pump inhibitors [PPIs]), the outcomes after fundoplication in this subset of patients are suboptimal. Multiple studies show worse outcomes with regards to resolution of reflux symptoms in patients whose conditions do not respond to antisecretory medications. Although GERD refractory to pharmacologic therapy should remain an operative indication, physiologic testing must show that pathologic acid reflux exists and that when reflux occurs that it correlates with the patient's symptoms.

Ideal candidates for an antireflux operation are patients who show a response to medical therapy but are either unwilling or unable to take daily medications. As more data become available detailing the risks associated with long-term PPI use, such as osteoporosis, this operative indication may represent a larger portion of antireflux operations performed. Additional operative indications for an anti-reflux procedure include noncompliance with medical therapy, complications of GERD, and atypical symptoms of GERD, such as chest pain, asthma, chronic cough, hoarseness, dental erosions, idiopathic pulmonary fibrosis, recurrent pneumonia, aspiration, and chronic bronchitis (Box 1).

Absolute contraindications to an anti-reflux procedure are few but most importantly include patients with esophageal cancer or those with Barrett's mucosa with untreated high-grade dysplasia. Although multiple relative contraindications exist, obesity is perhaps the most significant. Obesity is a well-established risk factor for the development of GERD, and symptoms typically improve with weight loss. Furthermore, obesity has been shown to adversely impact the durability of an antireflux operation. As such, patients with body mass index (BMI) greater than 35 kg/m^2 are more likely to benefit from a weight loss procedure, such as Roux-en-Y gastric bypass, than fundoplication and should be referred accordingly (see Box 1).

PREOPERATIVE EVALUATION

A systematic evaluation is necessary before consideration of an anti-reflux procedure. Initial evaluation of all patients should include a thorough history and physical examination. Patient reflux history is predictive of operative success and should center on duration, pattern, and type of reflux symptoms. Patients with typical symptoms of GERD, such as heartburn and regurgitation, tend to have a better response to fundoplication than those with atypical symptoms. Evidence also suggests that patients who experience worse symptoms in a supine rather than upright position have better outcomes after fundoplication. A thorough history of previous and current medical therapies attempted, and compliance with therapy, must also be obtained. A good response to antisecretory medications is generally predictive of a good surgical outcome. After a thorough initial evaluation, all patients deemed candidates for an antireflux procedure should undergo a preoperative evaluation that includes the following studies: endoscopy, upper gastrointestinal (UGI) series, manometry, and ambulatory pH monitoring (Box 2).

Endoscopy

Endoscopy has a high specificity for diagnosing of GERD. Visual or histopathologic changes of the esophageal mucosa that are present on endoscopy are diagnostic of GERD, with specificity upwards of 95%. Biopsy of the mucosa is an essential procedure in evaluation of patients with reflux or dysphagia. Although Barrett's esophagus (BE) often has a characteristic salmon color, visual inspection alone is inadequate for this diagnosis. Endoscopic findings are very specific for GERD, but endoscopy lacks sensitivity. Approximately 50% of patients with GERD have normal endoscopic findings and are thus classified as having nonerosive reflux disease (NERD) or

BOX 1: Indications and contraindications to an antireflux procedure in patients with gastroesophageal reflux disease (GERD)

Indications
Failed optimal medical management
Noncompliance with medical therapy
Unwillingness to take lifelong medications
Severe esophagitis on endoscopy
Complications of GERD (benign stricture, Barrett's esophagus, bleeding, ulceration)
Extraesophageal atypical reflux symptoms

Contraindications
Absolute
Presence of esophageal cancer
Barrett's mucosa with high-grade dysplasia
Inability to tolerate anesthesia
High surgical risk as a result of comorbidities
Portal hypertension and uncorrectable coagulopathy

Relative
Body mass index ≥35 kg/m^2
Surgeon experience

BOX 2: Key tenets of preoperative patient evaluation

Patient History
Response to antisecretory therapy
Compliance with antisecretory therapy
Typical versus atypical reflux symptoms
Pattern of reflux (upright versus supine)
Comorbidities
History of abdominal surgery

Physical Examination

Diagnostic Studies
Endoscopy
- Assesses for esophagitis and other complications of gastroesophageal reflux disease (GERD)
- Detects presence of Barrett's esophagus
- Detects esophageal cancer
- Identifies presence of a hiatal hernia

Upper Gastrointestinal
- Detects and characterizes a hiatal hernia
- Evaluates for a short esophagus
- Demonstrates reflux in patients with nonerosive reflux disease (NERD) or atypical GERD

Esophageal Manometry
- Evaluates for motility disorders

pH Monitoring
- Confirmatory study in patients with NERD or atypical GERD

uncomplicated GERD. Perhaps more important than diagnosis is the ability of endoscopy to detect complications of gastroesophageal reflux. Such complications include erosive esophagitis, peptic stricture, BE, esophageal cancer, gastric outlet obstruction, and other potentially significant UGI findings that impact operative management.

Upper Gastrointestinal Series

Although not all surgeons find a UGI series useful, the authors obtain it fairly liberally. The benefit of a UGI series pertains more to the diagnosis and characterization of a potential hiatal hernia and to the opportunity to observe esophageal motility fluoroscopically. A close association between reflux and presence of hiatal hernia has been found. A hiatal hernia results in reflux both by affecting the competence of the lower esophageal sphincter (LES) and by compromising esophageal acid clearance once reflux has occurred. Thus, presence of a hiatal hernia necessitates repair during an antireflux procedure. A UGI provides valuable information regarding gastric morphology, size and type of hiatal hernia, presence of gastric volvulus, and other anatomic abnormalities, such as a "short" esophagus, that are useful for preoperative planning. Although a UGI has some utility in showing reflux and motility abnormalities in patients with atypical symptoms of GERD or in those with NERD, it cannot be used to determine the presence of pathologic reflux.

Esophageal Manometry

Data that show that the best predictor of postoperative dysphagia is the presence of preoperative dysphagia have led some surgeons to abandon this test as part of the preoperative evaluation. However, the authors routinely obtain esophageal manometry before recommending a fundoplication. Manometry occasionally provides an alternative diagnosis, such as achalasia, for which antireflux surgery may be contraindicated. In addition, manometric findings may lead to a modification of the surgical approach. In patients with markedly disordered peristalsis or very low amplitude contractions, a partial fundoplication or nonsurgical management should be considered. Ineffective clearance of small amounts of reflux can significantly contribute to symptoms in these patients. Although it reduces reflux, a complete fundoplication in this setting can also make esophageal clearance more difficult, which is one of the reasons a partial rather than complete fundoplication in the presence of esophageal dysmotility is controversial. Level II evidence suggests that patients with nonspecific esophageal motility disorders may be at increased risk for postoperative heartburn, regurgitation, and dysphagia after a complete fundoplication.

Ambulatory pH Monitoring

Ambulatory pH monitoring is the gold standard for confirmation of pathologic acid reflux and, even more importantly, of correlation with the patient's symptoms. A 24-hour pH test should be performed in patients with typical reflux symptoms who do not have evidence of mucosal damage on endoscopy and in all patients who have atypical symptoms. The only patients that do not need a 24-hour pH study are those who have typical symptoms of reflux, histologic evidence of esophagitis, and a good response to PPIs. Several key points are crucial in ensuring the validity of this study. First, the esophageal probe must be positioned correctly in the distal esophagus. The pH probe should be placed 5 cm above the manometrically determined upper limit of the LES. This distance is standardized and was chosen to avoid possible displacement of the probe within the stomach during swallowing. Confirmation of the LES is crucial because incorrect placement of the probe compromises the sensitivity of the test. Manometric placement is preferred; other methods of LES detection have been proven inaccurate and inferior in determination of LES position. In evaluation of patients for surgery, this test is most useful if patients discontinue use of antisecretory medications at least 1 week before the study. If the test is performed while patient's acid production is suppressed with medication, the test may not answer the question the surgeon should be asking—that is, is pathologic acid reflux causing the patient's symptoms? Patients who cannot discontinue their acid suppressive medications should be evaluated with esophageal impedance testing. Impedance testing has the ability to distinguish between acidic and nonacidic reflux but still captures all reflux events irrespective of pH.

SURGICAL TREATMENT OPTIONS

Once a patient has met the requirements for antireflux surgery and has undergone the appropriate preoperative evaluation, surgical options may then be discussed. The probability of an antireflux operation relieving a patient's symptoms is directly related to how well the patient's symptoms have been correlated to the physiology. When a solid cause and effect relationship is established, good outcomes are routine. A variety of operative techniques and approaches to antireflux surgery have been described (Box 3). A laparoscopic transabdominal approach is the preferred approach for most patients undergoing a primary antireflux operation. Transthoracic and open abdominal approaches are typically reserved for patients who need revisional antireflux operations, those who have had multiple previous abdominal operations, and those with other contraindications to laparoscopic surgery. The benefits of a laparoscopic approach include shorter recovery time, decreased pain, decreased rate of hernia formation and other wound complications, and perhaps most importantly, improved visualization of hiatal structures. In the United States, a 360-degree fundoplication is the most common operation performed. In Europe, however, surgeons are more inclined to perform partial fundoplication. Several recent randomized controlled studies have showed comparable efficacy between 360-degree and 270-degree fundoplication. Nonetheless, proponents of the full 360-degree fundoplication argue that durability of the Nissen fundoplication is superior to that of partial fundoplication. Advocates of partial fundoplication argue that the ability of their patients to vomit and a lower incidence rate of bloating symptoms make partial fundoplication the procedure of choice. Regardless of the specific fundoplication performed, the principles of the operation remain the same. The purpose of the antireflux operation is to restore the functional and mechanical competence of the LES, reconstruct the diaphragmatic hiatus, and repair any hiatal hernia if present.

MINIMALLY INVASIVE SURGICAL TECHNIQUE

Proper operative instruments, port placement, and patient positioning are key factors to consider for the operation. The patient is placed in the supine position with the surgeon standing on the patient's right side and the assistant at the patient's left side. Laparoscopic monitors are placed at eye level at each side of the patient. Five trocars, two 10-mm and three 5-mm, are used for the operation. A Veress needle is placed in the left upper quadrant and is used to establish pneumoperitoneum. Once the abdomen has been insufflated to 15 mm Hg, a 10-mm supraumbilical trocar is placed off of the midline towards the patient's left side. This trocar serves as the camera port and is placed in this position to improve visualization of the hiatus and not interfere with working ports. A 5-mm port is then placed laterally in the right upper quadrant for a flexible arm liver retractor. After placement of the liver retractor, a 5-mm port for the surgeon's left hand is placed just below the right subcostal margin in the midclavicular line, and a 10-mm port for the surgeon's right hand is placed along the left subcostal margin at the midclavicular line. A 5-mm assistant port is also placed laterally in the left upper quadrant. A 30-degree laparoscope is preferred for this procedure. Correct port placement is critical to ensuring proper visualization of hiatal structures and optimizing ergonomics for hiatal dissection and laparoscopic suturing (Figure 1).

With the patient in reverse Trendelenburg's position, the dissection is initiated with division of the gastrohepatic ligament. Care must be taken at this point to identify a completely replaced left hepatic artery. Oftentimes, an accessory hepatic artery is encountered. If present, one may attempt to preserve this vessel; however, if it impedes exposure or positioning of the fundoplication, division is recommended and typically inconsequential. If the vessel is large and concern exists that the vessel provides most of the arterial supply to the left lobe of the liver, it should be temporarily occluded and the liver observed for ischemia. Once the gastrohepatic ligament has been divided, the right crus is identified and the phrenoesophageal ligament opened. Care must be taken during this portion of the procedure to ensure that only the peritoneum is opened because deeper dissection may result in injury to the anterior vagus nerve or esophagus. Once the phrenoesophageal ligament is opened, the right crus is mobilized from the esophagus with careful blunt dissection. This dissection is carried anteriorly and circumferentially to the left crus. The anterior vagus nerve must be identified during this dissection to prevent inadvertent injury. Visualization for the caudal dissection onto the left crus can be hindered by fat, particularly in an obese patient. When this caudal dissection becomes challenging, division of the short gastric vessels usually provides improved exposure to the caudal portion of the left crus. Caution must be taken during this portion of the operation to ensure that the vessels are taken without any thermal injury to the stomach.

Once the left crus has been completely cleared, attention is then turned to creation of a posterior window behind the esophagus. This maneuver should be approached delicately, and the dissection should proceed easily to the other side. The posterior vagus nerve must be identified at this time. Once a window has been created, a vessel loop is placed around the esophagus to facilitate retraction. With the esophagus retracted upwards, attention can now be turned to crural closure. The crura are then closed starting caudally and moving in a cephalad direction with interrupted pledgeted nonabsorbable suture (Figure 2). Crural closure should be performed at low-pressure pneumoperitoneum (8–mm Hg to 9–mm Hg) to reduce diaphragmatic stretch and to more accurately approximate anatomy that will exist when the pneumoperitoneum is released. Crural closure should leave

BOX 3: Options for fundoplication

Complete Fundoplication
Nissen: 360-degree wrap

Partial Fundoplication
Toupet: Posterior 270-degree wrap
Anterior fundoplication: 180-degree or 90-degree
Hill Repair: Recreation of Angle of His and posterior gastropexy
Belsey Mark IV: Transthoracic 240-degree wrap

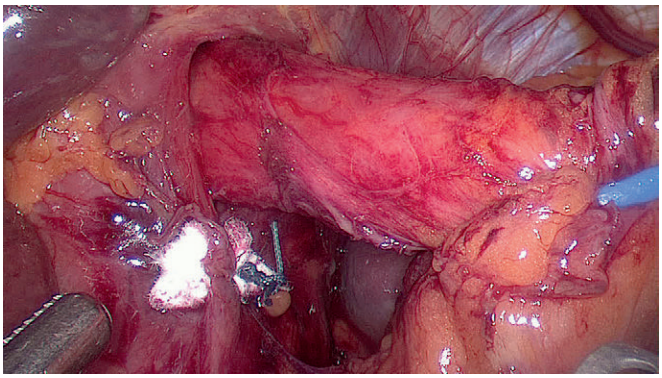

FIGURE 2 Closure of the diaphragmatic hiatus.

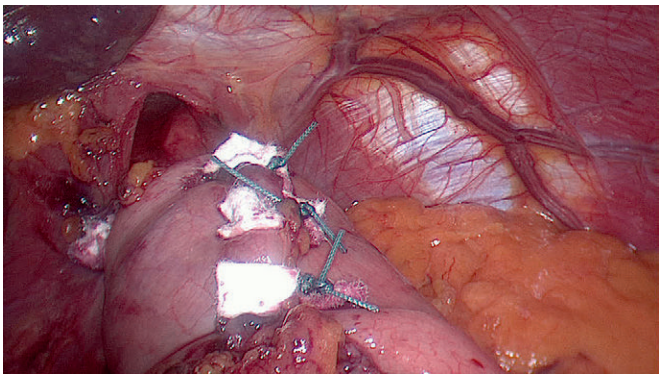

FIGURE 3 Completed 360-degree fundoplication.

approximately 1.5 cm of free space in the hiatus. An overzealous crural closure can lead to dysphagia that is unresponsive to esophageal dilation.

Once the crura have been reapproximated, the fundoplication is performed. The fundus of the stomach is grasped and brought underneath the esophagus. A "shoeshine" maneuver is then performed in which both sides of the fundus are grasped and pulled back and forth behind the esophagus to assess for proper orientation and tension. The remnants of the short gastric vessels should line up if the fundus has been delivered without twisting it. Once the fundus is pulled underneath the esophagus, it should remain in place after the grasper is released. If the fundus retracts back under the esophagus, further dissection to eliminate tension is necessary. A 56F bougie is then passed by either the surgeon or an experienced team member. Once the bougie is in place, a complete, 360-degree fundoplication is performed. A minimum of 2.5 cm of intra-abdominal esophageal length is necessary for an adequate wrap, and the fundoplication must be performed over the distal esophagus. Three nonabsorbable pledgeted sutures are used to create the wrap, all incorporating esophageal wall (Figure 3). At the conclusion of the operation, an endoscopy may be performed to assess the adequacy of the fundoplication. This is particularly useful in difficult cases or reoperations (Figure 4).

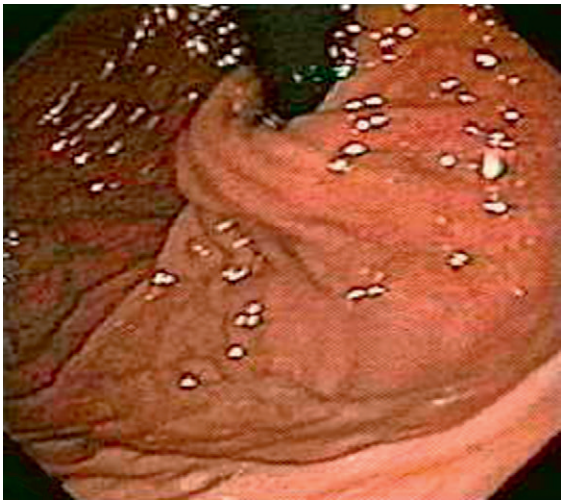

FIGURE 4 Normal endoscopic appearance of a 360-degree fundoplication.

POTENTIAL OPERATIVE PITFALLS

Bleeding

When dissection is performed in proper anatomic planes, significant bleeding is unusual. Bleeding during dissection of the right crus and GEJ usually originates from branches of the left gastric vessels and usually means the surgeon has dissected too close to the lesser curvature vessels. Care should be taken when energy devices are used for hemostasis in the GEJ region because these can easily cause a thermal injury to the vagus nerve. In some patients, the fundus and upper pole of the spleen appear fused and make division of the highest short gastric vessels difficult. This can be managed by carefully opening the peritoneum in this region and working layer by layer to isolate these vessels before dividing them. When bleeding occurs in this region, it can be controlled by applying pressure while the team sets up to make a definitive effort to stop the bleeding. The surgeon should have a low threshold to add an additional port so that exposure can be maintained or an additional instrument used to help get control of the bleeding.

Short Esophagus

The incidence rate of a "short" esophagus is estimated to be up to 10% in patients undergoing an antireflux procedure. A short esophagus is the result of chronic reflux disease that involves recurring cycles of inflammation and healing, with subsequent fibrosis. This entity can pose a unique challenge for the surgeon because sufficient intra-abdominal esophageal length is a key tenet to performance of a fundoplication. Failure to recognize and correct a short esophagus results in a higher potential for a "slipped" fundoplication, mediastinal herniation, and suboptimal operative outcome. In most patients, this entity can be managed with more extensive mediastinal mobilization of the esophagus and complete reduction of a hiatal hernia, if present. However, gaining more than 2 cm of esophageal length is difficult even if one mobilizes the esophagus all the way up to the aortic arch. Therefore, some patients need an esophageal lengthening procedure, such as a Collis gastroplasty. Attempts at full mobilization should be performed before any lengthening procedure, and intraabdominal esophageal length should be assessed after the crural closure is completed. Closure of the crura from a caudal to cephalad direction displaces the hiatal opening in an anterior and cephalad direction. In patients with moderate sized hiatal hernias, this maneuver can often gain several centimeters of intraabdominal length.

Esophageal or Gastric Perforation

A dreaded complication of an antireflux operation is an unrecognized intraoperative gastric or esophageal perforation. Injuries typically result from either thermal damage during dissection or excessive

traction on the stomach or esophagus. At the end of the operation, the stomach and distal esophagus should be thoroughly inspected for any evidence of compromise. An endoscopy may also help in identification of a perforation. If an injury is identified during surgery, depending on surgeon comfort level and skill set, it may be managed laparoscopically with oversewing of the defect. Larger defects may be excised and stapled closed. If any question as to the adequacy of repair exists, conversion to open surgery is necessary.

POSTOPERATIVE CARE

After the operation, patients are admitted to a regular hospital room. Neither a nasogastric tube nor a Foley catheter is placed in these patients. Use of narcotics is kept at a minimum, and standing ketorolac tromethamine is given routinely to reduce narcotic use. Patients are started on a clear liquid diet the next morning. Patients are discharged on postoperative day 1 and kept on a full liquid diet for 1 week, at which time a soft diet is introduced. A postoperative UGI study is not routinely obtained unless clinically indicated. Patients with chest pain, retching, or unexplained tachycardia should undergo immediate imaging to exclude the possibility of a herniated wrap.

COMMON POSTOPERATIVE PROBLEMS

Dysphagia

Most patients have some degree of dysphagia after fundoplication, which is why they are maintained on a liquid diet for 1 week after surgery with slow introduction of soft solids after that time. As long as the patient is able to take liquids and remain hydrated, they may be managed expectantly as an outpatient. Over time, the dysphagia should improve and eventually resolve. Dysphagia that persists more than 12 weeks is concerning and should be evaluated. Initial evaluation consists of an UGI to evaluate the anatomic position and tightness of the wrap. In patients with a tight wrap, serial endoscopic dilation can be attempted with good results. If dysphagia persists or an anatomic cause of dysphagia is identified, revision of the fundoplication is likely necessary.

Gas Bloat Syndrome

Gas bloat syndrome refers to recurrent abdominal pain and distention caused by air trapping in the stomach. Before modification of Nissen's original operation, this occurred in up to 40% of patients. However, with the adoption of the short and floppy wrap that is performed by most contemporary surgeons, the incidence rate of true gas bloat syndrome has decreased substantially. Although patients commonly experience some bloating and increased flatulence in the first several months after surgery, severe gas bloat syndrome is now uncommon. The diagnosis is made by obtaining a plain abdominal x-ray while the patient is symptomatic (Figure 5). If the stomach is gas filled and distended in the absence of bowel distention, then the diagnosis is secure. Confirmation can be achieved if placement of an nasogastric tube promptly relieves the patient's symptoms. Gas bloat syndrome can be exacerbated by dietary habits, such as drinking carbonated beverages, and behavioral habits, such as aerophagia. Initial treatment centers on dietary modification and use of prokinetic agents. These interventions are occasionally effective; however, most patients with true gas bloat syndrome need conversion of the full fundoplication to a partial wrap.

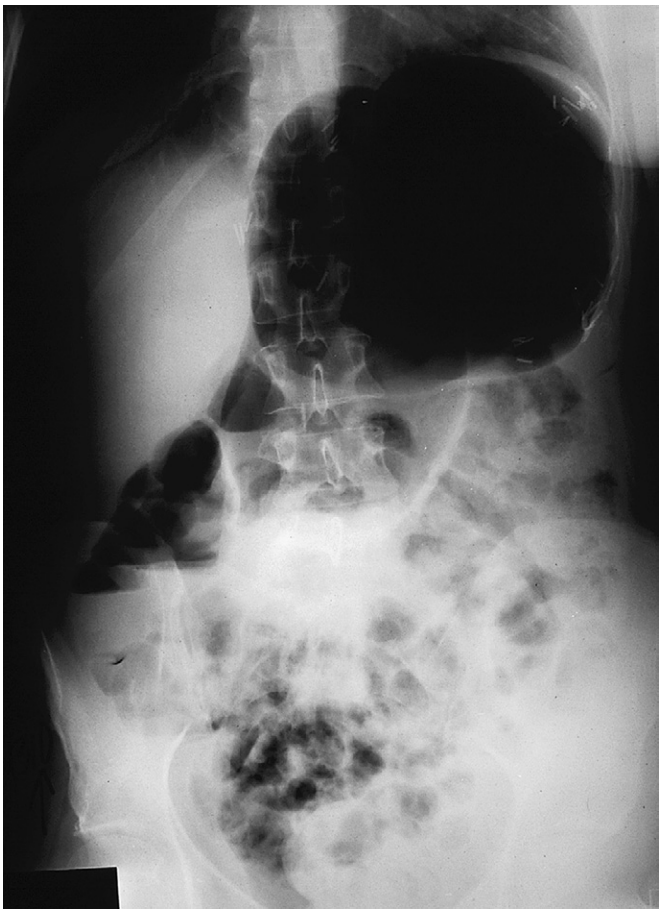

FIGURE 5 Abdominal x-ray showing distended stomach as seen in gas bloat syndrome.

REOPERATIVE FUNDOPLICATION

Failure rate of flowing fundoplication is estimated to be between 5% and 30%, depending on the series. Not every patient with a failed fundoplication needs reoperation. Candidates for reoperative surgery should have evidence of failure based on physiologic studies or an anatomic abnormality that can be surgically corrected. The most common indication for reoperation is recurrent symptoms from either a "slipped" fundoplication or herniation of the fundoplication into the mediastinum. Regardless of indication, the key principle of reoperative fundoplication is complete restoration of normal anatomy before any revision. Revisional surgery may be attempted laparoscopically; however, a low threshold for open conversion should be maintained. In patients in whom the revision cannot be completed laparoscopically because of dense adhesions or other anatomic abnormality, a transthoracic or thoracoabdominal approach may be beneficial.

EMERGING SURGICAL THERAPIES FOR GASTROESOPHAGEAL REFLUX DISEASE

Many innovative endoscopic therapies for GERD have been described. Although multiple devices have been developed for the endoscopic treatment of GERD, very few have had much long-term success. Several new endoluminal devices that create partial fundoplication

with robust fixation mechanisms are currently undergoing clinical trials. Another novel approach being introduced is augmentation of the LES with a ring of laparoscopically placed magnetic beads. More data are needed before the efficacy of these devices can be adequately evaluated. Given the high incidence of GERD and its impact on lifestyle, emerging therapies for GERD remain an area of intense activity for the foreseeable future.

Endoluminal Approaches to Gastroesophageal Reflux Disease

Mark R. Wendling, MD, and W. Scott Melvin, MD

INTRODUCTION

Gastroesophageal reflux disease (GERD) is a prevalent disease that greatly influences the quality of life of those it afflicts. Surgical fundoplication has become the gold standard treatment when medical therapy is no longer effective or desired. However, the side effect profile of traditional antireflux surgery leaves some patients and referring physicians hesitant, and the desire for endoluminal therapies has become evident.

In 2000, the EndoCinch (Bard Endoscopic Technologies, Billerica, Mass) was the first modern endoluminal therapy to gain U.S. Food and Drug Administration (FDA) approval. Since that time, numerous other devices have used myriad techniques in the attempt to achieve symptom and disease control. Some techniques, such as injection of bulking agents and partial-thickness gastric plication, are no longer available because of respective safety concerns and ineffectiveness. Currently, two treatments, the Stretta system (Mederi Therapeutics, Greenwich, Conn) and EsophyX (EndoGastric Solutions, Redmond, Wash), essentially constitute the landscape of FDA-approved devices commercially available today, with more techniques in various stages of development.

PREOPERATIVE CONSIDERATIONS

Indications for endoluminal therapy may be similar to those for Nissen fundoplication. However, with the reduction of side effects and decrease in invasiveness of endoluminal approaches, the indications could be expanded to those patients with less severe symptoms. Patients who wish to control GERD symptoms without medication or those in whom medication is no longer effective are candidates. Although the presence of a large hiatal hernia (>2 cm) and complications of reflux, such as severe esophagitis, stricture, and mucosal ulceration, represent indications for Nissen fundoplication, these are contraindications to endoluminal therapies. Other contraindications include Barrett's esophagus, portal hypertension, and motility disorders of the esophagus. In some studies, body mass index (BMI) of more than 35 is listed as a contraindication because symptoms are likely to improve with weight-reduction surgery. However, this is inconsistently applied, and a uniform cutoff has not been established.

Preoperative workup before endoluminal treatment first requires confirmation of the GERD diagnosis with 24-hour pH monitoring. Diagnostic upper endoscopy is also necessary to evaluate esophageal anatomy and rule out complications of GERD, which may represent contraindications to treatment. Because endoluminal treatments are limited to patients without esophageal motility disorders, manometry is also used.

OUTCOMES ASSESSMENT

Little agreement exists on what outcomes are most important in evaluation of endoluminal therapies for GERD. Treatment of GERD is based on the presence of clinically significant symptoms. Therefore, one could argue that the goal of therapy should be subjective improvement of these symptoms, which has traditionally been measured through surveys such as the GERD–health-related quality of life (GERD-HRQL) survey, the reflux symptom index (RSI) survey, successful discontinuation of proton pump inhibitor (PPI) therapy, and patient satisfaction metrics. However, any treatment that does not correct the underlying pathologic process and achieve disease control is seen as unacceptable to some. Normalization of objective indices, such as mean esophageal acid exposure time, quantification of reflux episodes, and DeMeester score, are customarily used as outcomes to assess for disease control. Currently, no endoluminal therapy has been able to show consistent normalization of pH metrics or healing of esophagitis. For this reason, Barrett's esophagus remains a contraindication to treatment.

Another topic of debate is whether these therapies should be compared with medical or surgical therapy when determining their efficacy. If endoluminal therapies are to be an addition to our treatment armamentarium of the spectrum of disease between the medical and surgical extremes, then direct comparison may not be applicable. The more important task is identifying the correct patient population for these therapies. When this population is determined, then useful comparisons can be made. However, if we do not identify this population, then any assessment will surely show endoluminal treatment to be inferior.

Controversy exists in regards to which outcomes to measure, what patient population to study, and what current therapies to compare them with. This creates quite a challenge in evaluating the merit of endoluminal therapies.

STRETTA

Background

The Stretta system (Figure 1) is the only device to use radiofrequency energy as a treatment for GERD. The system has been approved by the FDA since 2000 and consists of a flexible catheter with a 30F bougie tip and a balloon basket assembly with four 22-gauge, 5.5-mm–long, nickel-plated, radially placed electrodes. The catheter has two channels: a suction channel and another for cool water irrigation to keep mucosal temperature regulated. Stretta's mechanism remains unclear but could be induction of thermal injury to the lower esophageal sphincter (LES), which results in scarring and collagen deposition at the gastroesophageal junction (GEJ). This scarring decreases the compliance of the LES and may reduce transient LES relaxation. Another rational explanation is that fewer transient LES relaxations occur as a result of ablation of vagal afferent fibers.

Technique

The procedure is performed with conscious sedation with the patient in the left lateral decubitus position. First, upper endoscopy is performed. The esophageal and gastric anatomy is evaluated for any unexpected abnormality, and the distance from the incisors to the Z-line is measured. After a guidewire is placed through the working port, the endoscope is withdrawn. The radiofrequency delivery catheter is introduced orally over the guidewire into the stomach with fluoroscopic guidance. The device is withdrawn to approximately 2 cm proximal to the Z-line, and the balloon is inflated to 2.5 psi. This maneuver deploys the electrode needles into the muscular layer of the esophagus, and radiofrequency energy is delivered for 90 seconds. Tissue temperature is monitored with a built-in feedback thermostat to maintain muscular temperature at less than 85°C and mucosal temperatures at less than 50°C. After the application of energy, the needles are withdrawn and the balloon is deflated. The catheter is then rotated 45 degrees and the process is repeated, creating eight radial lesions at a given level. Radiofrequency energy is applied every 0.5cm, covering an area 2cm above and 1.5cm below the Z-line (Figure 2). The procedure is then completed with upper endoscopy to ensure the application of energy in the desired location and to evaluate for complications. The Stretta procedure takes approximately 40 minutes to complete.

Postoperative Care

The Stretta procedure is commonly performed as an outpatient procedure. Patients are kept on a liquid diet the day of the procedure and may resume a normal diet thereafter. Because the benefit of Stretta relies on scarring and collagen deposition for their effect, PPI therapy is continued and reevaluated at follow-up examination.

Outcomes

As the Stretta system has been available for more than a decade, a plethora of data has been published regarding its safety and efficacy. The procedure appears to be quite safe; most complications are minor and need no further intervention. A recently published systematic review found that, other than postprocedure pain, the most common complications were mucosal tears (4%), esophageal ulceration (4%), and dysphagia (3%). Esophageal perforation is exceedingly rare, and only one death has been reported from aspiration pneumonia.

At short-term follow-up examination, the Stretta procedure has shown to be reasonably effective. A randomized, double-blinded, sham-controlled, multicenter clinical trial evaluated 64 patients at 6-month and 12-month follow-up periods. No difference was seen in regards to PPI use or esophageal acid exposure times at 6 months. However, heartburn symptoms and GERD-HRQL scores were significantly better for the treatment group compared with those who underwent a sham procedure; this symptom improvement persisted at the 12-month follow-up period. Similar results were seen in another study of 94 patients with follow-up at 1 year. Again, mean heartburn scores (4 to 1; $P = 0.0001$), GERD-HRQL scores (27 to 9; $P = 0.0001$), and patient satisfaction were significantly improved. But unlike the previous study, PPI use decreased from 88% before the procedure to 30% after the procedure; esophageal acid exposure time was also significantly improved.

Long-term efficacy of the Stretta procedure has been less conclusive. In a study of the 4-year follow-up period, significant improvements in both heartburn and GERD-HRQL scores were reported. Also, 72.3% of patients were no longer taking PPIs. However, in

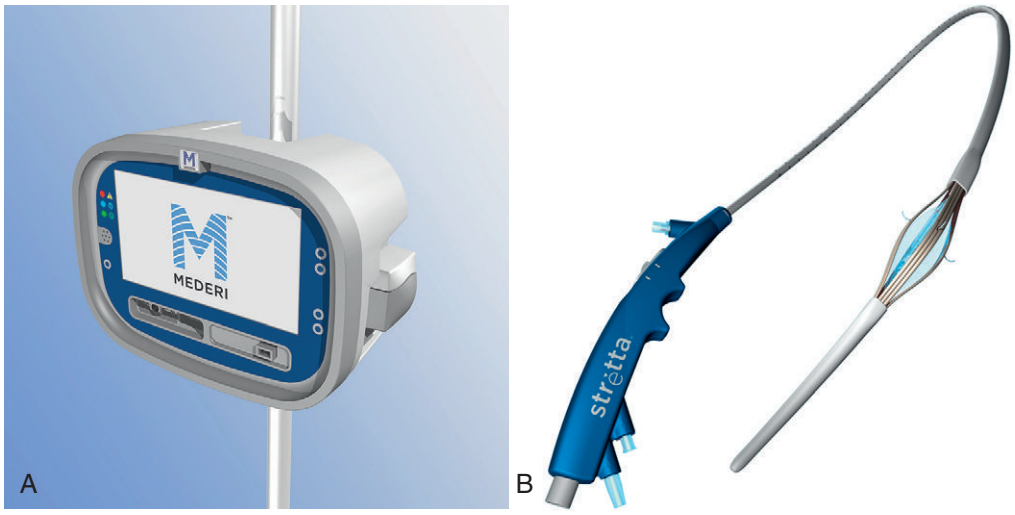

FIGURE 1 The Stretta system: **A,** radiofrequency generator; **B,** catheter. *(Courtesy of Mederi Therapeutics, Greenwich, Conn.)*

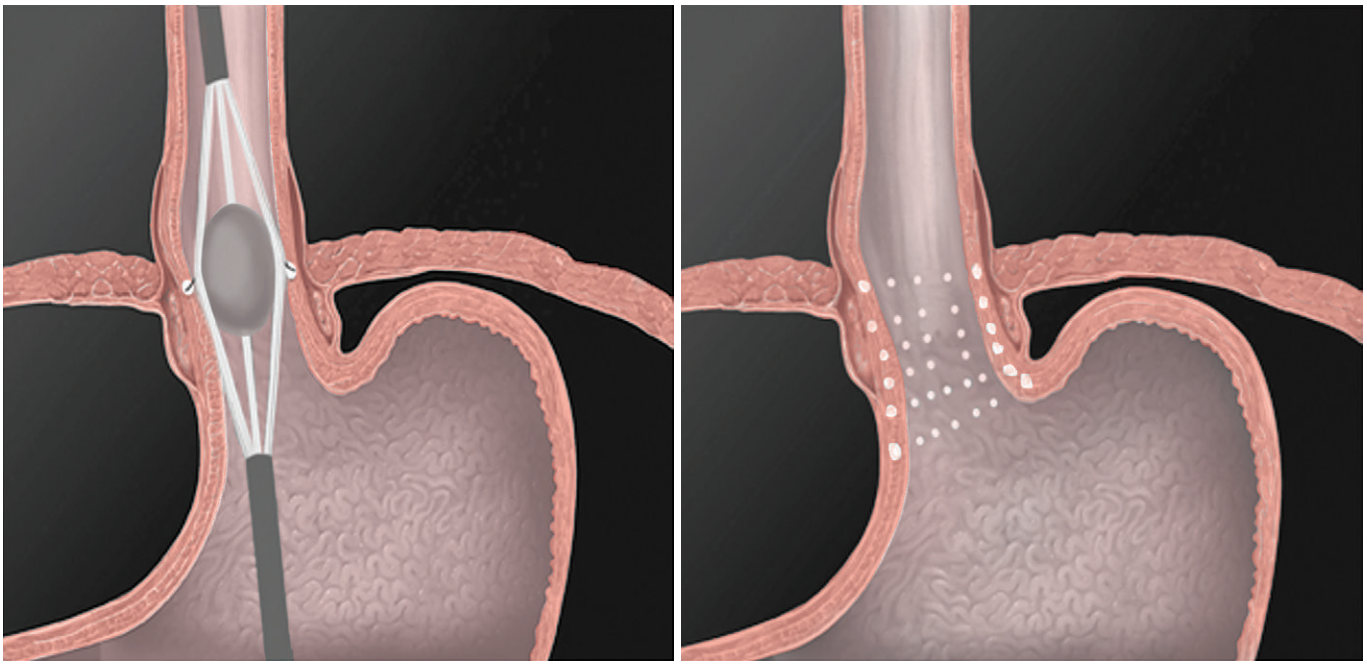

FIGURE 2 Serial application of radiofrequency energy at multiple levels along the lower esophageal sphincter with the Stretta system.

another study with a minimum of a 3-year follow-up period, 19 of 32 patients had been deemed treatment failures and went on to need a traditional antireflux operation. These differences were possibly the result of patient selection because findings showed that those whose conditions responded to the Stretta procedure had significantly lower preprocedure heartburn scores than those whose conditions did not respond.

Overall, a recent meta-analysis of the published literature from 2000 to 2010 identified 18 studies with a total of 1441 patients who underwent the Stretta procedure for treatment of GERD. Significant improvements in heartburn and patient satisfaction scores were found. GERD-HRQL scores also significantly improved and were on average normalized (26.11 vs 9.25; $P = 0.0001$) at a mean 19.8-month follow-up period. Esophageal acid exposure time (10.29 vs 6.51; $P = 0.0003$) and DeMeester score (44.37 vs 28.53; $P = 0.0074$) also improved significantly; however, they failed to normalize. LES pressure (mm Hg; 16.5 vs 20.24; $P = 0.0302$) also improved significantly. These data suggest that Stretta indeed produces significant improvement in reflux symptoms and improvement in objective GERD indices beyond the short-term follow-up period.

ESOPHYX

Background

The EsophyX device (Figure 3) consists of a disposable element that fits over a standard forward viewing endoscope and is used to perform transoral incisionless fundoplication (TIF). It is the most recent attempt in the use of endoluminal plication for the treatment of GERD. As previously mentioned, the EndoCinch device began this trend with the creation of a partial-thickness gastric plication, but it is no longer sold by Bard. Later, the NDO Full-Thickness Plicator (NDO Medical, Mansfield, Mass) gained FDA approval in 2004; as its name implies, it used full-thickness gastric plication for the treatment of GERD. The company has since ceased operations, and this product is off the market. EsophyX continues to evolve the technique of endoscopic plication with the creation of esophagogastric plication with rotational and longitudinal elements to reconstruct the gastroesophageal valve.

Technique

Transoral incisionless fundoplication is performed with the patient in the left lateral decubitus position with general anesthesia and nasotracheal intubation. Deep venous thrombosis prophylaxis is administered as a standard component of care for those undergoing general anesthesia. Because the plication is full thickness, preoperative antibiotics are administered.

Two physicians are needed to perform the procedure. The first operates the endoscope while the other operates the EsophyX device. Initial upper endoscopy is performed to assess for unexpected pathology. The endoscope is withdrawn and placed through the EsophyX device, and both are introduced into the esophagus to the stomach. The authors' practice is to dilate the esophagus with a 56F bougie before this introduction to ensure ease of passing the EsophyX device.

The device contains a vacuum invaginator, which is used to reduce small hiatal hernias by returning the squamocolumnar junction to a position below the diaphragm. A helical retractor is then deployed at the GEJ at the lesser curve to draw tissue into the device, creating a tissue fold with esophageal epithelium against the body of the device, gastric epithelium facing outwards and serosa in between. The helical retractor is used to manipulate the tissue to mold an omega-shaped valve with serial placement of polypropylene H fasteners full thickness across the tissue, thus creating a full-thickness, esophagogastric plication (Figure 4). The device is rotated both anteriorly and posteriorly to create multiple plication sets with H fasteners deployed at different distances from the GEJ. The authors strive to create an omega-shaped valve of at least 270 degrees in circumference and 3 cm in length and typically use an entire cartridge of H fasteners (20 fasteners) during the procedure. The device is then withdrawn, and the endoscope is reintroduced to evaluate the newly created valve and ensure hemostasis. The procedure commonly takes less than 90 minutes to complete.

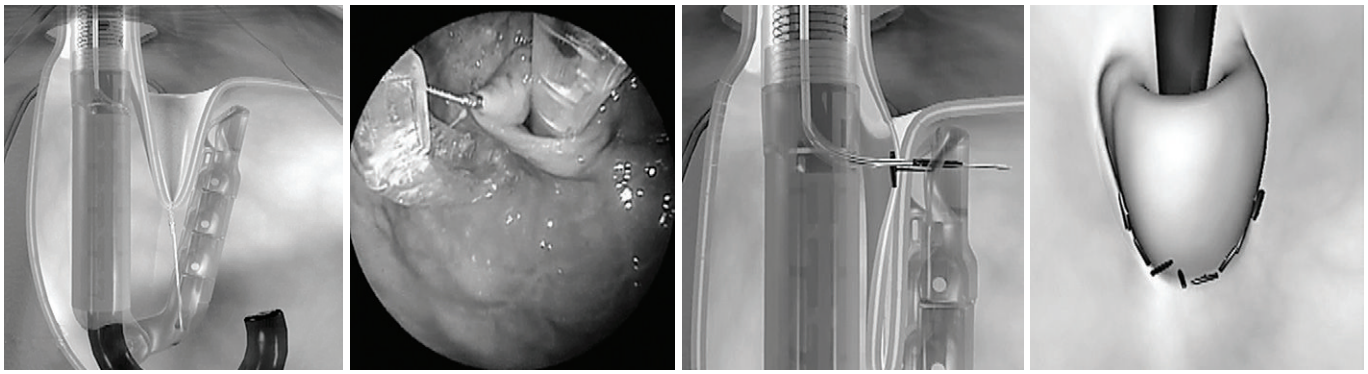

FIGURE 4 The EsophyX device drawing the gastroesophageal junction down into the jaws of the device, with full-thickness polypropylene H fasteners placed to mold an omega-shaped valve.

TABLE 1: Summary of outcome measures after transoral incisionless fundoplication

Outcome measure	Weighted mean	Number of studies measuring outcome	Mean follow-up period across studies (months)
Decrease in GERD-HRQL score	16.0	10	9.8
Decrease in RSI score	19.1	4	7.6
Patient satisfaction	72%	11	8.5
PPI discontinuation	67%	14	8.3

GERD-HRQL, Gastroesophageal reflux disease health-related quality of life; *PPI,* proton pump inhibitor; *RSI,* reflux symptom index.

Postoperative Care

Patients are observed overnight and discharged the next day. They remain on a liquid diet for up to 1 week and a soft diet until 2 to 3 weeks at follow-up examination. The authors' practice is to stop acid-reducing medications at the time of the procedure.

Outcomes

Because TIF is a relatively new procedure, the available data are immature. Currently, no randomized control trials compare TIF with either antireflux or PPI therapy. Many of the observational studies that have been performed have relatively small patient numbers. Also, the results of these studies have had significant variability.

Among the initial reports of TIF was a multicenter study of 86 patients. At the 12-month follow-up period, all hiatal hernias remained reduced. Median GERD-HRQL scores improved from 24 before TIF to 7 after TIF ($P = 0.0001$). PPIs were discontinued by 68% of the study population, and patient satisfaction was 65%. Another study of 37 consecutive patients at a single center found that atypical symptoms improved after TIF as measured with the RSI survey. Improvement from a mean score of 22.8 to 12.9 ($P = 0.003$) after TIF was shown. A statistically significant decrease in regurgitation scores was also seen (11.2 vs 4.3; $P = 0.006$). In a global assessment of the 24 patients who underwent pH testing off PPIs both before surgery and at follow-up examination, 54% were found to be in complete remission, needed no PPIs, and had normalized pH studies.

The authors recently conducted a systematic review of the published literature on TIF. A summary of the results can be found in Table 1. The 15 studies included reported on more than 550 procedures. Weighted means were calculated across the studies. Both GERD-HRQL scores (21.9 vs 5.9; $P < 0.0001$) and RSI scores (24.5 vs

5.4; $P = <0.0001$) were significantly reduced after TIF. Overall patient satisfaction was found to be 72% after the procedure. The overall rate of PPI discontinuation was 67% across all studies. TIF appears to be safe; the major complication rate was 3.2%. The most common complication reported was hemorrhage that necessitated transfusion. Four cases of esophageal perforation were reported across all studies. The total failure rate was 8.1% (patients subsequently needed either Nissen fundoplication or redo-TIF). Currently, no studies have been able to show consistent normalization of pH metrics.

Multiple prospective clinical trials are currently underway. The Randomized EsophyX Versus Sham/Placebo Controlled TIF Trial (RESPECT study) is a multicenter randomized sham-controlled trial of 120 patients to evaluate the safety and effectiveness of TIF. The TIF versus Medical PPI Management of Refractory GERD Symptoms (TEMPO) trial is a multicenter randomized trial that will compare TIF directly with PPI therapy in 42 patients. Other sham-controlled trials are taking place in Europe as well. When these data become available, we will have a much better picture of whether EsophyX will live up to it promising potential.

FUTURE METHODS

In 2012, the SRS flexible endoscope (Medigus Ltd, Omer, Israel) gained FDA approval for endoluminal treatment of GERD. The SRS endoscope combines a miniaturized video camera, a surgical stapler, and ultrasonic sights for alignment in a single instrument (Figure 5). The SRS is designed to allow one to perform a true endoscopic 180-degree anterior fundoplication by stapling the stomach to the esophagus in two or three locations with a quintuplet of standard B-shaped, 4.8-mm titanium staples in each location. The safety and efficacy is currently being evaluated by an industry-sponsored multicenter clinical trial. Other significant endoluminal devices are under development for the reconstruction of the GEJ and may eventually allow more patients whose conditions are managed with medical therapy to be treated surgically.

SUMMARY

Development of an effective endoluminal treatment for GERD has proven as difficult as it is enticing. Most attempts have resulted in products that are off the market. Multiple factors are responsible for the demise of previous therapies, and product development remains a high-risk proposition. Payers have not consistently been willing to cover these procedures because of high costs and lack of conclusive evidence of long-term benefit beyond standard medical and surgical therapy. Still, the proliferation of devices continues. Matching current treatments with severity of disease, a niche exists between PPI use for mild symptoms and surgical intervention for severe disease. Filling this gap with endoluminal therapies seems logical and guarantees further effort on this front.

The current systems of Stretta and EsophyX have shown promising short-term results like many endoluminal therapies before them. Some positive data for Stretta exist in long-term follow-up periods, but the results are far from conclusive. Data on long-term efficacy of EsophyX are not yet available but may be promising based on favorable mid-term results. The greatest challenge may be identification of the correct patient population for these procedures. Currently, most patients being offered endoluminal treatments are at the severe end to the spectrum of disease. Well-designed clinical trials are needed not only to further describe efficacy but also to identify optimal candidates for these procedures.

The Management of Barrett's Esophagus

Mario D. Terán, MD, and Malcolm V. Brock, MD

INTRODUCTION

The understanding of Barrett's esophagus (BE) has changed dramatically since 1950, when Norman Barrett first described his finding of a distal esophageal ulcer associated with esophagitis and columnar epithelium. Since Dr. Barrett's initial observation, the condition that bears his name has received multiple descriptions, formal definitions, and clinical associations. Today, BE is defined as the pathologic replacement of the esophagus' normal stratified squamous epithelium with an intestinal-like columnar epithelium. This replacement, also known as *intestinal metaplasia,* is a clear abnormality and is induced by chronic esophageal injury and inflammation caused by gastroesophageal reflux disease (GERD). It is conservatively estimated that 6% to 15% of American patients with GERD develop BE.

CLINICAL IMPACT

By far the greatest clinical concern with BE is that it is the most identifiable risk factor for the progression to esophageal adenocarcinoma (EAC), a malignancy with one of the fastest rising incidence rates worldwide. Multiple studies have shown that the presence of BE can confer at least a fortyfold increase in risk for the development of EAC. However, despite the increased cancer risk, most patients with BE do not progress to EAC; the overall annual rate of neoplastic transformation is approximately 0.5%. However, because of the aggressive and lethal nature of EAC (overall 5-year survival <17%), diagnosis, surveillance, and treatment of BE are sought by both patients and physicians alike.

The natural progression of BE to carcinoma develops over time; prospective studies have demonstrated the transformation of nondysplastic columnar epithelium to dysplasia and eventually to invasive carcinoma. The transition through the dysplastic phase is further characterized as low- or high-grade dysplasia. Low-grade dysplasia (LGD) is distinguished from high-grade dysplasia (HGD) according to the degree of architectural and cytologic aberrations of the cells (Figure 1). However, the characterization of dysplasia is largely subjective, inasmuch as studies have shown poor interobserver agreement among experienced pathologists in diagnosing LGD (<50% interobserver agreement) and HGD (85% interobserver agreement). The difficulty in determining the severity of dysplasia with reproducible accuracy has led to controversy in quantifying the risk of progression through the dysplastic phase. As a result, the annual rates of dysplasia-to-cancer progression estimated in published studies vary from 0.9% to 13.5%. In addition, although biomarkers of dysplastic progression remain an active area of research, no biologic markers of progression that distinguish LGD from HGD have been clinically defined. Currently, HGD is regarded as the most reliable predictor for the development of invasive malignancy. A meta-analysis demonstrated that the overall risk of progression from HGD to EAC is 6% per patient per year.

Despite controversies surrounding the dysplastic progression and risk stratification of BE, there is overwhelming consensus on the primary cause: chronic mucosal injury induced by GERD. Exposure to both the acidic and alkali (unconjugated bile acids) substances, through reflux, has been shown, in multiple in vitro and in vivo studies, to activate inflammatory pathways, promote cellular proliferation, and induce genetic alterations. These latter aberrations have even been shown to be correlated with increasing severity of gastrointestinal reflux exposure. In clinical studies of patients with GERD in which patients with and without BE were compared, findings have corroborated with wet-laboratory results, inasmuch as patients with BE have a greater severity of reflux symptoms, significantly higher esophageal acid exposure, and increased frequencies of erosive esophagitis, stricture formation, and ulceration than do patients without BE. Thus the presence of BE alone is an indication of severe GERD and necessitates treatment. These investigations have also revealed additional clinical risk factors for BE, such as age higher than 50 years, male gender, white race, presence of hiatal hernia, elevated body mass index, and a high distribution of intraabdominal body fat.

CLINICAL FEATURES

As the definition of BE has evolved considerably since its inception, so has its clinical characterization. Historically, BE was diagnosed and classified on the basis of (1) the length of visible columnar epithelium-lined esophageal mucosa present above the gastroesophageal junction (GEJ) and (2) the identification of intestinal metaplasia on histologic study (i.e., goblet cells; Figures 2 and 3). Hence, classic "long-segment" BE was defined endoscopically as columnar epithelium-lined esophageal mucosa extending more than 3 cm above the GEJ; "short-segment" BE, as columnar epithelium-lined esophageal mucosa within 3 cm of the GEJ. However, this classification did not account for the identification of gastric cardia-type intestinal metaplasia on biopsy when no obvious columnar epithelium was seen endoscopically. This latter entity was later defined as "ultra–short-segment" BE, or *cardia intestinal metaplasia,* and its significance has been extremely controversial. Currently, BE is diagnosed according to two criteria: when any length of columnar epithelia is visualized endoscopically and then confirmed histologically as present in the esophagus above the GEJ. Any intestinal-type epithelium in the esophagus is thus a clear abnormality and predisposes to cancer. Moreover, there is still clinical value in recording and measuring the extent of BE in the esophagus during endoscopic examination because cancer risk has been shown to be correlated with the extent of metaplastic lining. However, historical subjective classifications—such as the terms "long," "short," and "ultra-short"—have been replaced by the systematic recording of the circumferential extent and maximal length of BE. Known as the *Prague C and M criteria,* the circumferential extent (C) and the maximal extent (M) of BE above the GEJ are now used as a grading system to document and characterize BE.

TREATMENT OF NONDYSPLASTIC BARRETT'S ESOPHAGUS

Medical Management and Treatment

One of the principal treatment goals for any patient with BE is to control the GERD effectively. Medical therapy, consisting primarily of proton-pump inhibitors (PPIs), are a first-line therapy of any patient with BE and symptomatic GERD. Overall, PPIs are generally well tolerated and have been effective in controlling GERD symptoms and healing erosive esophagitis. However, the rate at which PPIs reduce EAC is unknown because it would be unethical to perform any prospective study of the incidence rates of EAC in patients with GERD taking PPIs versus a placebo. However, studies such as A Phase III, Randomized Study of Aspirin and Esomeprazole Chemoprevention in Barrett's Metaplasia (AspECT trial) in the United Kingdom

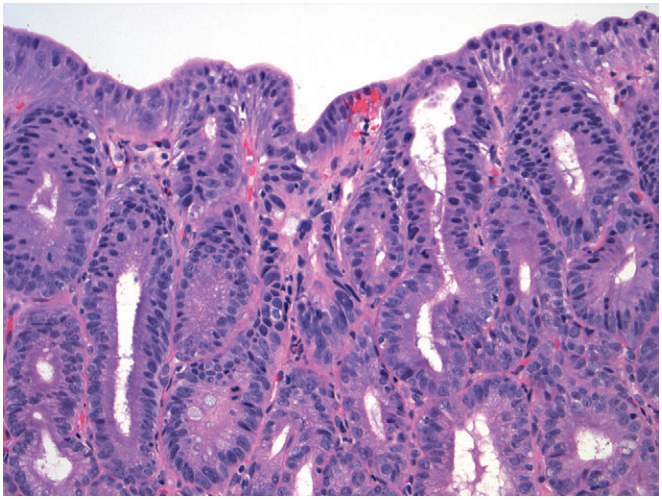

FIGURE 1 Barrett's esophagus (BE): intestinal metaplasia (IM) with high-grade dysplasia (HGD).

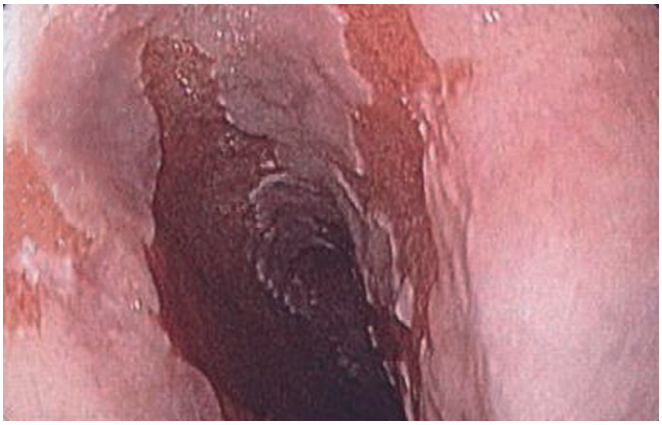

FIGURE 2 Long-segment Barrett's esophagus.

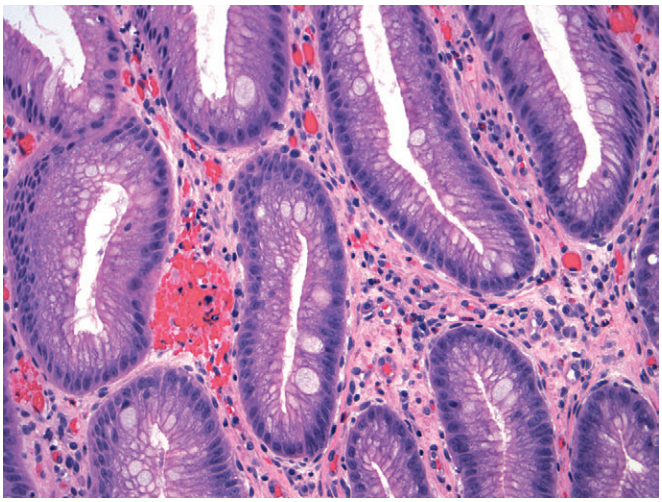

FIGURE 3 Barrett's esophagus/intestinal metaplasia (BE/IM) with goblet cells.

are attempts to investigate the prophylactic effects of PPIs in preventing esophageal cancer. In the AspECT trial, 5000 patients with BE were randomly assigned to receive either low-dose or high-dose PPIs; the primary outcome measure was progression of BE to HGD or EAC (completion of trial expected in 2019).

The long-term safety of PPI use has come into question. In 2010, the U.S. Food and Drug Administration (FDA) issued warnings regarding the potential for spine, hip, and wrist fractures among long-term PPI users. In addition, by increasing gastric pH levels, PPIs may also encourage the overgrowth of gut microflora, thereby increasing the susceptibility to bacterial infection. In a systematic review published in 2011, PPI users were found to have increased susceptibility for *Salmonella, Campylobacter,* and *Clostridium. difficile* infections. *C. difficile* infection had the strongest correlation with PPI use. Of 27 studies, 17 demonstrated a positive association (relative risk = 1.2 to 5.0). As with any medication, the potential adverse effects must be weighed against the potential benefits in each patient.

In addition to PPIs, nonsteroidal antiinflammatory drugs (NSAIDs), specifically cyclooxygenase-2 inhibitors, have also been identified as possibly chemopreventive agents in the progression of BE to cancer and as therapeutic agents in EAC. In in vitro studies, NSAIDs have been shown to decrease the proliferation of BE cells. Furthermore, in 2005, Vaughan and associates showed in a prospective study that these agents seemed to decrease the neoplastic progression of BE to EAC; the 5-year cumulative incidence was 14.3% among patients not taking NSAIDs, in contrast to 6.6% of patients taking NSAIDs. The AspECT trial is intended to evaluate the chemopreventive effects of PPIs, as well as aspirin, in two conditions. Despite available evidence suggesting a prophylactic effect of NSAIDs against EAC, it is not yet clear whether this outweighs the long-term risks of these medications. Therefore, initiating NSAID treatment in a patient with BE for the sole purpose of EAC chemoprevention is currently not recommended.

Antireflux Surgery

Antireflux surgery has been shown to be an effective treatment strategy for most patients with GERD and BE. Long-term results are equal or superior to those of medical therapy. In a study with a 12-year follow-up period, patients randomly assigned to undergo fundoplication had significantly higher remission rates of GERD than did those treated with omeprazole (53% vs 45%; $P = 0.02$). According to a 2010 Cochrane review of four controlled randomized trials with more than 1200 patients randomly assigned to undergo either surgery or medical management, GERD-specific quality of life was significantly higher with surgery than with medical management. In addition, symptoms of heartburn, reflux, and bloating were much better after surgery than after medical therapy.

Antireflux surgery has also produced higher rates of BE regression than has medical therapy. In a 2006 study, Rossi and associates compared the effects of medical therapy and Nissen fundoplication on LGD regression and, in a multivariate analysis, determined that Nissen fundoplication was the only factor significantly associated with the regression of LGD in nondysplastic BE (odds ratio = 15.33; $P = 0.033$). In a systematic review, Chang and colleagues in 2007 reached a similar conclusion. In this review, the probability of regression to lower grades of dysplasia, nondysplastic BE, or nonmetaplastic tissue was 15.4% in surgically treated patients but only 1.9% in patients receiving medical therapy ($P = 0.004$). The long-term effects of antireflux surgery in the prevention of EAC, however, remain controversial. In the same review, Chang and colleagues found among controlled studies no significant difference in EAC incidence rates between surgically and medically treated patients (6.5 vs 4.8 per 1000 patient-years; $P = 0.32$).

Endoscopic Therapies

Endoscopic therapies for the management and treatment of GERD and nondysplastic BE are constantly evolving. Methods have included radiofrequency augmentation of the lower esophageal sphincter, endoscopic suturing of the lower esophageal sphincter, and transoral

incisionless fundoplication. However, none of these methods has demonstrated long-term improvement in pH levels or cessation of the need for antireflux medications. A 2012 study showed that at 36 months, the majority of patients who underwent transoral incisionless fundoplication had required additional medical therapy or a surgical revision of the fundoplication. Sphincter augmentation by means of a system of titanium beads (the LINX Reflux Management System) has shown promise in the long-term control of GERD. After 4 years, patients with this device were found consistently to have symptom relief and pH control. However, more data are required before widespread routine use can be recommended.

Other treatment modalities such as radiofrequency ablation (RFA) and photodynamic therapy (PDT) have been shown to eradicate BE cells and promote reversion of the mucosa in BE to normal squamous epithelium. RFA has successfully achieved reversion in 97% of patients with nondysplastic BE by means of a balloon-based device (HALO^{360} System). Of importance, however, is that no data from controlled trials in nondysplastic BE have shown that endoscopic ablative therapies are more effective at reducing cancer risk or are more cost effective than periodic long-term endoscopic surveillance.

TREATMENT OF DYSPLASTIC BARRETT'S ESOPHAGUS

Despite the controversies in factors for risk progression and overall risk, dysplastic formation remains a significant neoplastic progression and warrants frequent surveillance and consideration of eradication treatment modalities. In patients with dysplastic BE, endoscopic surveillance varies with the severity of dysplasia. Surveillance is recommended every 6 to 12 months for patients with LGD and every 3 months for patients with HGD who have not undergone ablative therapy. During a surveillance examination, four-quadrant biopsy specimens should be taken at 2-cm intervals in patients without dysplasia and at 1-cm intervals in patients with established dysplasia. Any additional mucosal irregularities should also be sampled. Submitted biopsy specimens should be reviewed by two pathologists, with preferably one with expertise in gastrointestinal pathology, because disparities in intraobserver agreement are often reported.

Endoscopic Ablative Treatments

Current endoscopic ablative treatments include RFA, PDT, argon plasma coagulation, and cryoablation (Figures 4 through 6). RFA and PDT are very effective in the treatment of dysplastic BE. RFA has been shown to lead to reversion to normal squamous epithelium in more than 90% of patients with LGD. In 2009, researchers in a large sham-controlled U.S. trial reported that RFA therapy in HGD reduced the progression to EAC. In that study, 127 patients with dysplastic BE were assigned to receive either RFA therapy or a sham procedure. Of the patients with HGD who received RFA, 2.4% developed EAC, whereas of those who received sham therapy, 19% developed EAC (P <0.001). Overall, 9.3% of patients who received sham therapy, in comparison with 1.2% who received RFA, progressed to cancer (P = 0.45).

Like RFA, PDT also leads to the destruction of BE cells. After systemic administration of a photosensitizer such as porfimer sodium that accumulates in HGD and neoplastic cells, endoscopic delivery of a low-energy, nonthermal laser beam activates the photosensitizer, enabling singlet oxygen formation and subsequent cell destruction. In 2005, Overholt and colleagues published the results of a multicenter, prospective, randomized controlled trial in which PDT plus omeprazole was compared with omeprazole alone in patients with HGD. They found that HGD was eliminated in 77% of patients receiving PDT plus omeprazole but in only 39% of patients who received only omeprazole (P <0.0001). In addition, invasive cancer developed in only 13% of patients who received PDT plus omeprazole, in comparison with 28% of patients treated with omeprazole alone (P = 0.006). These effects remained durable inasmuch as after 5 years, cancer had developed in only 15% of patients who received PDT plus omeprazole, in comparison with 29% of those receiving only omeprazole (P = 0.027).

No controlled trials have been performed to compare the effectiveness of RFA with that of PDT. Both methods have been shown to have low complication rates and are well tolerated by patients. PDT

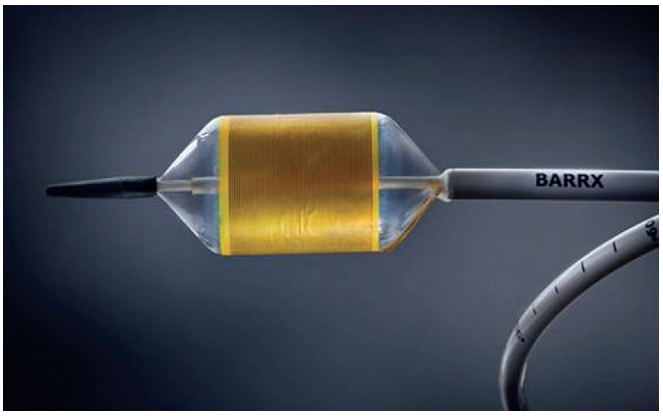

FIGURE 5 HALO^{360} device. *(Courtesy Covidien LP d/b/a* BÂRRX *Medical, Sunnyvale, CA.)*

FIGURE 6 Metaplastic esophageal mucosa treated with a radiofrequency ablation HALO^{360} device. *(Courtesy Covidien LP d/b/a* BÂRRX *Medical, Sunnyvale, CA.)*

does produce a greater depth of ablation than does RFA, although with higher complication rates. Both modalities have limited usefulness in assessing the depth of HGD, as well as in detecting foci of unsuspected EAC. It has been estimated that EAC can be found in 25% to 75% of patients with HGD undergoing esophagectomy; more recent data favor the lower end of this estimate.

Endoscopic Mucosal Resection

Endoscopic mucosal resection (EMR) is another important modality in the treatment of HGD and intramucosal carcinomas (Figures 7 through 11). EMR is now offered as a curative treatment for HGD or early EAC, with or without conjunctive ablative therapies (i.e., RFA or PDT). In addition, a major advantage of EMR over ablative treatments is the ability to obtain a large specimen in biopsy that is both lateral and deep to irregular dysplastic lesions. A single-institution study of the efficacy of EMR treatment on HGD or mucosal adenocarcinoma showed that after a mean follow-up of 63.6 months, complete response was seen in 96.6% of patients, and the 5-year survival rate was 84%. Eligibility criteria for the use of EMR as a definitive therapy include focal HGD or stage T1a intramucosal lesion smaller than 2 cm in diameter, no evidence of lymph node involvement or systemic disease, flat or polypoid lesions without ulceration, and lesions without lymphovascular invasion.

Esophagectomy

Historically, an esophagectomy was the "gold standard" in the treatment of HGD. Currently, 70% to 80% of patients with HGD are successfully treated instead with endoscopic eradication therapies. A common argument opposing the use of esophagectomy has been the magnitude of the procedure, as well as the rates of associated morbidity and mortality. However, because no molecular markers have been developed and validated to identify occult EAC, esophagectomy not only cures HGD in patients with undiagnosed carcinomas but also serves as an effective prophylaxis. Studies have also shown that the historical concern over high reported mortality rates with esophagectomies may be inflated. In 2007, Williams and colleagues reviewed 22 published reports on the outcomes of esophagectomy for patients with HGD. They found the overall perioperative mortality rate to be 0.94%, and in 17 of the reviewed reports, the mortality rate was 0.

Longitudinal studies have demonstrated that the quality of life after an esophagectomy is good to excellent and can return to preoperative levels. Despite an initial and prolonged adjustment period, patients who underwent esophagectomy for HGD have demonstrated quality-of-life scores similar to national norms by 5 years later. The new techniques of vagal-sparing esophagectomies and minimally invasive esophagectomies may further improve the quality of life for these patients.

SUMMARY

The diagnosis, risk assessment, and management of BE have been highly dynamic since their inception. However, with the rising incidence rate of EAC and its poor associated outcomes, the management and early treatment of BE has the potential to affect public health greatly. Control of a patient's underlying GERD has to be the initial step of BE management. Once BE is diagnosed, patients should undergo endoscopic surveillance, with the frequency determined according to the severity of their dysplasia. Although the therapeutic armamentarium for BE has expanded, judicious evaluation, good judgment, and thorough patient discussions are still needed to evaluate the best therapeutic options for each individual. Much still remains to be learned concerning the management and treatment of BE, and clinicians must be able to adapt and implement new information as it becomes available to achieve the best possible outcomes.

Endoscopic Treatment of Barrett's Esophagus

Nassrene Elmadhun, MD, and Michael Kent, MD

INTRODUCTION

Barrett's esophagus (BE) is an acquired condition in which the normal squamous epithelial lining of the esophagus is replaced with columnar epithelium and characteristic goblet cells, also known as intestinal metaplasia. BE develops as a result of long-standing gastroesophageal reflux disease and occurs in 10% to 15% of patients undergoing upper gastrointestinal endoscopy for reflux symptoms. BE increases the risk of development of esophageal adenocarcinoma (EAC) by 30 to 125 times. In the United States, the prevalence rate of BE is estimated to be 5.6%, and the annual risk of EAC is 0.5% per year. Esophageal carcinogenesis involves the progression of intestinal metaplasia to dysplasia and finally to adenocarcinoma. In a randomized control trial of patients with BE followed endoscopically over the course of 1 year, 22.7% of patients with low-grade dysplasia (LGD) and 19% of patients with high-grade dysplasia (HGD) had complete regression of dysplasia without treatment. However, 19% of patients with HGD had disease progression to EAC. Given that EAC is one of the fastest rising solid cancers in the Western world, with a dismal 5-year survival rate of 12%, there is increased public health interest for targeted therapies to treat individuals at high risk.

HISTOLOGIC FEATURES OF BARRETT'S ESOPHAGUS

Barrett's esophagus classically appears on endoscopy as salmon-colored "tongues" or extensions of mucosa that stretch into the tubular esophagus from the esophagogastric junction. The American Gastroenterological Association recommends standardized four-quadrant biopsies at intervals of every other centimeter of suspected BE and specific biopsy of any mucosal irregularities (such as nodules and ulcers). Histologic classification of BE dysplasia is as follows:

1. Negative for dysplasia: This classification indicates benign BE with intestinal metaplasia and columnar epithelium. All cells have normal morphology.
2. Indefinite for dysplasia: These biopsy results show mucosal injury and regenerative changes as a result of long-standing reflux disease. Distinguishing between regeneration and dysplasia is difficult. In this case, providers may repeat the endoscopy after a course of treatment with a secretory inhibitor to reduce the acid reflux–induced cellular injury.
3. Low-grade dysplasia: This classification designates atypical epithelium with increased mitosis and nuclear-to-cytoplasmic ratio, but the crypt architecture is preserved.
4. High-grade dysplasia: This classification designates abnormal columnar epithelium with loss of cell polarity, atypical mitotic activity, loss of goblet cells, and distortion of the crypt architecture.
5. Intramucosal adenocarcinoma: This classification is defined by dysplasia that penetrates the basement membrane and infiltrates into the lamina propria but not into the submucosa. Lesions that penetrate past the lamina propria or muscularis mucosa are designated as T1b invasive EAC.

An important note is that these histologic changes and degree of dysplasia occur on a continuum, and pathologists may find difficulty in distinguishing LGD from HGD. In fact, significant interobserver variability occurs even among experienced gastrointestinal pathologists. As a result, the American Gastroenterological Association recommends that all dysplasia diagnoses are confirmed by at least one other experienced gastrointestinal pathologist given the implications of a dysplasia diagnosis on treatment and management.

SURVEILLANCE ALGORITHM FOR BARRETT'S ESOPHAGUS

In patients with BE without dysplasia, endoscopy is recommended in 3-year to 5-year intervals. Patients with BE and LGD should undergo surveillance endoscopy every 6 to 12 months. Although endoscopic surveillance for patients with BE and no dysplasia or LGD is the standard of care, little evidence supports the assumption that surveillance reduces the number of deaths from EAC. Treatment of patients with nondysplastic BE or with LGD is also controversial. In a randomized prospective study conducted by Parrilla and colleagues, 101 patients with nondysplastic BE or LGD were randomized to antireflux surgery and medical therapy. After a mean follow-up period of 5 years, HGD developed in 5% of the medical arm and 3% of the surgical arm, which was not statistically different. This result was corroborated by a meta-analysis published by Chang and colleagues in 2007 that showed no difference in EAC incidence rate between antireflux surgery and antisecretory medical therapy. Given the lack of data on the benefit of antireflux medical or surgical therapy, treatment of nondysplastic BE with the intention to prevent EAC is cost ineffective.

In patients with HGD, surveillance endoscopy should be conducted every 3 months in the absence of endoscopic eradication or surgical therapy. HGD is of particular importance because these patients are at high risk for development of EAC. In a study of 30 patients with HGD who were undergoing prophylactic esophagectomy, 43% had occult adenocarcinoma on pathology. Certain features of HGD confer a higher risk of development of EAC, including multifocal HGD or an endoscopically visible lesion, such as ulceration or a discrete nodule. Patients with these concerning features have an estimated risk of concurrent EAC of 60% to 78%, but patients with unifocal, flat HGD have a 17% risk of concurrent EAC. Patients with HGD and low-risk features should be treated endoscopically with the intention to eradicate BE and prevent neoplastic progression. Although most patients with HGD can be treated endoscopically, major medical societies recommend that patients with high-risk features or intramucosal EAC are evaluated for esophagectomy in a high-volume center by an experienced esophageal surgeon. However, patients who refuse esophagectomy or have conditions that are unfit for surgery should undergo endoscopic ablation as an alternative to surgery.

ENDOSCOPIC ABLATION THERAPIES

Several endoscopic ablation therapies have been described to manage BE with HGD and include thermal ablation (including multipolar electrocoagulation [MPEC] and argon beam plasma coagulation [ABPC]), chemical ablation (photodynamic therapy [PDT]), cryotherapy, and radiofrequency ablation (RFA). The goal for all ablation therapies is to eradicate BE and repopulation with normal squamous cells. Ideally, ablation should extend through the muscularis mucosa. Ablation, however, should not extend to the submucosa because that can increase the risk of stricture (Figure 1).

Thermal Ablation

Multipolar electrocoagulation involves passing a current between electrodes, which are in direct contact with the tissue. ABPC transfers monopolar electrocautery to the tissue via the flow of ionized argon gas plasma. ABPC distributes the ablation more evenly than MPEC, and the ablation depth can be better controlled. These techniques are falling out of favor because they require multiple treatment sessions and the depth of ablation is not well controlled, which results in complications such as stricture and perforation. Also, reports of

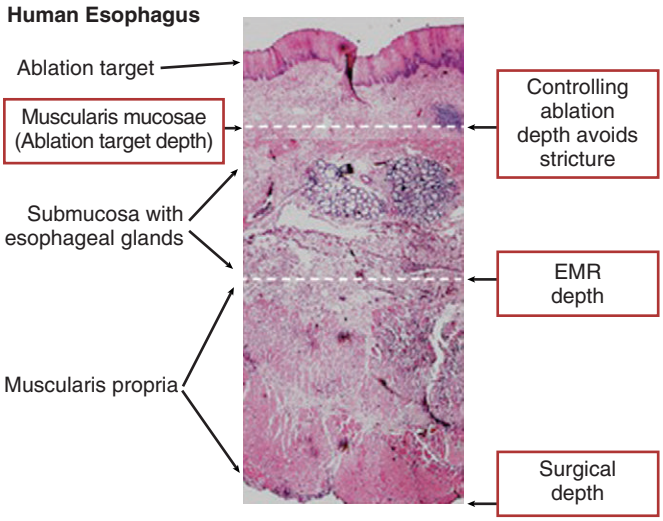

FIGURE 1 Histology of the normal layers of the esophagus. Appropriate ablation and resection depths are noted for the varying endoscopic treatments of Barrett's esophagus. *EMR,* Endoscopic mucosal resection.

buried BE have been documented after MPEC and ABPC, in which islands of intestinal metaplasia are found under normal-appearing regenerated squamous mucosa that may progress to occult EAC.

Photodynamic Therapy

Photodynamic therapy involves the administration of an inactive photosensitizing agent before endoscopy, which accumulates preferentially in diseased esophageal mucosa. The photosensitizing agent is then activated by a wavelength-specific light during endoscopy, which triggers the formation of oxygen radicals and eradication of BE. PDT is also falling out of favor because of skin photosensitivity that can last for weeks to months, symptomatic strictures in 36% of patients, high cost, and buried BE in 58% of patients.

Cryospray Ablation

Cryospray ablation (CSA) is a noncontact method that uses endoscopically applied low-pressure liquid nitrogen and carbon dioxide spray to eradicate BE. The rapid tissue freeze-thaw cycle results in destruction of diseased epithelium followed by the regeneration of normal squamous epithelium. The depth is limited to 2 mm and requires repeat CSA sessions every 4 to 6 weeks until BE is completely eradicated. Early results reported that 79% to 87% of patients with HGD had no evidence of dysplasia after CSA and that 46% to 78% of patients had complete eradication of BE. Side effects of CSA are generally mild and consist mainly of noncardiac/acid reflux–like chest pain that lasts a few days after treatment. One case of gastric perforation was reported in a patient with Marfan syndrome. As a result, the stomach must be decompressed because the carbon insufflates the stomach.

Cryospray Ablation Technique

With moderate sedation, a surveillance endoscopy is performed. An orogastric tube is then advanced to the stomach and connected to continuous suction to allow for decompression of the stomach and esophagus. The cryotherapy catheter is passed through the working port of the endoscope and extended beyond the tip of the endoscope. With direct visualization, liquid nitrogen is sprayed through the catheter for 10-second intervals for four cycles to freeze the mucosa. Between cycles, the tissue is given 45 seconds to thaw. This process is repeated until all abnormal esophageal tissue is treated. The patients are discharged home the same day.

Radiofrequency Ablation

Radiofrequency ablation delivers bipolar energy via direct contact with esophageal mucosa in a controlled duration and intensity for reliable tissue penetration without submucosal injury. The initial treatment uses a sizing balloon catheter to deliver circumferential treatment (Figure 2, *A*). Subsequent treatments for focal disease deliver RFA through a targeted ablation catheter that is mounted to the tip of an endoscope (Figure 2, *B*). Unlike PDT, CSA, or other thermal ablation techniques, RFA is precisely programmed through the energy generator to deliver high power with a controlled energy density, while the balloon catheter allows for uniform mucosa electrode contact, which results in controlled ablation depth. However, the target lesions must be flat to ensure adequate ablation.

Multiple prospective trials have shown that RFA is a safe, effective, and reliable ablation tool to eradicate BE and dysplasia. Fleischer and colleagues conducted the Ablation of Intestinal Metaplasia (AIMII) trials, a prospective multicenter trial to evaluate the use of RFA to eradicate BE in patients without dysplasia after a 2.5-year and 5-year follow-up period. They found that at 12 months, 70% of patients

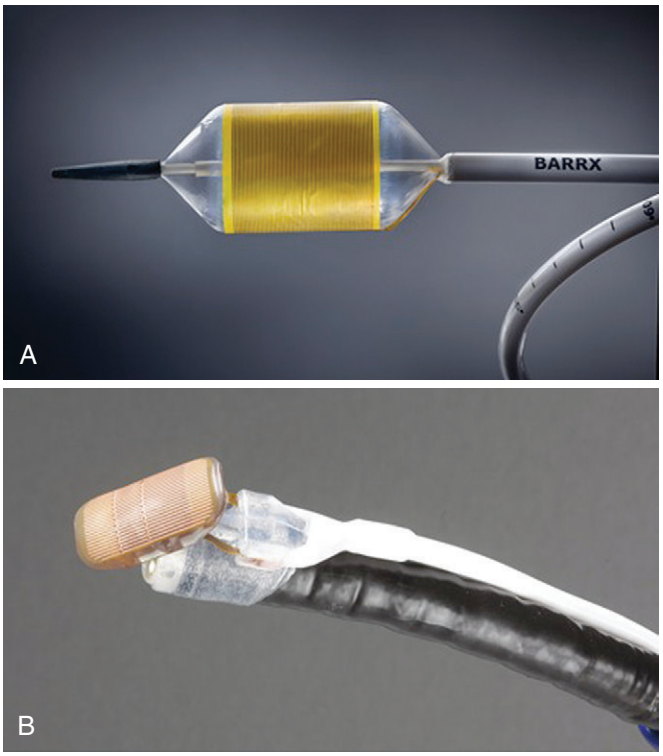

FIGURE 2 Radiofrequency ablation catheters. **A,** Balloon catheter used for initial circumferential ablation of Barrett's esophagus. **B,** Focal treatment catheter used in subsequent treatments to ablate small residual areas of disease.

with nondysplastic BE who had one treatment session of RFA had complete eradication of BE. After a 2.5-year follow-up period and repeat focal treatment for the remaining 30% with residual disease, 98.4% of patients had complete eradication of BE. After 5 years, 92% had complete eradication of BE. Although patients with BE and HGD clearly should undergo treatment, the current literature does not support routine treatment for nondysplastic BE. Nevertheless, this study established the safety and efficacy of RFA; AIMII reported no buried glands in the 2396 specimens analyzed and no strictures or serious complications.

Shaheen and colleagues published the first multicenter sham-controlled trial of 127 patients with LGD and HGD randomized to RFA or sham procedure. At 12 months, 90% of patients with LGD and 81% of patients with HGD had complete eradication of dysplasia. Patients who underwent RFA had less disease progression and less EAC (3.6% and 1.2%, respectively) compared with the control group (16.3% and 9.3%, respectively). The authors noted that the decreased incidence rate of cancer in this study should be viewed with caution as a shift of a single incidence of cancer would have resulted in a loss of statistical significance. They also reported one case of upper gastrointestinal bleeding, a 6% rate of esophageal stricture, and a 5.1% rate of buried BE. In comparison, these complication rates are lower than those reported in the literature for PDT and other ablation therapies. Therefore, RFA has supplanted many of the other ablative technique as a safe and effective ablation tool.

Radiofrequency Ablation Technique

With moderate sedation, an endoscope is passed into the esophagus and the esophageal mucosa is sprayed with 1% acetylcysteine and flushed with water to remove esophageal mucus. The inner diameter of the esophagus is then measured with a sizing catheter passed over a guidewire through the endoscope working port. The sizing

catheter is removed, and an appropriately sized treatment balloon catheter is then passed into the esophagus. The balloon is deployed 1 cm above the proximal margin of BE. The energy generator delivers approximately 300 W in a density of 12 to 15 J/cm^2 in less than 300 ms. The delivered treatment is circumferential and is 3 cm in length. The balloon is then repositioned, moving distally down the esophagus with a small amount of overlap. After the treatment, the esophagus is inspected to ensure that all the BE is adequately treated. Patients are generally discharged the same day, with a follow-up endoscopy in 3 months. If residual BE is seen on follow-up endoscopy, ablation is carried out with either a balloon catheter (for large areas of BE) or a focal ablation catheter (for smaller lesions; Figure 2,*B)*. The focal ablation catheter is mounted to the tip of the endoscope, so the operator must be careful when advancing the endoscope from the oropharynx through the upper esophageal sphincter to avoid injury.

ENDOSCOPIC MUCOSAL RESECTION

Endoscopic mucosal resection (EMR) involves the resection of mucosa and submucosal layer down to the muscularis propria. EMR has emerged as a safe and effective treatment of BE with HGD or intramucosal EAC. Although esophagectomy is the most conservative therapy for patients who are good surgical candidates with HGD or intramucosal EAC, it also carries a 1% mortality rate in high-volume centers and can be as high as 10% or more in low-volume centers. Therefore, although esophagectomy is an established therapy for BE with HGD, EMR is increasing in popularity as an esophageal-sparing procedure for patients with low risk for nodal spread.

Endoscopic ultrasound scan (EUS) should be performed in all patients with BE and focal nodules or ulcers to evaluate the depth of invasion and periesophageal lymphadenopathy. Although EUS is a useful tool for EAC staging, providers need to be cautious because EUS is often not sensitive enough to differentiate superficial tumors. In a blinded trial of 100 patients with suspicion of early esophageal cancer, patients underwent endoscopy and EUS followed by esophagectomy. Although EUS was 90% sensitive for mucosal involvement, the sensitivity for submucosal invasion was only 48%.

After appropriate staging including EUS and preliminary endoscopy with standard BE biopsies, EMR can be considered if the HGD or intramucosal EAC is considered low risk for nodal disease. Indications for EMR include:

1. Small lesions (<2 cm).
2. Nonulcerated lesions.
3. Lesions without submucosal invasion.
4. Lesions without lymphovascular invasion.
5. Well-differentiated or moderately differentiated lesions.

Ell and colleagues have published several prospective studies investigating the efficacy and safety of EMR in patients with HGD and intramucosal EAC. In the study published in 2000, they found that 97% of patients with HGD had complete remission at 1 year. In 2007, the same group found that 88% of patients with low-risk intramucosal EAC had complete remission at 36 months after EMR treatment. After a 5-year follow-up period, 96% of patients with HGD and intramucosal EAC had complete remission and 3.7% needed curative esophagectomy. In these studies, patients followed a rigorous follow-up schedule with endoscopies at 1, 2, 3, 6, 9, and 12 months and then every 6 months for an additional 5 years. Every other follow-up examination also included EUS, computed tomographic (CT) scan, and abdominal ultrasound scan. Such a vigorous follow-up routine is certainly not feasible outside of a research study setting.

The most commonly reported complications are bleeding and stenosis. The risk of stenosis increases particularly after multiple or circumferential treatments. Although arterial bleeding is uncommon, venous bleeding is not and can usually be managed endoscopically with injection. Stenosis can take months to develop and can be managed with serial dilations. Esophageal perforation has also been reported at a rate of 0.06% to 5%.

Endoscopic Mucosal Resection Technique

Many EMR techniques have been described in the literature. In general, moderate sedation is used and an endoscope is passed into the esophagus for initial surveillance.

Snare Technique

If the lesion is polypoid and small, no submucosal injection is necessary to elevate the lesion. A diathermy snare is advanced through the working port of the endoscope and positioned around the base of the lesion. The snare is then tightened securely around the lesion and resected with electrocautery.

If the lesion is small and flat, a 1:100,000 dilution of epinephrine in saline solution is injected in the submucosa to elevate the target lesion, creating a pseudopolyp. The snare is introduced and used to capture and ligate the lesion. A double-channeled endoscope can be useful in the snare technique, with one port used to pass the snare and the other port used to pass a grasping forceps to aid in pulling the lesion into the snare. The double-channeled endoscope can be too bulky to carry out technically difficult resections in the esophagus, especially if the esophagus is tortuous or if the lesion is at the esophagogastric junction.

"Suck and Cut" Technique

Ligation Technique

A variceal ligation device is used to suction the target lesion into the cylinder of the ligation device. A rubber band is released around the lesion, creating a pseudopolyp. A diathermy snare is then looped around the pseudopolyp to resect the lesion.

Cap Technique

The target lesion should first be marked with electrocautery because the lesion can be difficult to identify after submucosal injection. The submucosa is injected with a saline-epinephrine solution. A special transparent cap is then affixed to the end of the endoscope (Figure 3). A diathermy snare is advanced through the working port, and the lesion is sucked into the cap and resected with the diathermy snare. A prospective randomized trial that compared the cap technique with the ligation technique in 100 consecutive EMRs for early EAC did not find any differences in the incidence of bleeding, diameter of the resected specimen, or the resection area. Therefore, these two techniques can safely be used interchangeably according to operator preference.

ENDOSCOPIC SUBMUCOSAL DISSECTION

Endoscopic submucosal dissection (ESD) is an endoscopic resection technique that was developed in Japan to resect large (>2 cm), flat, or ulcerated esophageal tumors and the surrounding mucosa in an en bloc fashion. Ulcerated lesions and large lesions (>2 cm) cannot be resected en bloc with negative lateral margins with standard EMR techniques. Ulcerated lesions are often fixed to the submucosa and muscularis propria and therefore cannot be elevated with a submucosal injection. Large lesions can only be resected in a piecemeal fashion with EMR, which increases the risk of recurrence from residual dysplastic tissue. Therefore, ESD was developed for the treatment of early esophageal cancer limited to the epithelium or lamina

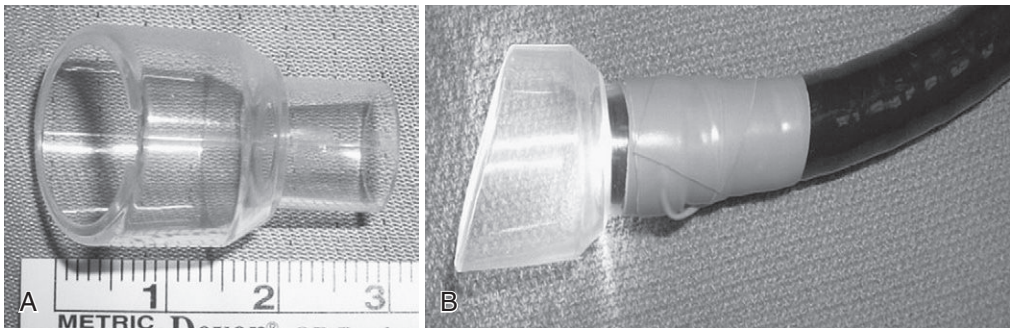

FIGURE 3 Endoscopic mucosal resection cap technique instruments. **A,** Olympus cap. **B,** Cap affixed to the end of a standard flexible endoscope. *(From Watson TJ: Endoscopic resection for Barrett's esophagus with high-grade dysplasia or early esophageal adenocarcinoma,* Semin Thorac Cardiovasc Surg *20(4):310–319, 2008, Figure 2).*

propria for patients who are poor surgical candidates or who refuse esophagectomy. Although ESD is one of the gold standards for treatment of early esophageal cancer in Japan, it is not widely available in the United States. Notably, the predominant esophageal neoplasm in Japan is squamous cell carcinoma, whereas the predominant esophageal carcinoma in the United States is adenocarcinoma. All of the reports out of Japan describe ESD for squamous cell carcinoma. Unlike adenocarcinoma, squamous cell carcinoma does not arise from BE and tends to arise in the middle third of the esophagus where the esophagus is tubular and technically more amenable to a complex dissection compared with the esophagogastric junction.

In a prospective study of 102 patients with early squamous cell carcinoma by Oyama and colleagues, ESD was technically successful in resecting the tumor en bloc in 95% of patients with a 6% rate of pneumomediastinum. In 2007, the Japanese Gastroenterological Endoscopy Society reported an impressive 3-year survival rate of 95% for early esophageal squamous cell carcinoma resected with ESD. However, ESD carries a perforation rate as high as 10% compared with 0.6% to 0.5% with EMR. Bleeding and stricture have also been reported with ESD, and it is a time-consuming, technically challenging procedure with a steep learning curve. Also, unlike EMR, which can be performed in an outpatient setting, ESD requires hospitalization after the procedure so the patient can be closely monitored for complications, such as bleeding and perforation, and to slowly advance the diet in a controlled manner.

Endoscopic Submucosal Resection Technique

After surveillance esophagoscopy, the margins of the lesions are marked with electrocautery and the submucosa is injected with 1% hyaluronic acid solution to create a submucosal cushion to lift the lesion. Specialized ESD electrocautery instruments are used to make a circumferential incision around the lesion. The lesion is then carefully dissected from the connective tissue of the submucosa underlying the lesion. Follow-up endoscopy is usually performed after 2 months to assess the healing and to evaluate for recurrence.

SUMMARY

Endoscopic techniques including ablation and EMR have emerged as useful tools for treatment of dysplastic BE. In patients with BE and LGD, screening endoscopy is adequate and no further treatment is necessary. In patients with BE and HGD, RFA, cryotherapy, and EMR are reasonable esophageal-sparing therapies. However, patients with HGD who refuse esophagectomy or have significant comorbidities that preclude surgery must be committed to multiple endoscopies because many of these therapies require several repeat treatment sessions and follow-up examinations. Management of patients with dysplastic BE should be individualized and in collaboration with providers experienced in endoscopy and esophageal surgery.

PARAESOPHAGEAL HERNIA

Benedetto Mungo, MD, Daniela Molena, MD, and Malcolm V. Brock, MD

DEFINITION

The first description of a paraesophageal hernia (PEH) may be attributed to Henry Ingersoll Bowditch. He reported, in 1853, some "dilatation of the esophageal opening" in postmortem assessments, observing that the "esophagus presented a very abrupt change of its course. In all, it descended through the diaphragm as usual but turned back toward the left to enter the abnormal aperture caused by the hernia and to join the stomach in the chest."

It is estimated that the prevalence of hiatal hernias in the population ranges from 10% to 60%, in relation to age.

Sliding hiatal hernias represent more than 95% of all hiatal hernias, while PEHs account for the remaining 5%.

Late-middle-aged and older individuals are more affected by large hiatal hernias compared with younger people (occurrence before age 50 is infrequent); hence, the need for PEH surgery is increasing in the West as the population progressively becomes older.

Hiatal hernias are usually classified into four types.

- Type I, or sliding hiatal hernias, are characterized by the migration of the gastroesophageal junction (GEJ) above the diaphragm, allowed by laxity of the phrenoesophageal ligament, with the contextual creation of a peritoneal sac (Figure 1). This condition results in the typical distortion of the physiologic anatomy of the GEJ, represented by the absence of an adequate portion of intraabdominal esophagus, along with an increasing opening of the angle of His. These hernias can be observed in cases of increased intraabdominal pressure that occurs, for example, in obese or pregnant patients and in patients with constipation.
- True PEHs, or Type II, are the rarest of all hiatal hernias. These are characterized by the intrathoracic migration of the fundus of the stomach alongside the esophagus, while the GEJ remains in the abdomen, below the diaphragm. The combination of anterior weakness in the phrenoesophageal ligament, contextual weakening of the pleuroperitoneal membrane, and enlargement of the esophageal diaphragmatic hiatus may permit the herniation of the fundus and the body of the stomach into the thorax. At the same time, the GEJ stays in its usual intraabdominal location, held in place by the posterolateral attachments of the phrenoesophageal ligaments, which are not altered.
- Type III hiatal hernias represent a combination of sliding hernias and type II hernias and account for the majority of PEHs (Figure 2). In this condition, both the GEJ and the cranial portion of the stomach migrate across the esophageal hiatus of the diaphragm, and the gastric fundus takes its place alongside the esophagus, above the intrathoracic GEJ.
- Type IV PEH occurs when another abdominal organ, such as the spleen, the small intestine, or, more frequently, the colon herniates and joins the stomach in the intrathoracic sac. This is the result of an increased intraabdominal pressure in the presence of a large hiatal defect and abnormal laxity of the gastrosplenic and gastrocolic ligaments (Figure 3). Type IV PEH may or, less frequently, may not be associated with an abnormal location of the GEJ.

The term *giant paraesophageal hernia* is used to describe a hiatal hernia in which 30% or more of the stomach is herniated into the thorax.

The intrathoracic stomach, instead, is the condition in which nearly all of the stomach lies within the chest. If the stomach herniates into the thorax through a defect adjacent to the esophageal

FIGURE 2 Air contrast/barium radiograph showing a type III hiatal hernia. The gastroesophageal junction (GE) has slid above the diaphragm, as in a type I hernia, and the fundus of the stomach is herniated alongside the esophagus above the GEJ, as in a type II hernia.

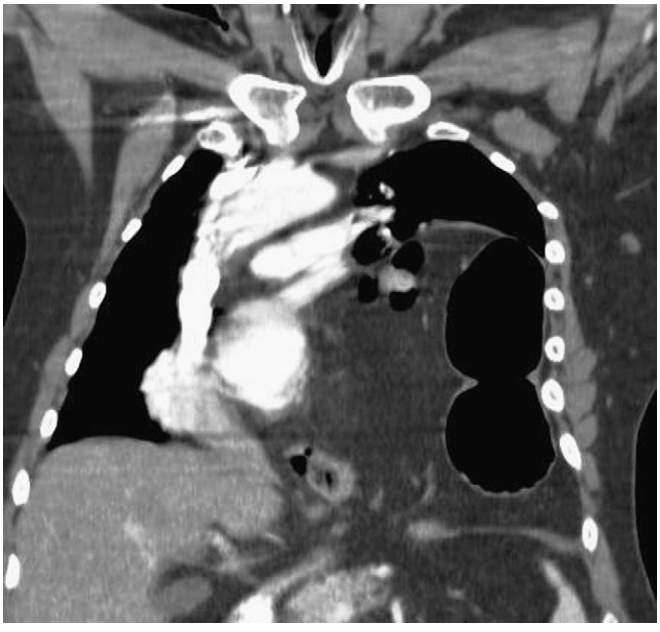

FIGURE 3 Computed tomographic scan showing a type IV giant paraesophageal hernia. The entire stomach and part of the colon and of the small bowel are displaced in the thorax.

hiatus and not through the esophageal hiatus itself, the resulting condition is commonly named *parahiatal hernia* and represents a different and less frequent pathologic entity.

CLINICAL MANIFESTATION

The clinical presentation of a patient with PEH can be heterogeneous. A significant percentage of these patients may be asymptomatic, and the PEH can be an incidental finding in the course of radiographic investigations for another condition.

The patients with PEH may complain of obstructive symptoms, which usually manifest intermittently, related to gastric twisting within the intrathoracic hernia sac. This is due to the upside-down rotational movement that the stomach, attached to the GEJ and the pylorus, is forced to undergo as it ascends into the sac. If the gastric twisting or rotation causes a transient obstruction of the GEJ, the patient experiences acute dysphagia and regurgitation. Obstruction of the distal stomach, on the other hand, may cause gastric distension, which results in nausea, vomiting, palpitation, shortness of breath, dyspnea, chest pain (which often radiates toward the back), and early satiety.

Moreover, after meals, the ingested bolus enters the herniated stomach, causing distension, which results in postprandial fullness and pain that can be confused with angina. The food-related symptoms can cause so much discomfort that the patient may avoid eating altogether; this situation can lead to significant weight loss.

PEH manifests itself not only through obstruction-related symptoms. During the passage of the stomach through the hiatus, the engorged gastric mucosa of the opposing gastric walls may ulcerate, because of repeated friction, and give rise to the so-called Cameron ulcers, which can lead to bleeding and chronic iron-deficiency anemia. This blood loss–related anemia can become symptomatic (pallor, palpitations, exertional dyspnea), but symptoms usually occur in the absence of bleeding, hematemesis, or melena. Type IV PEHs may also show obstructive symptoms that are attributable to other herniated organs, such as the colon or small intestine.

Gastroesophageal reflux disease (GERD) symptoms such as heartburn are sometimes present but are far less common in sliding hernias. In fact, despite the gastric dilation usually found in PEH, the presence of a normal-functioning lower esophageal sphincter prevents reflux and, consequently, esophagitis and esophageal ulceration. If gastric obstruction caused by rotation or twisting fails to resolve, the result is acute gastric volvulus. This represents an emergent condition that can lead to incarceration, strangulation, and gastric ischemia. Occasionally, a gastric volvulus can manifest as conspicuous bleeding, infarction, necrosis, and gastric perforation. A gastric volvulus is a well-known life-threatening complication of PEH, and patients affected by this condition may present with Borchardt's triad, originally described in 1904, which consists of epigastric or chest pain, retching without vomiting, and inability to pass a nasogastric tube (Figure 4).

PATHOPHISIOLOGY

The pathophysiology of hiatal hernias is, to date, not completely understood. There is no dominant pathogenic theory to explain them, and, thus, hiatal hernias are probably caused by a combination of factors such as the following:

- Widening of the esophageal hiatus of the diaphragm due to developmental defects or in response to acquired molecular and cellular changes
- Alterations in collagen metabolism
- Increased intraabdominal pressure and subsequent creation of an abdominal-thoracic pressure gradient
- Esophageal shortening due to fibrosis or excessive vagal nerve stimulation
- Aging-related acquired laxity of the phrenoesophageal membrane

Modifications in the structure of the periesophageal ligaments and of the muscular crura of the diaphragm, due to compromised integrity of muscle fibers and components of the extracellular matrix,

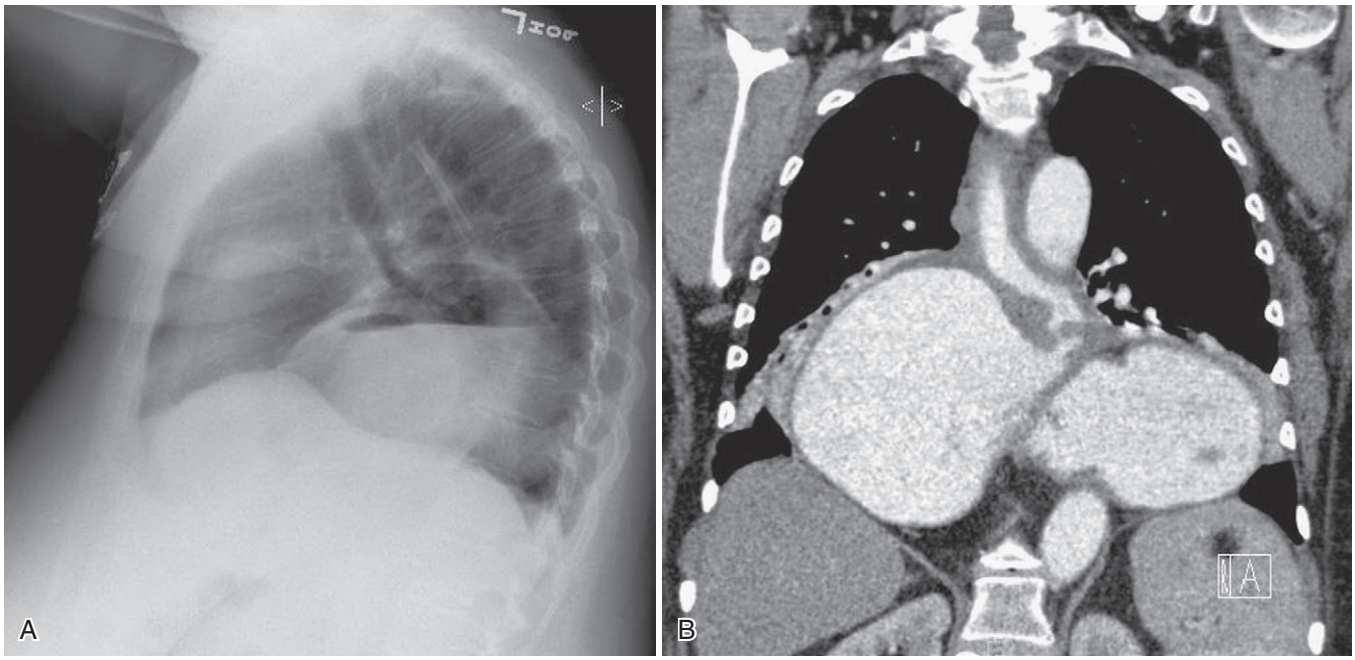

FIGURE 4 Anterolateral chest radiograph **(A)** and computed tomographic (CT) scan **(B)** showing a gastric volvulus in a patient affected by paraesophageal hernia (PEH) with an intrathoracic stomach. A retrocardiac fluid level is evident in the *left* image. The CT scan demonstrates an esophageal tortuosity caused by the thoracic migration of the stomach.

may predispose individuals to the progressive formation of an intrathoracic hernia sac.

Moreover, the increase in intraabdominal pressure promotes the migration of the cranial portions of the stomach into the sac, within the thorax. If the ligaments of the GEJ remain intact, the stomach ascends adjacent to the esophagus through a rotational movement (hence the name "rolling hernia") that creates predisposing conditions for future volvulization. Because of this movement, the stomach may lay upside-down in the mediastinum and exert even further traction on the greater omentum and on other abdominal organs, such as the colon or the spleen. A gastric volvulus is the most common severe complication of PEH and represents one of the most frequent causes of gastric volvulization in the adult population.

There are three ways the stomach can rotate to give rise to a gastric volvulus: organoaxial rotation, mesenteroaxial rotation, and combined rotation. In an organoaxial gastric volvulus, the most frequent type (approximately 60% of cases), the stomach rotates horizontally around an axis passing through the GEJ and the pylorus, while the antrum rotates in an opposite direction to the fundus.

In a mesenteroaxial gastric volvulus, the stomach rotates vertically so that the posterior surface of the stomach progressively brings itself anteriorly (Figure 5). This rotation is less frequent, occurs intermittently, and is usually incomplete. Accordingly, vascular compromise is less frequent compared with organoaxial volvulus. When the stomach rotates both mesenteroaxially and organoaxially, it is called a combined gastric volvulus; this type of stomach rotation is rare.

Diagnosis

Physical examination often provides poor clues to the diagnosis, leaving radiology and flexible endoscopy to play the central role in the diagnostic process. PEHs are sometimes found incidentally on routine chest radiographs, and they appear as a shadow in the posterior mediastinum or as a retrocardiac mass with or without an air-fluid level. The latter is often suggestive of gastric volvulus (see Figure 4). Barium contrast fluoroscopy of the upper gastrointestinal tract is one of the most important diagnostic tools in PEH. Not only can it show the presence of PEH in almost all patients, but it can provide precious information on the anatomy of the hernia, orientation of the stomach (as well as its relationship to the esophagus), and location of the GEJ.

Although it is difficult, except in obvious cases, to diagnose the so-called short esophagus with contrast fluoroscopy, the latter is helpful in identifying patients at risk of having this condition. Finally, barium contrast studies can help to select patients with esophageal motor dysfunction (uncoordinated contractility of the esophageal body and poor esophageal clearance of contrast) who should undergo a manometric study.

Upper endoscopy should also be used in patients with PEH, since it allows assessment of the intrathoracic stomach, the presence of Cameron ulcers, and the ability to evaluate the degree of esophageal mucosal inflammation, gastritis, gastric mucosal venous engorgement, stricture, and other associated pathologies such as Barrett's esophagus and cancer (Figure 6). If esophageal dysmotility is suspected, a preoperatory manometric assessment is recommended.

Esophageal manometry or, if possible, high-resolution manometry (HRM), can provide useful information on intraluminal pressure, lower esophageal sphincter function, and coordinated contractile movements of the esophagus. These findings are important in guiding the surgeon to choose the most suitable antireflux procedure for each patient. In cases of severely impaired peristalsis, a partial fundoplication is preferred to a 360-degree fundoplication, because it reduces the risk of postoperative dysphagia. However, manometric probe placement in PEH patients can be difficult; therefore, the study is not always performed. A 24- to 48-hour pH test is not routinely needed because it does not change the surgical management.

Finally, in selected patients, computed tomographic (CT) scan may be useful as a second-level exam to assess the widening of the esophageal hiatus, PEH size, content and position, and orientation of the herniated stomach.

THERAPY

Indications for Surgery

There is unanimous agreement among surgeons that symptomatic hernias require surgery as the mainstay of therapy. On the contrary, the management of asymptomatic or mildly symptomatic patients remains controversial. A well-known probabilistic model, built to evaluate the risks versus benefits of elective repair of asymptomatic large paraesophageal hiatus hernia, determined that the risk of elective repair exceeded any benefits in otherwise asymptomatic patients aged 65 years or older. At the same time, the results of emergent surgery for acute PEH have improved through the years. Therefore, we prefer a conservative approach and suggest "watchful waiting" for asymptomatic, or minimally symptomatic patients. This is especially true for elderly patients with many comorbidities.

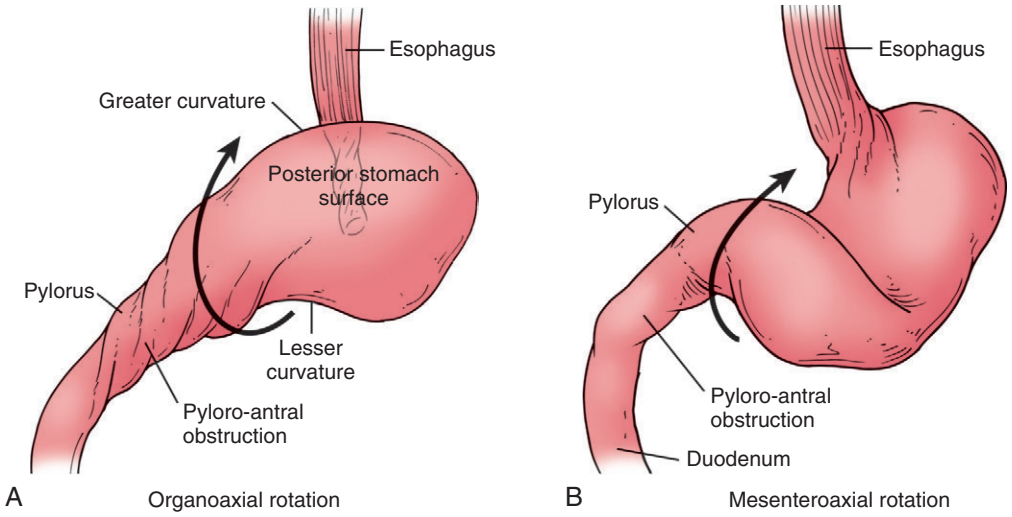

FIGURE 5 The two ways that the stomach can rotate when a volvulus occurs.

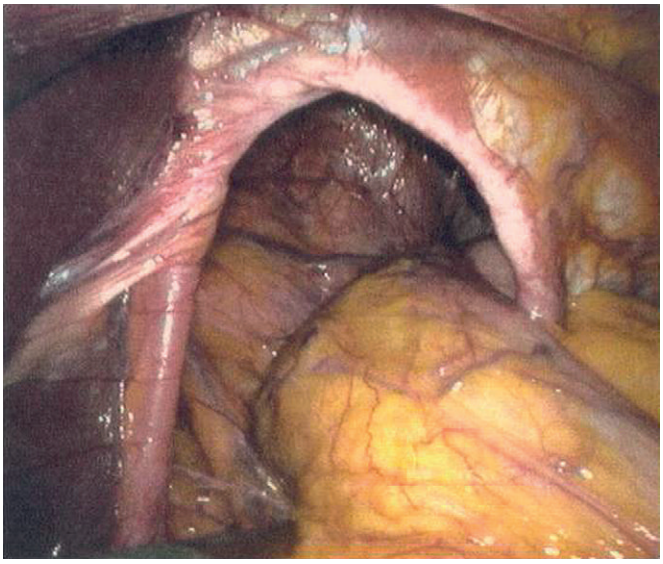

FIGURE 8 A laparoscopic view of an enlarged esophageal hiatus.

Surgical Anatomy

The esophagus enters the abdominal cavity through the diaphragmatic hiatus, whose borders are formed by the arms of the diaphragmatic crura and the median arcuate ligament (Figure 7). The esophageal hiatus is therefore a muscular structure, composed mainly of fibers belonging to the right crus, and its pliability makes it susceptible to visceral herniation. The anterior part of the crura is more tendinous and although anterior crural repair is technically easier and may seem a good choice, this technique leads to kinking of the esophagus that may cause dysphagia.

In the course of surgical repair, particular attention must be paid not to compromise crural integrity during sac dissection, in order to prevent recurrences. When performing surgical procedures on the esophageal hiatus, it is mandatory to recognize and preserve the contiguous structures, which could be accidentally injured. The anterior and posterior vagal trunks cross the hiatus along the esophagus, together with the esophageal branches of the left gastric artery and vein, and some lymphatic vessels.

The thoracic duct, the celiac ganglia, the phrenic artery and vein, the mediastinal pleura, and an inconstant aberrant left hepatic artery lie close to the hiatus and should also be preserved.

The phrenoesophageal ligament, or Laimer's membrane, is an elastic connective tissue membrane that ensures the proximity between the diaphragm and the esophagus, permitting, however, some vertical sliding of the latter.

An anterior weakness in Laimer's membrane, together with a contextual weakening of the pleuroperitoneal membrane and the enlargement of the esophageal diaphragmatic hiatus, may permit the herniation of the fundus and the body of the stomach into the thorax, alongside the esophagus (Figure 8).

There is usually a fat pad surrounding the GEJ, which should be dissected carefully during the course of a PEH repair to enhance visualization and mobilization. One of the anatomic structures that maintains the location of the GEJ is the mesoesophagus, a dense fibrous cellular tissue, included in the posterior gap between the peritoneal leaflets interposed between the esophagus, the aorta, and the diaphragmatic pillars.

The mesoesophagus is prolonged inferiorly by the gastrophrenic ligament, whose dissection is necessary when the gastric fundus is mobilized to strengthen the fundoplication.

Surgical Approach

After an informed consent is obtained, the patient is taken to the operating room, accurately positioned, and given antithrombotic and

antibiotic prophylaxis. We usually operate with the patient in reverse Trendelenburg, with the surgeon on the patient's right side and the assistant on the left. We use a 12-mm Visiport trocar (Covidien, Mansfield, Mass) to enter the abdominal cavity with a 0-degree scope, insufflation to a pressure of 15 mm Hg and using a camera angled to 45 degrees. A thorough exploration of the peritoneal cavity is performed. A second 12-mm port is placed in the midline, at about 15 cm from the xyphoid process; this port is used for the camera. A camera holder is used for assistance. A 12-mm trocar and a 5-mm trocar are placed in the right upper quadrant, as showed in Figure 9, and both are used by the surgeon. An additional 5-mm trocar is placed in the left upper quadrant and is used by the assistant. After positioning the patient in steep reversed Trendelenburg, a Nathanson liver retractor is placed through a small subxyphoid incision to hold the liver in place. The important steps of the operation are listed below.

Excision of the Hernia Sac

To begin the dissection of the hernia sac, the displaced organs should be carefully reduced, as far as possible, into the abdominal cavity. It is important that the traction should be placed on the hernia sac and not on the stomach, which could be inadvertently injured. A Penrose drain is used around the stomach or the esophagus to facilitate dissection. The complete reduction of the herniated organs can be achieved only by dissecting the sac off the mediastinum. It is important to remain in the correct avascular plane during the dissection, in order to avoid injury to intrathoracic structures that may have been displaced by the hernia. Once reduced into the abdomen, the sac can be excised, accurately preserving the vagal nerves. The complete sac dissection and excision and respect for the crural integrity are crucial for a successful and long lasting repair. If this procedure is carried out correctly and the surgical handling of the crura is minimized, no muscular fibers should be visible, at a glance, on the crural surface.

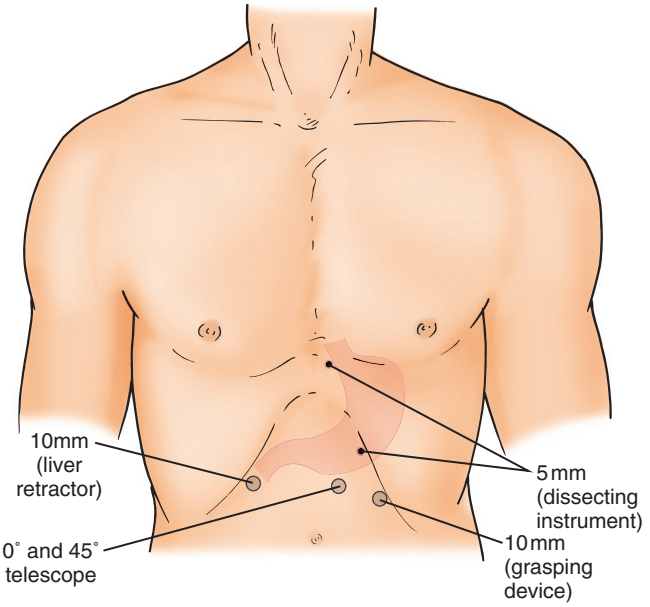

FIGURE 9 Port placement for paraesophageal hernia (PEH) repair. The *red* spot is the camera, the *green* one the liver retractor, and the *blue* spots the operative trocars. *(Modified from Landreneau RF, Del Pino M, Santos R: Management of paraesophageal hernias,* Surg Clin North Am *85:411, 2005.)*

Assessment of Adequate Intraabdominal Esophageal Length and Management of a Short Esophagus

The preoperative diagnosis of short esophagus is unpredictable and therefore the surgeon must rely on the intraoperative assessment. If at least 2.5 to 3 cm of distal esophagus can be surgically mobilized into the abdomen without tension, no further esophageal lengthening procedures are required. We prefer to dissect the gastric fat pad off the GEJ to enhance visualization of the GEJ and more accurately evaluate the esophageal length by direct visualization of the serosal lining of the cardia. This will also facilitate the creation of a window between the esophagus and the posterior vagus nerve where the stomach will be passed to create the fundoplication. We then divide the short gastric vessels completely to allow full mobilization of the gastric fundus. This will allow constructing a tension-free wrap and, in addition, will provide a useful landmark for keeping the fundoplication correctly oriented. To gain an adequate intraabdominal esophageal length, we perform an extended mediastinal dissection up to the level of the inferior pulmonary veins. A Collis gastroplasty is needed when the esophageal intraabdominal length is not satisfactory despite extensive mobilization. In this case, our preferred technique is a laparoscopic wedge Collis gastroplasty with Endo GIA stapler (Covidien, Mansfield, Mass) over a 52F or 54F bougie (see Collis Gastroplasty in the next section for more details).

Creating the Antireflux Barrier

The esophageal dissection and the disruption of the phrenoesophageal ligament predispose to the onset of GERD symptoms. The creation of a gastric fundoplication protects the esophagus from reflux and, at the same time, represents a method of fixation for the stomach to prevent reherniation.

We usually rely on the results of barium swallow and, occasionally, esophageal manometry to choose the most suitable fundoplication for each patient: in case of severely impaired peristalsis, a partial posterior fundoplication is preferred to a complete wrap. The wrap is created around a 54F or 56F bougie carefully inserted into the esophagus under direct vision. The anterior fundic lip is pulled through the window previously created behind the GEJ, and the surgeon must pay attention to maintain the correct anteroposterior orientation so that the anterior aspect of the stomach would lie against the posterior side of the esophagus. We use three nonabsorbable stitches for a Nissen fundoplication, only the proximal one of them including the esophageal muscle; in a Toupet fundoplication the gastric valves are sutured to each side of the esophagus with one row of three nonabsorbable stitches, the proximal stitch including the diaphragm. If the tension of the wrap has been calibrated correctly, after removal of the bougie, there should be room for a blunt instrument to be inserted easily between the stomach and esophagus.

Repairing the Hiatus

To obtain a tension-free crural closure, we perform a meticulous dissection of all crural attachments with contextual sparing of the crural peritoneal lining and of the pleural reflection. We usually perform a primary tension-free posterior closure of the hiatus with nonabsorbable 0 stitches. In the presence of a very wide hiatal opening, we consider placing additional anterior interrupted stitches, always paying attention not to induce an iatrogenic kinking of the distal esophagus.

We do not routinely buttress the primary closure with a mesh or use pledgeted sutures. In selected cases, in the presence of weak crural

muscle or when there is not a tension-free crural reapproximation, we reinforce the hiatal closure by placing a biologic mesh as an onlay to buttress the underlying suture. The mesh is sutured at the corners with 2-0 absorbable stitches and then glued to the crural surface using fibrin glue.

Gastropexy

An anterior gastropexy is routinely performed to decrease recurrence. The pneumoperitoneum is reduced to 8 mm Hg. Two nonabsorbable 0 stitches are placed into the anterior stomach wall and secured to the left anterior abdominal wall with the help of a Carter-Thompson suture passer (Box 1).

INSIGHTS AND CONTROVERSIES IN PARAESOPHAGEAL HERNIA SURGERY

Surgical Management of Acute Paraesophageal Hernia

Acute PEH can present as a potentially life-threatening surgical emergency. Even asymptomatic patients with PEH may be subject to this dreadful condition, usually presenting with sudden chest or abdominal pain, dysphagia, vomiting, retching, severe bleeding due to mucosal venous engorgement, and severe anemia. This may happen when the gastric twisting causing obstruction fails to resolve and, on the contrary, evolves into a gastric volvulus, which can lead to strangulation, gastric ischemia, and gastric rupture. This unfortunate evolution can be so rapid that the patient can present on admission with respiratory failure or systemic sepsis.

In patients presenting with acute symptoms, nasogastric tube decompression of the stomach should always be attempted. If successful, this maneuver, together with appropriate and prompt fluid resuscitation, can preempt emergent surgery and provide time to perform better preoperative studies, allow patient stabilization, and permit more elective laparoscopic repair.

If nasogastric tube decompression fails or if the condition has already evolved to include serious gastric ischemia or gastric perforation, emergent surgery, traditionally performed with an open approach, either through the abdomen or chest, should be considered.

In selected patients, emergent laparoscopic repair of PEH can be safe and feasible.

BOX 1: Technical pearls

- Operate with the patient in the **supine position**, in **reverse Trendelenburg**, to improve visualization and accessibility of the hiatal area.
- Place **traction on the hernia sac** and not on the stomach while trying to reduce the organs into the abdomen.
- Use a **Penrose drain** around the stomach or the esophagus to facilitate dissection.
- Remain in the correct **avascular plane** during the sac dissection.
- Respect the **crural integrity** and the **crural peritoneal** lining during dissection.
- **Dissect the gastric fat pad** and **preserve the vagus nerves.**
- Be sure to **gain** at least **2.5 to 3 cm of tension-free** distal **esophagus** into the abdomen.
- Perform an **extended mediastinal dissection** to lengthen the esophagus and only use Collis gastroplasty as a last resort.
- Create a window between the esophagus and the posterior vagus nerve for the fundoplication.
- Divide the short gastric vessels completely.
- Rely on the results of **barium swallow and esophageal manometry** to choose the most suitable fundoplication.
- Construct the wrap around a **54F or 56F** intraesophageal **bougie.**
- Pay attention to the **correct anteroposterior orientation** of the fundic lip.
- Perform a **primary tension-free posterior closure** of the hiatus with nonabsorbable stitches.
- Use additional anterior interrupted stitches only in the presence of a very wide hiatal opening.
- Use biologic mesh only for selected cases, fixing it with cardinal stitches and glue.
- Add an **anterior gastropexy** to secure the stomach within the abdomen.

Laparoscopic Versus Open

Both laparoscopic and laparotomic surgical repair have good symptomatic results and similar recurrence rates. Open surgery for PEH can be performed through an abdominal or a thoracic approach. Similar results have been described with both techniques even if some small differences have emerged. Recurrences are slightly less frequent in transthoracic approaches, but significant postoperative pain and morbidity are less represented with the transabdominal approach. Moreover, the finding of a "short esophagus" is more common in the transthoracic approach (maybe suggesting a technique-related bias); therefore, more esophageal lengthening procedures are carried out with consequent enhanced risk of staple line leak.

There is documented evidence that patients who underwent laparoscopic surgery have better scores in quality-of-life measures. In addition, laparoscopic surgery has the advantage of ensuring reduced morbidity, shorter hospital stay, and faster recovery, particularly in the elderly and patients with comorbidities. Currently, laparoscopic repair of PEHs has reported mortality rates ranging from 0.3% to 0.5%, versus 2% with open surgery. The median length of stay after open PEH repair is 7 to 10 days, and the overall morbidity is reported to be approximately 20%. In comparison, the median length of stay after laparoscopy is 3 days, and postoperative complication rates are reported to range between 0 and 15%.

In addition, technical advantages have been attributed to laparoscopy, such as better visualization of the hiatal region and easier esophageal mobilization in the mediastinum.

These data suggest that laparoscopic repair should be considered, when possible, the first choice for surgical treatment of PEH.

Open surgery for PEH still plays an important role in an emergency context, in cases of contraindications to pneumoperitoneum, and for those patients who have had multiple previous repairs. However, it is not to be forgotten that laparoscopy for PEH is challenging and should be performed by surgeons who are experienced in antireflux surgery and technically skilled in minimally invasive surgical approaches.

A Novel Approach: Robotic-Assisted Surgery

Robotic-assisted surgery (RAS) represents a novel approach to PEH repair that could be advantageous for the surgeon, especially during the most challenging cases. According to a few recent studies, RAS may prove useful in overcoming some well-known pitfalls of

traditional laparoscopic PEH repair, such as an unstable video camera platform, physiologic tremor, limited motion of straight laparoscopic instruments, two-dimensional imaging, and poor ergonomics for the surgeon. Some potential advantages of RAS are a better degree of freedom of the robotic instruments, hand-like motions of the instruments, and three-dimensional visualization with depth perception and magnification effect.

In the course of surgery for PEH, the robotic system has proven to be particularly useful in situations when movements are limited by fixed anatomic structures, such as through the narrow hiatus or in the case of an upside-down stomach. Moreover, thanks to the articulated robotic tools, there has been a remarkable improvement in intracorporeal suturing, in tying knots, and in allowing an easier dissection of the fundus. Finally, the intraoperative blood loss is reported to be lower and the learning curve for the surgeon to be shorter than in traditional laparoscopic surgery. However, RAS isn't flawless. The loss of tactile feedback, for example, could make knot tightening with the proper force challenging and increase the risk of damage to nearby structures. Finally, it must be remembered that RAS is very expensive, and this could constitute a limitation to its widespread adaptation.

"To Mesh or Not to Mesh?"

The use of prosthetic mesh for PEH repair is still debated. The most common use of mesh is for reinforcement of the hiatal closure by placing the mesh as an onlay to buttress the underlying suture. In the literature, however, mesh has been used in a bridging fashion to tailor and narrow the esophageal hiatus, especially in the case of a marked crural defect, or to cover a lateral relaxing diaphragmatic incision made to allow a tension-free primary closure of the crura. The prosthesis can be fixed to the crura by means of absorbable or nonabsorbable sutures, tacks, or glue.

Many different types of meshes have been employed for PEH surgery, including the following:

- Synthetic nonabsorbable meshes (polypropylene, Gore-Tex polytetrafluoroethylene [W. L. Gore & Associates, Flagstaff, Ariz], polyester)
- Synthetic absorbable meshes (polyglactin)
- Bioprosthetic meshes (porcine small intestinal submucosa, acellular human dermis)

The claimed advantage to using mesh is the reduction of the recurrence rate as supported by the analysis of numerous published series. Nevertheless, the placement of a prosthesis close to the esophagus unquestionably carries a burden of risks: mesh erosion into the esophageal lumen, fibrosis of the hiatus leading to progressive stenosis and consequent dysphagia, esophageal obstruction, fistulization or perforation, and foreign body reactions.

These complications are not to be underestimated, because they can be life threatening and/or require further drastic measures like esophagogastrectomy or esophagectomy. These consequences have progressively led to the abandonment of permanent meshes for PEH surgery.

Biologic meshes, thanks to their capability of being progressively colonized and replaced by autologous tissue, may help surgeons avoid these dreadful complications and are still considered helpful adjuncts to esophageal hiatus surgery. Animal studies and a wide experience in surgery for abdominal wall defect repair show that biologic meshes may ensure adequate tensile strength and, at the same time, form minimal adhesions. Furthermore, they are more resistant to infections and induce less fibrosis compared with synthetic meshes.

A multicenter prospective randomized study showed that a biologic mesh–buttressed repair significantly decreased recurrence rates at 6 months. However, the long-term 5-year follow-up from the same study showed the recurrence rate to be about 50% for both buttressed and nonbuttressed PEH repairs.

In conclusion, surgeons should knowingly balance the risk of complications and the possible reduction in recurrence rate before making their choice.

Collis Gastroplasty

A shortened esophagus may jeopardize optimal outcome for PEH surgery, increasing the risk of recurrence by placing excessive axial tension on the repair. It is believed that the acquired shortening of the esophagus is caused by repeated acid-related damage against the lower esophageal wall. The subsequent injury and repetitive healing leads to fibrotic remodeling (in particular, affecting the outer longitudinal muscle) that progressively causes contracture and shortening of the esophagus. While a severely shortened esophagus is detectable by contrast fluoroscopy, less obvious shortening is often a subjective intraoperative diagnosis. Predictors of esophageal shortening have been proposed, such as the endoscopic finding of esophageal stricture, but there is no unanimous consensus on how to define a shortened esophagus preoperatively. Moreover, the overall concept of a short esophagus is controversial, and the number of lengthening procedures performed reflects the orientation of each surgical school ranging between 0 and more than 50%.

Collis gastroplasty has been reported to decrease recurrence rates in several published series (Figure 10). However, this procedure is associated with a small but significant risk of staple-line leakage and therefore adds morbidity and mortality to PEH repair. Moreover, the results of Collis gastroplasty have not been studied. Although the procedure is claimed to have similar results to a Nissen

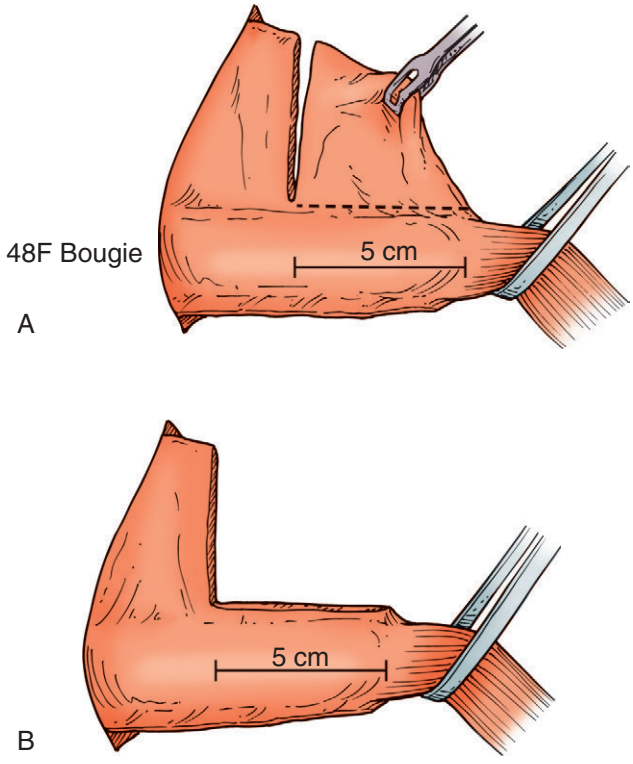

FIGURE 10 A laparoscopic Collis gastroplasty. **A,** The stomach is divided with an Endo GIA from the greater curvature down to a 52F or 54F bougie placed along the lesser curvature and 5 cm from the gastroesophageal junction (GEJ). **B,** A wedge of stomach is removed by dividing the stomach with an Endo GIA along the bougie up to the GEJ. This usually requires that the Endo GIA is placed through the left lateral flank port. The remaining fundus and body of the stomach are advanced cephalad to form the fundoplication around the newly constructed gastroplasty tube.

fundoplication, problems with dysphagia and poor control of GERD have been reported. This is usually because the fundoplication was constructed too inferiorly, often below a portion of aperistaltic stomach or neoesophagus, which maintains its secretory properties. Therefore, balancing the risks and benefits of a Collis should be considered before performing this procedure.

Antireflux Procedure

The choice of adding or not adding an antireflux procedure to the surgical repair of PEH represents another controversial surgical decision. If the majority of surgeons agree that constructing a fundoplication is recommended for those patients with PEH affected by reflux symptoms, the addition of this procedure in absence of such symptoms often remains a subjective choice. Those who always choose to perform a fundoplication advocate that it could be useful to place an intraabdominal buttress, which may help, together with the crural closure, to prevent reherniation of the stomach. Moreover, it could help prevent the future onset of reflux symptoms in patients in which further hiatal surgery would be challenging.

Those who do not routinely perform a fundoplication in asymptomatic or in minimally symptomatic patients assert, on the contrary, that the side effects of a fundoplication overwhelm the possible reduction in recurrence rates.

We prefer to add a fundoplication to our PEH repairs not only to improve gastric fixation below the diaphragm but also to treat GERD, which is often present and underestimated (Figure 11). Furthermore, the extensive esophageal dissection and mobilization during the repair destroys the phrenoesophageal attachments and places patients at a high risk for GERD postoperatively.

The decision about the use of a partial versus a complete wrap is made by carefully evaluating esophageal peristalsis. The first carries a lower risk of postoperative dysphagia but is less effective and less durable against reflux symptoms. The use of a barium swallow evaluation and, in selected cases, esophageal manometry helps the surgeon choose the most suitable antireflux procedure for each patient. In the case of severely impaired peristalsis, a partial fundoplication is preferred to a Nissen procedure to reduce the risk of postoperative dysphagia.

RESULTS

Although PEH repairs are technically challenging, the perioperative morbidity is low and the short- and long-term results are encouraging. Among the most frequent complications, traumatic visceral injury is reported in as many as 4% to 10% of the patients. It is thought to be due to either improper surgical tissue handling or traumatic bougie insertion. However, in many cases, a trained laparoscopist can manage these events intraoperatively, with little impact on the final result of the operation. Delayed perforations, either due to missed intraoperative injury or ischemic necrosis, will almost inevitably require revisional surgery. Other reported complications include vagus nerve injury, which is likely to cause delayed gastric emptying; pneumothorax due to pleural violation during mediastinal dissection; and complications such as pneumonia, respiratory distress, and myocardial infarction, which are more often observed in elderly patients.

The long-term symptomatic outcome of repair of PEH is very good, with reported success rates ranging from 80% to 90%, depending on the series.

Anatomic and radiologic recurrences, detected through videoesophagram or upper endoscopy, are higher than clinically symptomatic recurrences and may occur in more than 50% of PEH surgical repairs. Most radiologic hernia recurrences after PEH repair are asymptomatic or minimally symptomatic and follow a benign course, requiring no further therapy, and only 3% to 5% of patients develop large recurrent PEH with significant symptoms requiring revisional surgery.

It is believed that many factors contribute to a predisposition to recurrence, including tension on the crural repair, short esophagus, large hiatal defects, attenuated crural muscle fibers, inadequate mobilization of the esophagus, and inappropriate diaphragmatic stressors in the early postoperative period, such as vomiting and retching. Recurrences usually occur in the early postoperative period and are

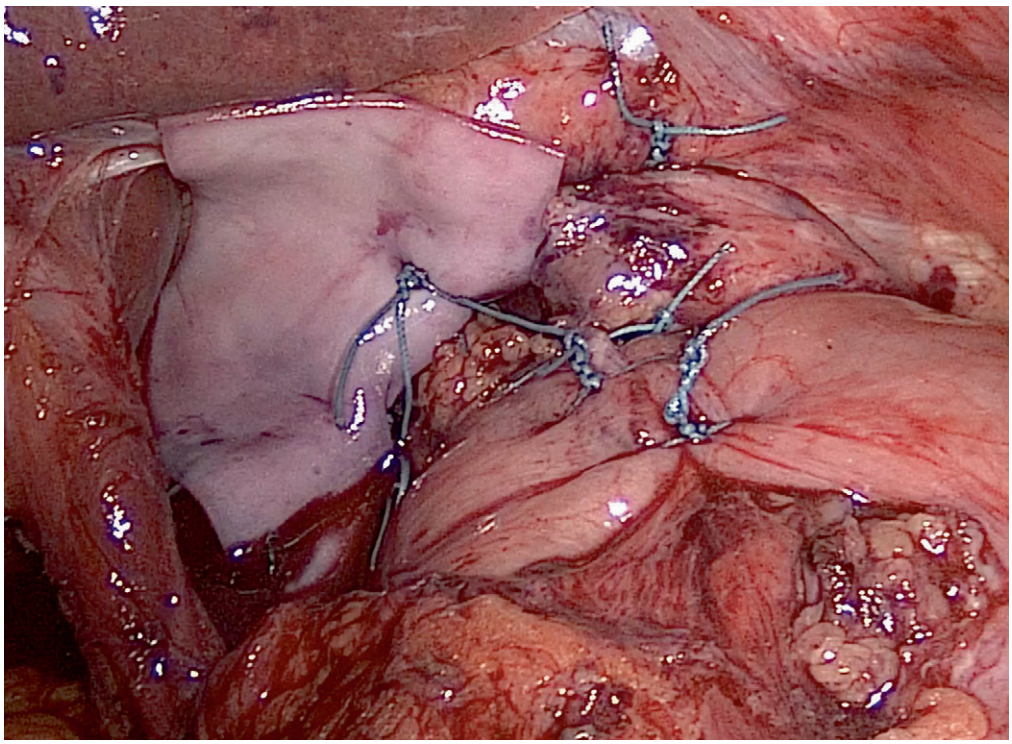

FIGURE 11 A laparoscopic view of a Nissen fundoplication. A biologic mesh–buttressed hiatal closure is visible as well.

often represented by intrathoracic migration of the fundoplication, when present, or wrap disruption with recurrent herniation.

It has been also postulated that recurrent PEHs have a lower risk of evolving into a gastric volvulus. This is probably due to the presence of adhesions in the hiatal area and around the upper stomach that prevent the stomach from rotating and twisting within the new hernia sac.

SUMMARY

PEHs are far less common than type I hiatal hernias, but they can lead to dreadful complications. They are probably caused by a synergic effect of increasing abdominal pressure and weakening of the ligamentous structures of the GEJ region.

Rarely symptomatic, PEHs can commonly manifest through obstruction-related symptoms, GERD-related symptoms or complications, bleeding, or arrhythmias. Evaluation with endoscopy, videoesophagram, and occasionally esophageal manometry should be considered in choosing the correct surgical procedure.

The gold standard treatment for PEH is laparoscopic repair following some key steps:

1. Excision of the hernia sac
2. Assessment of adequate intraabdominal esophageal length and management of a shortened esophagus
3. Repair of the hiatal defect
4. Gastric fixation and antireflux barrier

There are numerous controversies concerning selected topics in PEH repair, and the surgeon should have a deep knowledge of this subject, in order to make the best choice for every patient.

Finally, the results of laparoscopic PEH repair are very good, but laparoscopy for PEH is challenging and should be performed by surgeons who are experienced in antireflux surgery and technically skilled in minimally invasive surgical approaches.

The Management of Pharyngeal Esophageal (Zenker's) Diverticula

Richard F. Heitmiller, MD, FACS

INTRODUCTION

Pharyngeal esophageal diverticula, more commonly referred to as Zenker's diverticula, are uncommon, benign, easy to diagnose, and safe to treat regardless of patient age. The three types of esophageal diverticula are Zenker's (upper), parabronchial (middle), and epiphrenic (lower). Zenker's is the most common type, accounting for almost two thirds of esophageal diverticula. In addition to anatomic location, diverticula are also classified by their etiology as pulsion (Zenker's and epiphrenic) and traction (parabronchial) types. This classification underscores diverticular etiology and factors into the rationale for specific surgical repair methods.

A Zenker's diverticulum is a posterior, midline outpouching of pharyngeal mucosa, just proximal to the cricopharyngeal muscle through an area of anatomic weakness known as Killian's triangle. It is therefore actually a preesophageal diverticulum. It is also a false diverticulum because only the mucosa herniates, not all layers of the bowel wall. Zenker's diverticula are uncommon, although undoubtedly many result in minimal symptoms and are never discovered. They are diagnosed in patients over a very large age range that spans from 30 years to well above 90 years. They are most prevalent in patients in the 6th decade of life. Zenker's diverticulum is more common in males than in females by a ratio of approximately 3:1 (Table 1).

HISTORY

Historically, symptomatic Zenker's diverticulum was a serious disease process that often resulted in death from malnutrition, aspiration pneumonia, or both. In 1877, Zenker and von Ziemsen described the postmortem findings in 34 patients with pharyngeal esophageal diverticula, proposed their etiology, and correlated the anatomic findings with patient symptoms. It was the correlation of anatomic findings to clinical symptoms that established Zenker's name as the moniker for this disease process. Their detailed findings are as specific and relevant today as they were then. They also are credited with classifying esophageal diverticula into pulsion and traction types. However, the ability to diagnose diverticula preceded the ability to treat them. As Zenker and von Ziemsen wrote, "the radical cure of diverticula by operative procedure from without is at the present time one of our vain wishes . . ." Initial attempts to treat patients by instilling caustic fluids into the diverticulum led to disastrous outcomes, including aspiration pneumonia, leakage with mediastinitis, and death. Early open repairs fared no better. The first successful open surgical repair is credited to Wheeler in Dublin (1885), and the first successful repair in the United States is credited to Mixter in Boston (1895). These early repairs were heroic surgeries with long hospital stays. Currently, surgical repair can be performed quickly and safely with short lengths of stay and excellent results.

ETIOLOGY

A Zenker's diverticulum is a benign, acquired abnormality that is either slow in development or delayed in onset, which leads to patients presenting most commonly between ages 50 and 80 years. A great deal has been published on the pathophysiology of Zenker's. The characteristic mucosal outpouching is thought to develop as a result of an imbalance between pressure developed by posterior pharyngeal muscular contraction and weakness of the mucosa in Killian's triangle. Either hypertensive upper esophageal sphincter (UES), or

TABLE 1: Zenker's diverticulum: Summary

Age (y)	Mean: 68; range, 30-90
Gender (male : female)	3 : 1
Symptoms	Dysphagia Regurgitation Cough Choking episodes Globus sensation

CP, Cricopharyngeal.

one that relaxes in a poorly coordinated fashion, have been cited as causes of pharyngeal high pressure. Whether these diverticula arise more from high pressure, intrinsic wall weakness, or a combination is unclear.

Jones states in her comprehensive text that "In our experience, almost all patients with Zenker's diverticulum have esophageal disorders such as gastroesophageal reflux, segmental spasm, acid-induced spasm, hiatal hernia, or Schatzi's ring." Therefore, the data suggest that a Zenker's diverticulum is rarely a truly isolated esophageal disorder.

Documented cases are found of posterior pharyngeal mucosal ulceration or focal injury from an impacted foreign body that subsequently led to diverticular formation as well. Whether these cases would have developed anyway and were initiated by wall weakness or not is unclear.

SYMPTOMS

Dysphagia is the most common symptom. Swallowed food and fluid preferentially fill the diverticulum, which then distends and compresses the adjacent esophagus in the confines of the tight cervical space. Radiographically, this is clearly depicted (Figure 1). The compressed cervical esophagus is often thought to be strictured because of its appearance, but the author has never seen this to be so. Patients report that it is easiest for them to eat in the morning. As the day progresses, they have increasing dysphagia as the diverticulum fills. Diverticular contents have only one way out, which is back into the pharynx, leading to regurgitation, cough, and choking episodes. Choking episodes may wake a patient up at night and, in the worst case, are associated with a history of pneumonia. In addition, patients may have vague reports of a lump in the throat. Many have a characteristic voice, described as a "wet" voice, which sounds as if a person were talking while gargling a small quantity of fluid.

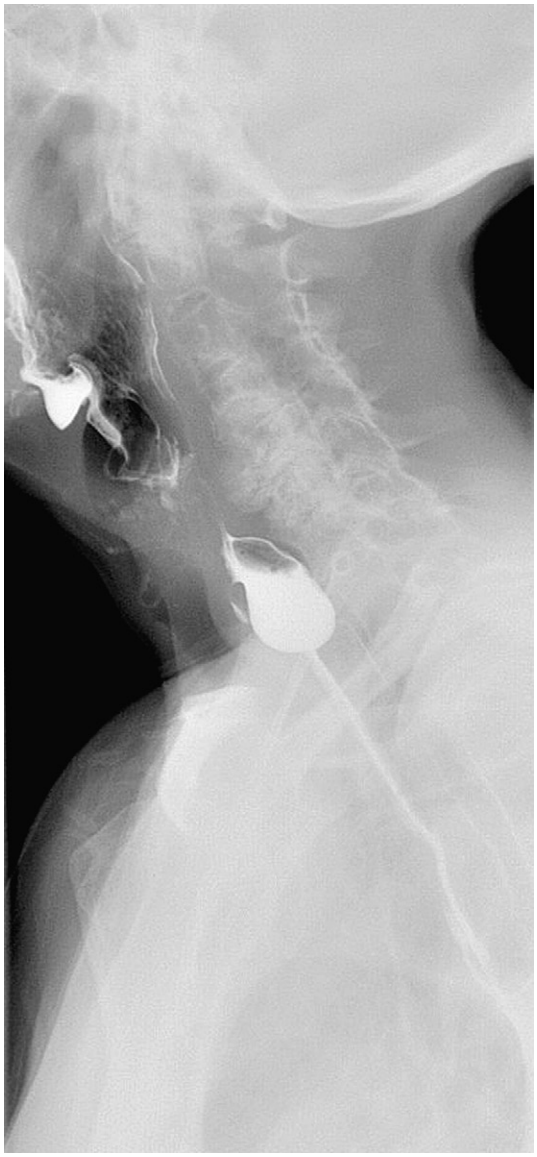

FIGURE 1 Select lateral spot image from contrast esophagogram showing moderate sized Zenker's diverticulum with compression of adjacent cervical esophagus.

DIAGNOSIS

Even in their classic form, the symptoms of Zenker's diverticulum are suggestive, not diagnostic, of the disease. A contrast swallow is the ideal first test. It is readily available and well tolerated by patients. The radiologist should be told that this may be a patient with Zenker's so that precautions against possible aspiration can be taken and appropriate views obtained. Video esophagography is superior to fluoroscopy and spot films in that it can screen for possible pharyngoesophageal motility disorders in addition to defining anatomy. Unless the contrast swallow reveals some unusual esophageal findings, endoscopy is not needed.

INDICATIONS FOR SURGERY

Once the diagnosis is made, the author explains to patients what they have, that it is a benign process, and how it accounts for their symptoms. Patients are followed as long as they are comfortable with their

symptoms. Once patients are tired of dealing with the swallowing symptoms, the author has them return for surgery. Prominent respiratory symptoms, such as nighttime choking episodes or history of pneumonia that sounds like aspiration, however, are an indication for surgical repair. Dysphagia with weight loss is another indication for surgery, although significant weight loss is no longer commonly encountered.

OPERATIVE TECHNIQUE

Three operative techniques have been described for management of Zenker's: diverticulectomy with primary repair and cricopharyngeal myotomy, diverticular suspension to the prevertebral fascia and cricopharyngeal myotomy, and transoral endoscopic stapled diverticulectomy. A modification of the last technique uses the harmonic scalpel or laser to create an open channel between the diverticulum into the adjacent esophagus. Only the first, diverticulectomy with primary closure and myotomy, is discussed here. This procedure is simple, safe, and fast and directly corrects the functional (cricopharyngeus muscle) and anatomic (diverticulum) abnormality. A neck incision is well tolerated, and the evolution of stapling devices has made this direct repair even faster. The author has never encountered a patient who was a candidate for any procedure who could not tolerate this form of repair, regardless of age.

For diverticulectomy with primary repair and cricopharyngeal myotomy, patients are at nothing by mouth (NPO) status before surgery. Preoperative prophylactic antibiotics are routine. General endotracheal anesthesia is used, and patients are positioned supine with the neck in extension. Sweet commented that hyperextension of the neck was to be avoided because it narrowed the space between the airway and the spine. The author asks anesthesia colleagues to hold off putting anything into the esophagus at this time because it would preferentially tend to go into the diverticulum. A left neck incision is used because this is most comfortable for right-handed surgeons. The left side could be used if indicated. A modified collar incision is preferred, similar to that used with thyroid surgery except it is slightly higher in the neck and extends asymmetrically to the left side. Use the cricoids cartilage as the landmark to determine the exact location of this incision.

The incision is carried down to the prevertebral space, retracting the sternocleidomastoid muscle laterally, passing medial to the carotid sheath contents, and dividing the omohyoid and superior thyroid vessels as needed. Bluntly develop the posterior esophageal, prevertebral space. Avoid this dissection too far proximally because it tends to adversely affect postoperative pharyngeal function. With the posterior pharynx, left piriform sinus, and distal cervical esophagus exposed, have the anesthesiologist pass an orogastric catheter past the diverticulum into the cervical esophagus. This could be a nasogastric tube passed through the mouth or just an esophageal stethoscope. With this tube in place to help with orientation, dissect posteriorly to identify the diverticulum. The bigger the diverticulum, the easier it is to find. Most of the time, the diverticulum is easy to find. To help with exposure, a small rake or set of retracting hooks can be used to grasp the left posterior edge of the laryngeal cartilage, which rotates the larynx to the right, improving posterior exposure. The recurrent laryngeal nerve is protected in this fashion. Pharyngoscopy may also be used during surgery to help find difficult diverticula or ones in which the anatomy is confusing. Once the diverticulum is identified, take a moment to be sure identification is correct. With the target structure grasped, review its appearance and origin in relation to the cricoid cartilage. The author has seen cases in which the ipsilateral piriform sinus has been mistakenly resected. Once identification is ensured, dissect the diverticulum down to its neck. Generally, there is a good but somewhat vascular plane between the pseudocapsule covering the diverticulum and the mucosa. By doing so, you ensure you have the right structure and that it is completely removed. Either staple the diverticulum flush with the esophagus and remove it (use the indwelling catheter to ensure the esophagus passes over and past your staple line) or resect the diverticulum and close the mucosal defect primarily in two layers of inverting sutures. No indwelling bougie or spacer is needed. Overtightening of the gastrointestinal tract from this repair is not possible. A 30-mm right angled stapler works well, given its 90-degree configuration that fits into the prevertebral space. However, the newer linear staplers are getting smaller, and the tip articulates so that it can be a good choice as well. The author always closes the adjacent muscle over the stapled closure with interrupted sutures.

Cricopharyngeal myotomy is performed in a different plane from the diverticular suture line closure, usually 90 degrees to the ipsilateral operative side. Use the cricoids cartilage as a landmark and divide the muscle down to the mucosa with scissors. Extend slightly proximal and then distal to the level of the cricoid so that the length of myotomy is approximately 3 cm total.

The wound is irrigated and closed in layers. The author uses a closed suction drain that does not lie adjacent to the suture or stapled line and is removed the next day. Drain use is not imperative. When patients undergo extubation in the operating room at case conclusion, no tubes are left in the esophagus.

POSTOPERATIVE CARE

After surgery, patients are admitted to the hospital. Continued antibiotics are not needed. Patients are kept NPO and hydrated with maintenance intravenous fluids. If a cervical drain is used, it is removed the next day. The wound is left uncovered so it can easily be seen and inspected. Signs of a leak are fevers; tachycardia; increasing neck pain; wound redness, swelling, or drainage; and leukocytosis. Signs are generally not subtle. On postoperative day 3, a contrast swallow is obtained. Radiology should be warned about the possibility of some aspiration. The swallowing study confirms complete diverticular removal and no suture or staple line leak. After successful study, the diet is advanced to soft regular and the patient is discharged home. Observation of patients after surgery during the time of greatest risk for aspiration and leakage is still important. After discharge, patients return to the office in approximately 3 weeks for their first visit.

RESULTS

As mentioned previously, open repair is safe and effective. Overall, the safety of the procedure continues to improve with advancements in anesthesia and patient care. A summary of the open method results show complication rates of approximately 4% to 10%, mortality rates of 0 to 2% (but more recently <1%), good to excellent swallowing achieved in 75% to 99% of patients, and recurrence rates of about 3% or less (see Table 1). Complications include temporary swallowing or speech changes, local wound infections or hematoma, pneumonia, and rarely recurrent laryngeal nerve injury, which should be very uncommon because the repair and retraction is posterior and superior to the nerve path and insertion point.

CONCLUSION

Zenker's diverticulum is an uncommon, benign esophageal disorder that is easy to diagnose and safe to treat with surgery regardless of patient age. Functional results are good, and clinical recurrence rates very low.

The Management of Achalasia of the Esophagus

Sheraz R. Markar, MD, and Donald E. Low, MD

BACKGROUND

Esophageal achalasia is a rare motility disorder that affects 1 person per 100,000 and is characterized by the failure of the lower esophageal sphincter (LES) to relax appropriately in response to swallowing and the decrease or absence of peristalsis. Findings that have been associated with the diagnosis include myenteric inflammation with associated injury and loss of ganglion cells, along with fibrosis of myenteric nerves, reduced synthesis of nitric oxide, and vasoactive intestinal polypeptide. The exact etiology of achalasia remains unknown; however, autoimmune-mediated destruction of inhibitory neurons is a possible explanation. Common symptoms associated with achalasia include progressive chest pain, odynophagia, dysphagia, regurgitation, and weight loss.

DIAGNOSIS

The diagnostic workup typically includes esophagogastroduodenoscopy (EGD), contrast esophagram, and esophageal manometry.

Esophagogastroduodenoscopy: EGD may show a dilated esophagus with retained saliva, fluid, and food and increased resistance to passage of the scope through the esophagogastric junction. EGD may also be used to assess for the presence of other diagnoses, including pseudoachalasia, esophageal tumors, reflux induced strictures, and eosinophilic esophagitis. Pseudoachalasia is defined as a spectrum of diseases that secondarily impair distal esophageal motility and imperfectly mimic achalasia. Originally described by Oglive in 1947, it is the result of a primary or metastatic submucosal cancer that involves the distal esophagus or esophagogastric junction. If pseudoachalasia is suggested on EGD, further investigations should include computed tomographic (CT) scan or endoscopic ultrasound scan. EGD is often suggestive but is not typically diagnostic of achalasia.

Contrast esophagram: The classic appearance seen with a contrast esophagram is tapering of the lower esophagus, described as a bird's beak (Figure 1). Other features may include a dilated esophageal body with an air-fluid level, the absence of a gastric air bubble, and absent or asynchronous esophageal contractions. Contrast studies have historically been considered diagnostic in approximately two thirds of patients.

Esophageal manometry: This test shows incomplete or absent LES relaxation and the absence of esophageal peristalsis during swallowing and sometimes elevated resting LES pressure. Manometry is considered the gold standard preoperative assessment and is diagnostic of achalasia in 90% of cases. Occasionally, manometric catheters do not pass into the stomach without fluoroscopic or endoscopic guidance.

Treatment for achalasia is not curative; it is primarily aimed at improving esophageal emptying by decreasing the functional obstruction at the level of the gastroesophageal junction, providing symptomatic relief and preventing the long-term development of megaesophagus.

MEDICAL THERAPY

Pharmacologic

Calcium channel blockers and long-acting nitrates that act as smooth muscle relaxants have been shown to be effective in reducing LES pressure and providing temporary relief of dysphagia in a small proportion of patients. However, their use is limited because they do not improve LES relaxation or peristalsis and they have a short duration of action and typically provide incomplete symptom relief. Their role is limited to symptom relief in patients with very early achalasia or those who are at high risk or refuse more aggressive treatments; in patients with severe achalasia, pharmacologic treatments have not been shown to be beneficial.

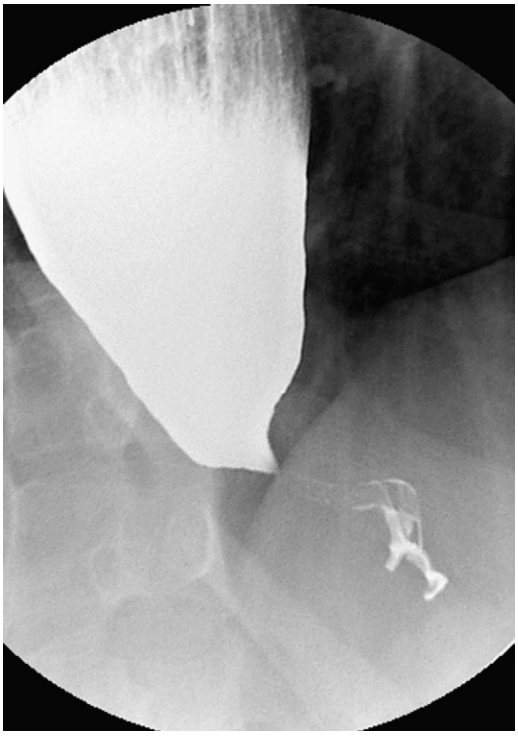
Botulinum Toxin Injection

Botulinum toxin is a neurotoxin that inhibits acetylcholine release at motor neuron presynaptic terminals and thereby promotes LES relaxation. Botulinum toxin is injected endoscopically with a sclerotherapy needle in four aliquots into each quadrant of the LES, with a total of 100 units. The complication rate associated with botulinum toxin injection is very low, and this method has been shown to provide a good short-term response, with symptomatic reduction in up to 75% of cases. However, beneficial effects decrease over time, with symptoms typically recurring in 1 to 4 months. A recent Cochrane review of four randomized controlled trials suggested that when compared with pneumatic dilation, botulinum toxin injection was less effective in the long-term control of symptoms arising from achalasia, with only 25.6% having symptomatic remission at 1 year compared with 70.2% in the pneumatic dilation group (Table 1). Furthermore, botulinum toxin injections can hypothetically produce submucosal scarring that impacts the dissection of the mucosal plane at myotomy, which some surgeons believe can increase the risk of intraoperative esophageal mucosal injury. Thus, currently botulinum toxin injection should be reserved for patients who do not wish to have other treatments or those who are at too high a risk for more

invasive procedures, including pneumatic dilation and surgical myotomy.

Esophageal Pneumatic Dilation

Endoscopic pneumatic dilation is considered the most effective nonsurgical treatment for the palliation of dysphagia associated with achalasia. Pneumatic dilation is preferred over standard balloon or bougie dilation because it not only stretches but also produces localized rupture of the LES muscle fibers. Most endoscopists advocate a sequential graded approach to pneumatic dilation, with noncompliant polyethylene balloon diameters currently used being 30, 35, and 40 mm. The most commonly used system is the Microinvasive Rigiflex balloon system (Boston Scientific Corporation, Natick, Mass). The balloon is placed across the LES, and position is confirmed with fluoroscopy with radiopaque markers on the catheter and within the balloon (Figure 2). The pressure necessary is usually 7 to 15 psi, with balloon inflation maintained for 15 to 60 seconds with confirmation of LES waist obliteration with fluoroscopy. Commonly, a multiple treatment regimen is used, based on active surveillance for symptomatic recurrence; this has been shown to be effective in the palliation of dysphagia associated with achalasia. The most severe complication associated with pneumatic dilation is esophageal perforation, which is quoted to occur in 4% to 7% of dilations and which occurred in 4% of patients in a recent randomized controlled trial. Esophageal perforation in this context is a serious complication, requiring urgent surgery, combining primary repair with surgical myotomy. Long-term functional results of perforation when managed by an experienced surgical team can be comparable with primary surgical treatment. Many gastroenterologists perform a postprocedure esophageal contrast swallow to rule out perforation before discharge from



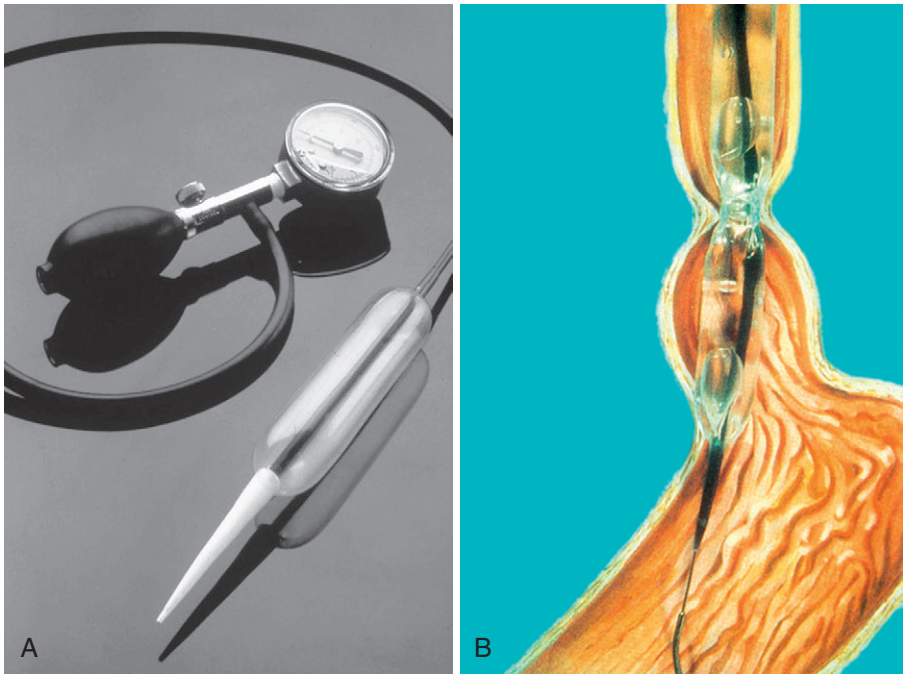


FIGURE 1 Contrast esophagram showing tapering of the lower esophagus with a classic bird's beak appearance.

TABLE 1: Endoscopic pneumatic dilation versus botulinum toxin injection in the management of primary achalasia

Follow-up period	Pneumatic dilation: symptom remission (N = 158)	Botulinum toxin: symptom remission (N = 121)
6 months	76%	26%
12 months	70%	25%

hospital. Furthermore, the long-term effectiveness of pneumatic dilation regimens is questionable, with treatment success rates of 50% at 5 years. A major advantage of pneumatic dilation is that it can be performed in an outpatient setting, enhancing its cost effectiveness in the treatment of esophageal achalasia.

Per-Oral Endoscopic Myotomy

Per-oral endoscopic myotomy (POEM) has been recently introduced as a potential new endoscopic approach to myotomy. Significant variability has been found in the technical approach used in POEM surgery. The most commonly described technique involves submucosal injection of saline solution at the midesophageal level approximately 13 cm from the gastroesophageal junction. A standard endoscope with a cap is introduced into the submucosal layer through a 2-cm longitudinal incision on the mucosal surface. A submucosal tunnel is then created and extended to 3 cm onto the stomach with a triangular tip knife and spray coagulation with direct endoscopic vision, or blunt dissection with the flexible endoscope or standard balloon dilation. Dissection of the circular muscle begins approximately 7 cm from the gastroesophageal junction with spray coagulation and a triangular tip knife. Division of the muscle continues for approximately 2 cm distal to the gastroesophageal junction; narrowing is typically seen endoscopically during passage through the LES. The outer longitudinal muscles are identified at the limit of the dissected area, and after myotomy, smooth passage of the endoscope through the gastroesophageal junction should be seen. The site of entry in the mucosa is then closed with hemostatic clips or fibrin glue. Table 2 discusses the results from clinical POEM studies to date. The attraction of this technique is the minimally invasive nature of the procedure, with no external scarring and less surgical stress, but the creation of a myotomy that replicates what is done surgically. This is an innovative and potentially important addition to the treatment approaches for achalasia. However, currently, insufficient follow-up assessment exists on the long-term success rate or consequences of POEM.

SURGICAL TREATMENT

Myotomy Technique and Outcomes

Surgical myotomy with division of the muscle fibers of the cardia for the treatment of achalasia was first described by Ernst Heller in 1913. Over the years, several technical issues have undergone clinical assessment; transthoracic versus transabdominal, open versus laparoscopic, and extended versus limited myotomy and whether a concomitant antireflux procedure including Nissen, Toupet, or Dor fundoplication should be done in conjunction with the myotomy. The authors describe the method of esophageal myotomy that is used routinely at their institution and discuss some of the issues regarding modifications of this technique.

Most commonly, the authors use a laparoscopic transabdominal approach to esophageal myotomy. The patient is positioned in a modified lithotomy position in reverse Trendenlenburg's position. A five-port technique is used: one camera port, two ports for retraction, and two working ports. The first incision is made typically one third to one half the distance from the umbilicus to the xiphisternum, to allow placement of a 12-mm Hassan or Optiview port (Johnson & Johnson, Calif). A 12-mm working port is placed in the left upper quadrant adjacent to the costal margin as high as possible but also maximizing triangulation of the right and left working ports. A 5-mm port is placed in the groove between the xiphisternum and the right costal margin to allow insertion of the liver retractor (Nathanson liver retractor, Cook Medical Bloomington, Ind), which is used to retract the liver anteriorly and to the right. Two further 5-mm ports are placed to the left and right of the camera port, the one on the right used for retraction and taking down the short gastric vessels and one on the left to be the other dissection or working port. The left 5-mm port is typically placed through or beneath the falciform ligament. The assistant stands on the left side of the patient, the camera operator to the right, and the operating surgeon between the legs.

Dissection begins with division of the phrenoesophageal membrane and gastrophrenic ligaments, with dissection extending posteriorly to the decussation of the crura. This dissection is continued circumferentially, the right and left crura are freed, and the dissection is carried into the mediastinum to allow adequate circumferential mobilization of the esophagus, which is encircled by a Penrose drain. Esophageal mobilization is continued until there are 4 to 5 cm below the hiatus without tension. This mobilization is done to a greater degree when the distal esophagus is tortuous. The authors divide the short gastric vessels and omental attachments over a distance of 15 cm until the fundus is completely free.

The anterior esophageal fat pad is removed down to the gastric serosa to expose the gastroesophageal junction and increase the ease of doing the myotomy. This dissection is typically started to the left of the anterior vagus nerve and can facilitate the mobilization of the anterior vagus nerve to the right to take it well away from the site of the proposed myotomy. The myotomy is initiated 1 to 2 cm above the esophagogastric junction, typically with hook cautery initially but then with blunt tearing of the last circular muscle fibers. The authors commonly extend the myotomy a minimum of 5 cm in a cephalad direction along the anterior esophagus then across the esophagogastric junction, continuing for a minimum of 2 cm caudally onto the stomach (Figure 3). The change from esophageal to gastric muscle

TABLE 2: Results from clinical trials of per-oral endoscopic myotomy

Author	No. of patients	Myotomy length (cm)	Follow-up period	Dysphagia score improvement	LES pressure change
Inoue (2010)	17	8.1 (6.1 in esophagus + 2 in stomach)	5 mo (1-16 mo)	10 to 1.3 (0-4)	52.4 to 19.8 (9.3-42.7)
Von Renteln (2011)	16	12 (8-17)	3 mo	94% patients with Eckhard score of ≤3	27.2 to 11.8

LES, Lower esophageal sphincter.

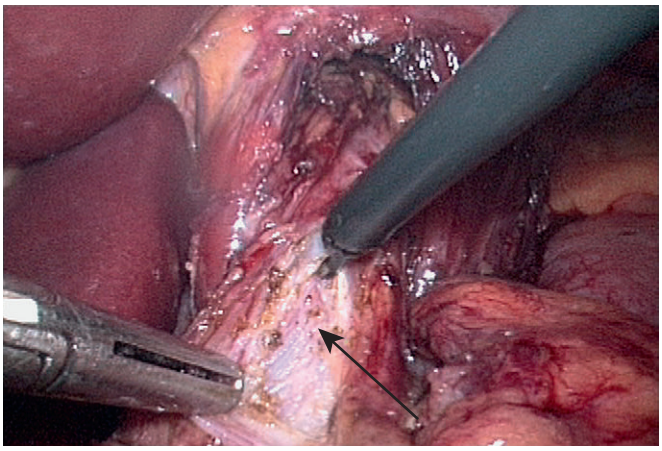

FIGURE 3 Myotomy dissection *(arrow)* extended 5 cm in a cephalad direction along the anterior esophagus and a minimum of 2 cm caudally onto the stomach.

fibers can be seen as they change from a horizontal circular orientation to an oblique direction and are more adherent to mucosa in the region of the LES. Once the myotomy is completed, a 48F to 52F bougie is passed with laparoscopic guidance, which stretches the mucosa and helps to ensure that all muscle fibers are divided. At the end of the myotomy, intraoperative endoscopy is selectively undertaken to confirm an adequate myotomy has been performed, with the easy passage of the endoscope into the stomach, and to transilluminate the mucosa, checking for defects with air insufflations. The crura are loosely opposed posterior to the esophagus with permanent sutures.

After myotomy, the authors typically perform an antireflux procedure, most commonly a Toupet but selectively a Dor fundoplication. For a Toupet fundoplication, the fundus is brought posterior to the esophagus where it should sit in place without any tendency to retract. The right limb of the fundus is then sutured to the right edge of the esophageal myotomy with three interrupted 2-0 Ethibond sutures (Ethicon, Johnson & Johnson, Calif) placed 1 cm apart and careful avoidance of the anterior vagus nerve. The most superior suture includes a bite of the edge of the hiatus and the fundus and esophageal muscular wall. The left limb of the fundus is then sutured in a similar manner to the left side of the esophageal myotomy with interrupted Ethibond sutures placed 1 cm apart to create a 2-cm fundoplication over 270 degrees. The fundus lateral to the fundoplication is tacked to the undersurface of the diaphragm with an additional 2-0 Ethibond suture to accentuate the antireflux valve and remove any residual drag on the repair sutures.

For a Dor fundoplication, the authors use interrupted sutures to fix the posterior wall of the left anterior fundus to the esophagus to the left of the myotomy and to the left crus of the diaphragm. The leading edge of the fundus is then positioned anteriorly to the esophagus overlying the myotomy and is sutured to the right side of the esophagus to the right of the myotomy, with separate sutures placed into the right crus of the diaphragm.

FURTHER DISCUSSION

Transthoracic Versus Transabdominal

Open transthoracic and transabdominal myotomy have similar outcomes in terms of postoperative complications, palliation of dysphagia, and symptom control for the treatment of achalasia. However, transabdominal esophageal myotomy is associated with less physiologic impact than a thoracotomy and, when combined with an antireflux procedure, produces less postoperative reflux.

Open Versus Laparoscopic Versus Thoracoscopic

In comparison of laparoscopic and thoracoscopic approaches with myotomy, the outcomes of the laparoscopic approach are superior, particularly with respect to symptomatic improvement. Laparoscopic myotomy has several advantages over an open approach, including reduced postoperative pain, length of hospital stay, and pulmonary dysfunction and shorter return to normal activities. The authors advocate the preferential use of laparoscopic esophageal myotomy with partial fundoplication for the treatment of achalasia, where a contraindication to laparoscopic surgery does not exist.

Length of Myotomy

Palliation of dysphagia remains the most important treatment outcome after surgical myotomy for achalasia; for this reason, a longer myotomy is considered the most appropriate approach in all cases. The acceptable length for myotomy ranges from 4 to 8 cm on the esophageal aspect and from 2 to 3 cm on the stomach. Within this range, symptomatic improvement and lower esophageal resting pressure reduction are equivalent.

Concomitant Antireflux Procedure: Nissen/Toupet/Dor

The authors advocate the use of a partial fundoplication procedure (Toupet or Dor) as a routine addition to the surgical esophageal myotomy for the treatment of achalasia. The rate of dysphagia improvement is not affected; however, the incidence rate of gastroesophageal reflux symptoms is greater when an antireflux procedure is not combined with myotomy. Furthermore, poor long-term outcomes associated with surgical myotomy are commonly the result of severe uncontrolled reflux. The authors preferentially use a Toupet or Dor fundoplication over a 360-degree Nissen fundoplication. Controversy exists as to whether a full 360-degree Nissen fundoplication increases the rate of dysphagia compared with an incomplete fundoplication. Currently, no significant difference in short-term clinical outcomes, including dysphagia control and reflux symptoms, has been shown in comparison of Toupet and Dor fundoplications after esophageal myotomy. Potential benefits of Toupet fundoplication include improved long-term reflux control; however, the benefits of Dor fundoplication include less disruption of hiatal anatomy and fundal coverage of the esophageal mucosa after myotomy. The authors use a Toupet reconstruction in most cases for better visualization during the myotomy and the production of a more robust antireflux gastroesophageal valve. There is a hypothetical advantage of using the two limbs of the fundoplication to hold the edges of the myotomy apart. In cases with concern regarding the integrity of the mucosa after myotomy, the authors use a Dor repair to allow fundal coverage of the esophageal mucosa.

Sigmoid Esophagus or Megaesophagus

Sigmoid esophagus is characterized by a widened (>6-cm diameter) and tortuous esophageal body that results in a sigmoid-shaped appearance and a more advanced stage of achalasia. Surgical treatment for sigmoid achalasia has traditionally been esophagectomy because the suggestion was that the dilated tortuous and aperistaltic esophagus would not empty sufficiently to improve dysphagia after myotomy of the LES. More recently, many surgeons have shown successful outcomes with myotomy and Dor fundoplication as the

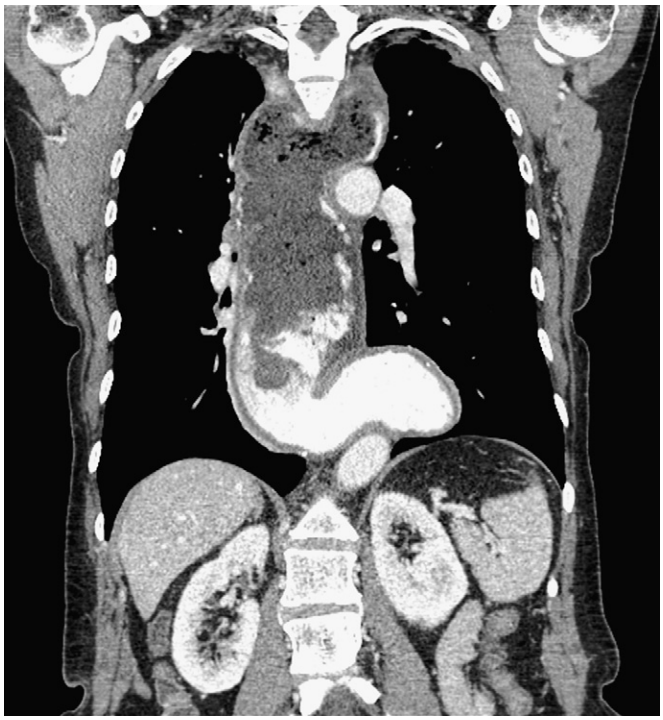

FIGURE 4 Computerized tomographic scan showing severe case of megaesophagus.

treatment of choice, with 92% of patients reporting improvement in dysphagia. The benefits of myotomy in this situation are clear with the avoidance of the morbidity and mortality associated with esophagectomy. However, in certain cases of megaesophagus (Figure 4), myotomy is unlikely to provide adequate relief from dysphagia, and primary esophageal resection is indicated.

Surgical Myotomy Versus Endoscopic Treatment

The debate regarding what is the "best" treatment for achalasia remains unresolved in the current literature. The advantages of endoscopic treatment with pneumatic dilation include a less invasive approach and good short-term relief of dysphagia. Many gastroenterologists find a 5% risk of perforation associated with this procedure unacceptable. There is also the well-documented issue of the need for sequential treatments in many patients.

Surgical myotomy when performed laparoscopically has the benefits of good long-term relief of dysphagia and symptom control. The disadvantages are related to the risks of surgery and include bleeding, infection, reflux symptoms, and esophageal perforation (although in the context of surgery, this is typically recognized and addressed at the time of the myotomy). The most recent multicenter randomized control trial comparing surgical myotomy with pneumatic dilation showed equivalent rates of success at 2 years. In spite of this trial showing a total perforation rate of 4%, the authors believe that in experienced hands pneumatic dilation should still remain a treatment option for patients. However, at their center, they are currently offering laparoscopic myotomy and antireflux reconstruction as primary treatment for all appropriate patients.

SUMMARY

Esophageal achalasia is a rare disorder, and treatment approach is dependent on several factors, including patient's severity of symptoms, patient's medical comorbidities and physiologic fitness, and the level of experience of the managing gastroenterologist or surgeon. Centers of excellence that are experienced in managing esophageal motility disorders including achalasia allow specialized gastroenterologists and surgeons to work together to provide the best outcomes for patients with esophageal achalasia.

Disorders of Esophageal Motility

Christopher M. Sciortino, MD, PhD, and Stephen C. Yang, MD

INTRODUCTION

Disorders of esophageal motility can result in major morbidity and decreased quality of life and, in some cases, in an increased risk of cancer and death. Several classes of motility disorders of the esophagus have been described, including primary esophageal motility disorders (Box 1), such as achalasia and the spastic dysmotility disorders (diffuse esophageal spasm), and secondary diseases (Box 2) that affect esophageal motility (scleroderma, diabetes). This chapter describes the types of esophageal motility disorders, their workup, and treatment options. Achalasia will not be discussed, as this disorder is the subject of another chapter in this textbook.

CLASSES OF ESOPHAGEAL MOTILITY DISORDERS

Spastic Dysmotility Disorders

Diffuse Esophageal Spasm

Diffuse esophageal spasm (DES) is a disorder that results from the uncoordinated contraction of the esophagus with subsequent loss of coordinated peristalsis. It is a rare disorder, constituting less than 10% of all motility abnormalities. The etiology is unknown, but similar to achalasia, there may be loss of neuronal activity and secretion of nitric oxide, vasoactive intestinal polypeptide, or both. Familial clustering has been identified in some studies. The most common presenting symptoms of patients with DES are noncardiac chest pain, globus, dysphagia, and modest weight loss. Many patients present after a negative cardiac workup for angina pectoris and thus can be differentiated with nonexertional onset. Dysphagia is usually sporadic, self-limiting, not associated with liquids or solids, and sometimes associated with extreme food temperatures. Although demographic studies are lacking, patients tend to be older (in their 60s or 70s) and may have a significant history of hypertension, anxiety, or psychiatric disorder. Gastroesophageal reflux disease (GERD) is a simultaneous finding in 20% to 50% of patients diagnosed with DES.

DES is diagnosed primarily with esophageal manometry, which demonstrates normal peristalsis with intermittent loss of coordinated contractions primarily in the lower esophagus; the lower esophageal sphincter (LES) functions normally. Some call this *distal* esophageal spasm rather than *diffuse* esophageal spasm. Simultaneous contractions are observed in more than 20% (but less than 100%) of wet swallows. Contractions have normal intensity, and LES tone is typically normal but may be hypertensive in some cases. Because symptoms may occur intermittently, diagnostic tests such as barium swallow may fail to diagnose DES; however, video esophagrams may be diagnostic in up to 50% of cases. Static pictures can depict the typical "corkscrew" or "rosary bead" pattern. Esophagogastroduodenoscopy usually fails to reveal any mucosal or structural abnormalities.

Treatment of DES ranges from reassurance to surgical myotomy. Initial treatment includes workup for possible underlying contributing factors (e.g., GERD, medications, stress). Patients frequently present after extensive cardiac workup. Depending on symptoms at presentation, patients may warrant a workup for GERD, including pH monitoring and endoscopic evaluation. Those patients found to have GERD should be treated and their symptoms tracked for reduction/resolution. Patients with ongoing symptoms may require a trial of medical therapy, including nitrates, calcium channel blockers, antidepressants, or sildenafil. Botulinum toxin as a treatment for DES has been described as having variable results.

Patients refractory to these therapies and who have intolerable symptoms may seek surgical consultation for a long esophageal myotomy. Results are optimal when effective contractions measured by manometry are below 30%. Surgery is aimed at eliminating the functional obstruction caused by the simultaneous muscular contractions, thereby relieving the propulsive contractions. The three issues that dictate the operative intervention include the extent of the myotomy, the need for a fundoplication, and the operative technique (right vs left, open vs minimally invasive). Length of the myotomy is based on manometry results regarding the proximal and distal extent. If it is carried through the esophagogastric junction (EGJ), fundoplication is considered, especially in patients with a history of GERD. Laparoscopic, video-assisted thoracic surgery (VATS), and robotic techniques are currently used to perform the myotomy. The authors prefer to approach it by VATS through the left chest. A synopsis of these variations is outlined in Table 1.

Single lung ventilation with a double-lumen tube or bronchial blocker is needed if the myotomy is done through the chest. The flexible esophagoscope or a Maloney dilator is left in place to help the esophageal myotomy dissection. Three or four port sites are placed along the fifth and eighth intercostal spaces along the anterior and posterior axillary lines. The inferior pulmonary ligament is mobilized. An area on the lateral lower side of the esophagus is picked to begin the site for the myotomy. The hook cautery or scissors is used to begin the dissection through the outer and inner circular muscle fibers until the mucosal layer is reached. Gentle dissection of the mucosa is performed to tease it off the muscle as the cautery is advanced superiorly and inferiorly to divide the muscle layers up to the desired level. The muscle is dissected for 50% of the circumference of the esophagus to prevent recurrence (Figure 1). Care is taken not to injure the vagus nerve. At the end, the esophagus is insufflated with the scope in place to check for violations of the mucosa. On the left side, the myotomy is carried up to the level of the aortic arch and 1 cm short of the hiatus if the EGJ is left intact; on the right, access can be obtained up to the level of the thoracic inlet. If a fundoplication is needed or if the myotomy is carried down across the EGJ (2 cm), then a modified Belsey fundoplication is performed. In this modification (Figure 2), a tongue of the gastric fundus is sutured over the myotomy site for a distance of 4 cm with two lines of sutures in front and in back of the myotomy (as opposed to the traditional three for a Belsey Mark IV fundoplication). After tucking the cardia under the diaphragmatic crura, the top sutures are passed through the diaphragm and tied.

Published results reveal resolution of symptoms and improved quality of life in approximately 70% of patients. Counseling patients about the potential for modest improvement of symptoms after myotomy is important to manage expectations given somewhat modest outcomes. Surgery for DES is somewhat controversial; results are not as good as with myotomy for achalasia.

Hypercontracting Esophagus (Nutcracker Esophagus)

Hypercontracting esophagus, also known as nutcracker esophagus, is a disorder resulting from increased intensity of esophageal contraction rather than disordered contraction. It is less common than DES,

BOX 1: Primary motility disorders of the esophagus

Hypertensive LES
Classic achalasia
Diffuse esophageal spasm
Atypical disorders of LES relaxation
Uncoordinated contraction

Hypercontraction
Hypertensive esophagus (nutcracker esophagus)
Hypertensive LES

Hypocontraction
Ineffective esophageal motility
Hypotensive LES

LES, Lower esophageal motility.

BOX 2: Secondary motility disorders of the esophagus

Malignancy (Pseudoachalasia)
Primary EGJ tumors (adenocarcinoma, squamous, lymphoma)
Remote EGJ tumors (lung, lymphoma, sarcoma, mesothelioma, gastric, liver)

Rheumatologic Disorders
Progressive systemic sclerosis (scleroderma)
Systemic lupus erythematosus
Mixed connective tissue disease
Raynaud's phenomenon
Sjögren's syndrome
Polymyositis

Infectious Diseases
Human immunodeficiency virus
Chagas' disease
Candida
Cytomegalovirus
Herpes simplex virus

Infiltrative Disorders
Amyloidosis
Leiomyomatosis
Eosinophilic esophagitis
Sarcoidosis

Miscellaneous
Congenital diaphragmatic web
Diabetes mellitus
Iatrogenic (postvagotomy, post–gastric banding)
Multiple endocrine neoplasia (type 2B)

EGJ, Esophagogastric junction.

Length of myotomy	Need for fundoplication	Procedure
Aortic arch → hiatus	No	L VATS or open thoracotomy, myotomy
Thoracic inlet → hiatus	No	R VATS or open thoracotomy, myotomy
Through EGJ	Yes	L VATS or open thoracotomy, myotomy with Belsey, or laparoscopic myotomy with partial fundoplication
Thoracic only	Yes	L VATS or open thoracotomy, myotomy with Belsey, or laparoscopic myotomy with partial fundoplication

EGJ, Esophagogastric junction; *L,* left; *R,* right; *VATS,* video-assisted thoracic surgery.

and GERD is less strongly associated with this disorder. The etiology is also unidentified, but like DES, some patients have been found to transition to classic achalasia and thus may be part of the clinical spectrum that eventually leads up to it. Pain is the usual presenting symptom with dysphagia a less common complaint. Compared to the other motility disorders, it has the poorest correlation with symptoms, yet it has the highest correlation with psychological issues. There is significant symptom overlap with irritable bowel syndrome, and up to 30% have a psychiatric illness.

Barium studies are usually normal, and nuclear emptying studies often produce conflicting results. Manometric findings are defined by either high-pressure contractions (>180 mm Hg) or swallow duration of greater than 6 seconds. The diagnosis requires the contraction amplitude to be greater than 2 standard deviations (SD) above normal, with all contractions peristaltic. The peristaltic wave progresses normally, and the LES has normal relaxation characteristics. Risk factor modification and reassurance are again the initial steps in treatment. Patients should be evaluated for GERD and treated if necessary. Medical management is similar to DES, relying primarily on calcium channel blockers. Dilation is not effective. Surgery is rarely used to treat hypercontracting esophagus because the outcomes are inconsistent at best. A long thoracic myotomy (as described for DES), although relieving the pain associated with contractions, may actually worsen the dysphagia.

Hypertensive Lower Esophageal Sphincter

Patients with hypertensive LES typically have symptoms of noncardiac chest pain, dysphagia, globus, and regurgitation. Hypertensive LES can be diagnosed concomitantly with nutcracker esophagus and GERD, but it is dissimilar in character to the reported occasional dysphagia. Manometric findings include normal peristaltic progression and LES pressure greater than the 95th percentile of normal (>45 mm Hg). Unlike achalasia, there is high residual pressure, and 50% have high-amplitude peristaltic contractions in the distal esophagus. Esophageal contrast studies show only a hiatal hernia in half of all patients.

Treatment is primarily aimed at controlling the primary symptoms of GERD with proton pump inhibitors and using interventions directed at the LES, including pharmacologic (e.g., Botox injection), and endoscopic (bougienage or balloon dilatation). Medical treatment with nitrates or calcium channel blockers is typically very effective. Surgery is reserved for patients with refractory symptoms. Those with isolated hypertensive LES should have a myotomy similar to achalasia and partial fundoplication. If GERD is present, then a Nissen fundoplication only should be performed. The approach can be done either by thoracoscopic, laparoscopic, or robotic approach. These techniques are described in other chapters.

Ineffective Motility Disorder

Hypocontracting, or ineffective, esophageal motility is a rare disorder, in which patients experience mild dysphagia or acid reflux but no chest pain. This condition is defined by the manometric findings of either nontransmitted or low-amplitude peristaltic contractions (<30 mm Hg) in more than 30% of wet swallows and a decreased LES tone. Contractions can also be characterized as spontaneous, prolonged duration (>6 seconds), retrograde, or triple-peaked. Peristaltic waves, if detectable, may be unable to clear barium from the esophagus. Some patients have associated GERD, but this is not universal. Prokinetic agents (metoclopramide) and/or GERD treatment may reduce symptoms, and surgery is rarely indicated.

Secondary Esophageal Motility Disorders

There is a wide spectrum of medical diseases that can have secondary consequences on the esophagus; these diseases are outlined in Box 2. They can be categorized based on associated rheumatologic diseases, infiltrative processes, infectious etiologies, or other, less common entities. Pseudoachalasia will not be covered.

Two connective tissue diseases that have frequent esophageal manifestations are progressive systemic sclerosis (PSS) or scleroderma and systemic lupus erythematosus (SLE). Both are autoimmune diseases that target the distal third of the esophagus. Esophageal symptoms occur in 50% to 90% of patients with PSS and 1% to 25% of patients with SLE, which can coexist with Raynaud's phenomena.

Many patients with PSS will have the complete manifestations of the CREST syndrome (*c*alcinosis, *R*aynaud's phenomenon, *e*sophageal dysfunction, *s*clerodactyly, and *t*elangiectasia), and demonstrate dysfunction of the distal esophagus and EGJ. Consequently, dysphagia and reflux are the two most common symptoms. Although the etiology of esophageal dysmotility is not clear, inflammation of esophageal smooth muscle or ischemic vascular changes to Auerbach's plexus have been proposed. Ultimately, all esophageal function studies are used in the evaluation. Video esophagram reveals dilation and marked aperistalsis in the distal one third of the esophagus. Twenty-four-hour pH probe monitoring will document reflux in up to 80% of patients, but not all symptoms will correlate with pathologic reflux. Manometric studies may demonstrate low-amplitude or absent peristalsis and reduced LES tone. Finally, endoscopy may reveal an asymptomatic esophageal stricture, infection (esophageal candidiasis), and/or ulceration, as medications may also contribute to symptoms.

Common to the rest of the miscellaneous diseases, patients with secondary esophageal motility disorders typically have dysphasia and mild pain usually related to the GERD. Management focuses on treatment of the underlying diseases. Infectious etiologies have a wide spectrum of effect on esophageal motility (usually hypocontractions) and on the LES (usually hypertension and incomplete relaxation). Inflammatory diseases such as eosinophilic esophagitis usually result in spasms or hypercontractility of the esophageal body. Neuropathic causes such as in advanced diabetes mellitus result in the obvious consequences of reduced amplitude in the upper and lower esophageal sphincters, slow transit time, and loss of peristaltic waves.

Overall therapy for patients with secondary esophageal motility disorders is directed at the underlying medical cause and conservative management of their swallowing symptoms. Since GERD is usually the root cause for the majority of symptoms, aggressive medical therapies and lifestyle changes are first instituted. Gastroparesis can be addressed pharmacologically. Surgical intervention is rarely indicated and thus is reserved for failure of medical therapies or when patients have end-stage disease, stricture, or perforation when salvage procedures are needed.

Patients who develop GERD should be considered for antireflux surgery to prevent stricture formation. Laparoscopic approaches are clearly the preferred route, given the presence of medical comorbidities, and are described in the Gastroesophageal Reflux Disease chapter. In planning the appropriate operative approach, other variables that should be taken into account include the presence of a distal stricture or shortened esophagus, aperistalsis or dilation of the distal esophagus, delayed gastric emptying, Barrett's metaplasia, and severity of bile reflux. Timing of the procedure is also a critical decision point, for input from a multidisciplinary team of those involved in the patient's care must figure in future interventions such as transplantation for associated organ failure and the use of higher dose immunosuppressive agents.

In deciding the appropriate operative intervention, one must achieve a delicate balance between dysphagia (too tight a wrap) and reflux (too loose). A partial fundoplication (Toupet) is preferred to minimize the risk of postoperative dysphagia secondary to inefficient peristalsis against a complete wrap (Nissen). Surgical results for the former are quite satisfactory, as the lower risk of progressive gastrointestinal symptoms (dysphagia, gas bloat) are balanced by the higher recurrence of reflux with a less than circumferential wrap (e.g., Toupet wrap). Long-term results in patients with PSS have shown a

benefit combining an esophageal lengthening procedure (Collis gastroplasty) with fundoplication. However, patients continue to have symptoms of reflux (25%) and dysphagia (40%). Thus, our preference is not to add a gastroplasty because of the associated risk of leaks, given the common presence of steroid use, and to perform only a partial 270-degree wrap. Results of preoperative studies on gastric emptying suggest that pyloromyotomy may be needed. Radical procedures such as biliary diversion and esophagectomy are reserved for palliative situations when carcinoma cannot be excluded, the presence of an untreatable stricture, or acute events such as perforation or bleeding.

The Management of Esophageal Carcinoma

Michal J. Lada, MD, and Jeffrey H. Peters, MD

Over the past several decades, there has been an unprecedented shift in the relative prevalence of the two primary histologic types of esophageal carcinoma. Historically, esophageal squamous cell carcinoma (SCC), largely related to tobacco and alcohol use, has accounted for more than 90% of esophageal malignancies. In the 1970s, the incidence of esophageal adenocarcinoma began rising steadily, at a relative rate unparalleled by any other cancer. Adenocarcinoma now makes up the predominant histologic type in most Western countries. Reasons for this dramatic change are not clear, although the increasing prevalence of both obesity and gastroesophageal reflux disease almost certainly plays a leading role. National Cancer Institute data indicate that 17,460 new cases of tubular esophageal cancer (13,950 male and 3510 female) and 15,070 deaths will occur in the United States in 2012. The prevalence nearly doubles when cancers of the gastric cardia are included.

ASSESSMENT OF THE EXTENT OF DISEASE AND SELECTION OF TREATMENT OPTIONS

Although the majority of patients with esophageal carcinoma have symptoms at the time of presentation, an important minority (15%-25% in most referral centers) are identified via surveillance of a known Barrett's esophagus or endoscopic evaluation for nonspecific symptoms and anemia. These patients form a group that has a high likelihood of intramucosal and early-stage disease and thus are more curable than those who present with dysphagia. In the majority of patients who present with symptoms, dysphagia and weight loss are the two most common presenting complaints. Other less common presenting symptoms include worsening gastroesophageal reflux disease symptoms (heartburn or regurgitation), chest pain, anorexia, and cough. Approximately two thirds of patients present with resectable disease, of which a majority (50%-60%) will have nodal metastases at the time of diagnosis. Metastases most often spread to regional, celiac, and supraclavicular lymph nodes as well as the liver, lungs, and adrenal glands. A multidisciplinary approach including surgery, gastroenterology, medical oncology, radiation oncology, and pathology is important to optimize stage-specific survival.

Initial staging includes upper endoscopy to assess the location, length, and circumference of the tumor; the extent of gastric cardia involvement, if any; and the suitability of the stomach for reconstruction. This is followed by positron emission tomography combined with a computed tomographic scan (PET-CT), possibly endoscopic ultrasound, and increasingly molecular staging such as HER-2 receptor testing. The seventh edition American Joint Commitee on Cancer (AJCC 2010) TNM classification for esophageal carcinoma is shown in Table 1. Recent data have suggested different outcomes for adenocarcinoma and SCC, which is now reflected in separate AJCC staging systems for each histologic type (Table 2). Other important changes also occurred in the seventh edition staging, including defining gastroesophageal junction tumors as esophageal and changing nodal classification from location to number of nodes.

Endoscopic ultrasound (EUS) may be a useful modality in the assessment of locoregional disease. Its accuracy is better in advanced compared to superficial disease; the latter is better staged with endoscopic mucosal resection (EMR) when possible. Combined with fine-needle aspiration (FNA), EUS provides the most accurate staging modality to prove regional lymph node involvement. T-stage accuracy is approximately 85%. Lymph nodes appear as hypoechoic, well-circumscribed areas greater than 10 mm in the area of the tumor. Lymph node FNA is possible if the needle tract is not obstructed by the tumor itself. For stenotic cancers, it may be difficult to pass the EUS probe distally. Patients with small (<1-1.5 cm) endoscopically visible lesions or identifiable areas should undergo EMR, which allows for accurate histologic distinction between mucosal (T1a) and submucosal (T1b) tumors. The former may be definitively treated with endoscopic methods, while submucosal lesions are best treated via surgical resection. This is due to the fact that esophageal lymphatics are located in the submucosa, leading to a low prevalence of nodal metastases in mucosal lesions. T1b lesions that penetrate the muscularis mucosa carry a potential for metastatic nodes of approximately 30%, rendering them more appropriate for esophagectomy.

An 18F-fluorodeoxyglucose positron emission tomography (PET) scan in combination with a CT scan is the single best systemic staging modality. This combination of PET-CT allows for optimization of the relationship of anatomic abnormalities to hypermetabolic areas (Figure 1). The magnitude of hypermetabolism, measured as the standard uptake value (SUV_{max}) has also been reported to have prognostic significance.

The identification of cancer-related biomarkers is becoming an increasingly important area of esophageal cancer treatment. The

TABLE 1: 2010 AJCC TNM classifications

Primary tumor (T)	
TX	Primary tumor cannot be assessed.
T0	No evidence of primary tumor.
Tis	High-grade dysplasia.
T1	Tumor invades lamina propria, muscularis mucosae, or submucosa.
T1a	Tumor invades lamina propria or muscularis mucosae.
T1b	Tumor invades submucosa.
T2	Tumor invades muscularis propria.
T3	Tumor invades adventitia.
T4	Tumor invades adjacent structures.
T4a	Resectable tumor invading pleura, pericardium, or diaphragm.
T4b	Unresectable tumor invading other adjacent structures, such as aorta, vertebral body, trachea, etc.
Regional lymph nodes (N)	
NX	Regional lymph nodes cannot be assessed.
N0	No regional lymph node metastasis.
N1	Metastases in 1 or 2 regional lymph nodes.
N2	Metastases in 3 to 6 regional lymph nodes.
N3	Metastases in 7 or more regional lymph nodes. Regional lymph node is defined as any periesophageal lymph node from the cervical lymph nodes to the celiac lymph nodes.
Distant metastasis (M)	
M0	No distant metastasis.
M1	Distant metastasis.
Histologic grade	
G1	Well differentiated.
G2	Moderately differentiated.
G3	Poorly differentiated.
G4	Undifferentiated.
Cancer location	
Upper Thoracic	20-25 cm from the incisors.
Middle Thoracic	>25-30 cm from the incisors.
Lower Thoracic	>30-40 cm from the incisors.
Esophagogastric Junction	Includes cancers whose epicenter is in the distal thoracic esophagus, esophagogastric junction, or the proximal 5 cm of the stomach that extends into the esophagogastric junction or distal thoracic esophagus.

immunohistochemical protein expression profile of markers, including Her2, p53, c-myc, Notch, and EGFR, has been analyzed with respect to esophageal carcinogenesis. Current evidence suggests that Her2 overexpression correlates with cancer progression and may be amenable to therapeutic intervention via medications such as trastuzumab. Although preliminary results are promising, extensive work remains to be done to formulate new treatment regimens or interventions based on a patient's genetic profile.

Despite all available diagnostic modalities—particularly esophagogastroduodenoscopy (EGD), EUS, and PET-CT—the clinical staging of esophageal adenocarcinoma is far from ideal. The TNM staging accuracy and the sensitivity and specificity of any individual modality have been widely reported. It is accepted that combinations of diagnostic modalities offer greater TNM clinical staging accuracy—approximately 80%—compared to the use of any single test. Furthermore, it has been reported that the accuracy of clinical staging significantly increases when the diagnostic tests are performed at a referral center and the results are analyzed by expert radiologists.

Due to the increasing implementation of neoadjuvant therapy in the treatment of esophageal carcinoma in the recent decade, pathologic staging classification has been altered so that it is no longer useful. Current staging systems are based on survival outcomes of patients undergoing esophagectomy alone; therefore, as a result, there is no good staging system as we move forward in 2012.

TREATMENT

Treatment of esophageal cancer, including the type of resection, can and should be individualized. Although far from precise, it is useful clinically to divide patients into those with a high probability of disease limited to the mucosa, those with a high probability of regional disease, and those with likely systemic disease. Among the most significant treatment advances in recent years are the successful management of intramucosal carcinoma with endoscopic therapeutics and the routine use of neoadjuvant multimodal chemoradiotherapy in patients undergoing surgical resection.

Neoadjuvant Chemotherapy and Chemoradiotherapy

Most patients with carcinoma extending beyond the mucosa will be candidates for neoadjuvant therapy. Although controversy remains regarding its use in patients with clinical T1b (submucosal by EMR) node negative (by EUS) tumors, the probability of nodal metastases (15%-25%) and the false negative rate of EUS (25%-40%) provide rationale for neoadjuvant therapy even in these patients. Several randomized trials and meta-analyses have compared various regimens of neoadjuvant chemotherapy only and combined chemoradiotherapy (CRT). Despite these data, a consensus standard remains to be determined. The most recent, and among the best of these, is the Dutch chemotherapy and radiation in esophageal surgery study (CROSS) trial that compared neoadjuvant CRT and surgery to surgery alone. Patients with resectable (T2-3NO-1, M0) tumors received weekly administrations of paclitaxel and carboplatin for 5 weeks with 41.4 Gy of concurrent radiotherapy. The trial included 368 patients, of which 75% had adenocarcinoma and 23% squamous cell cancer. The R0 resection rate was 92% in the CRT arm versus 69% in the surgery alone arm. Twenty-nine percent (47/161) of those undergoing resection after CRT had a pathologic complete response. Five-year survival (47% vs 34%) was significantly improved in the neoadjuvant group (Figure 2).

Preoperative and postoperative chemotherapy alone (epirubicin, cisplatin, and fluorouracil) was compared to surgery in the medical research council adjuvant gastric infusional chemotherapy (MAGIC) trial, which also showed a benefit of neoadjuvant chemotherapy. This UK-based trial included 503 patients randomized to surgery alone or surgery plus 3 cycles of preoperative and postoperative chemotherapy. Survival was significantly better in the group receiving chemotherapy (5-year: 36% vs 23%). Twenty-six percent of the patients

had carcinoma of the lower esophagus or GE junction. Either of these regimens is currently an acceptable option for treatment of patients with resectable esophageal adenocarcinoma, with evidence favoring combined CRT. Neoadjuvant combined chemoradiation utilizing 5-fluorouracil and cisplatin is the current standard for esophageal SCC.

Restaging via upper endoscopy and PET-CT should be performed following neoadjuvant treatment. A significant minority of patients (35%-50%) will achieve a clinical complete response (cCR, defined as endoscopic biopsy and PET-CT negative); therefore, surgical resection is currently recommended because most will have viable tumor identified in the surgical specimen.

Surgical Resection

High Probability of Localized Disease Confined to the Mucosa

Patients with invasive cancer penetrating beyond the basement membrane but limited to the mucosa (not penetrating through the muscularis mucosa; Figure 3), although once rare, currently comprise a significant proportion of patients with esophageal adenocarcinoma. Clinically, intramucosal cancer is characterized by minimal, if any, cancer-related symptoms and known Barrett's esophagus. As such, intramucosal cancer is usually identified via routine surveillance. Endoscopically, the tumors range from flat, nonvisible lesions to small (<1-2 cm), visible nodules. Proof that the neoplasia is confined to the mucosa is best provided by EMR of any and all identifiable areas. Both high-grade dysplasia and intramucosal esophageal adenocarcinoma are amenable to curative treatment via endoscopic intervention, including EMR and radiofrequency mucosal ablation (RFA) (Figure 4). Identifiable lesions are first excised via EMR followed by RFA ablation of the remaining Barrett's esophagus. Although no randomized, controlled trials of EMR versus esophagectomy exist, several case-control studies suggest that most, if not all, patients with intramucosal cancer have similar long-term outcomes with fewer complications following EMR than esophagectomy. Balancing this is the probability of recurrent dysplasia or carcinoma, which has been reported as high as 22%. Endoscopic therapy is often a lifelong process, not a single event. Complications of EMR are infrequent and include bleeding, esophageal perforation, and delayed strictures. The 5-year survival in patients with superficial cancer approaches 90%.

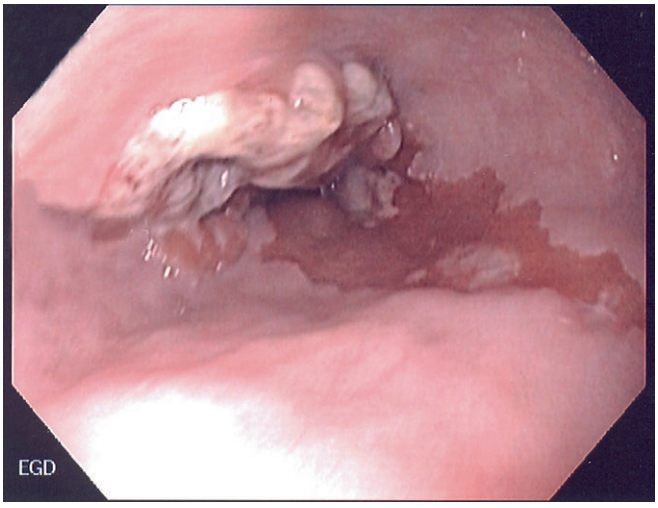

FIGURE 3 Endoscopic appearance of a tumor with a high probability of regional disease. Note a 2-cm to 3-cm 25% circumferential lesion and obvious Barrett's esophagus opposite the tumor. The lesion was identified incidentally via computed tomographic scan.

High Probability of Regional Disease

Patients with regional disease are characterized clinically as those with minimal symptoms, including the absence of weight loss or dysphagia, and small (<2-3 cm) partially circumferential tumors identified endoscopically. Although debated, the preponderance of current evidence suggests that surgical resection ideally consists of en bloc esophagectomy with mediastinal and upper abdominal lymphadenectomy.

High Probability of Systemic Disease

Patients with a high probability of systemic disease are characterized clinically as those with systemic symptoms of cancer (weight loss, pain, anorexia), dysphagia, and large (>3 cm), usually circumferential, tumors on endoscopy. Extended lymphadenectomy is less likely to be of benefit in this group, although given the clinical ambiguities of the classifications, overtreatment is preferable to undertreatment, particularly in young, otherwise healthy patients. Patients with extensive locoregional tumor invasion (stage T4b) and PET-positive metastatic disease benefit from a chemoradiation regimen rather than resection.

Options for Esophageal Resection

A variety of options are available for esophageal resection in patients with esophageal cancer. Each has unique and sometimes important characteristics that allow individualization of surgical decision making. They include transhiatal esophagectomy; combined abdominal and right transthoracic esophagectomy with intrathoracic anastomosis (Ivor Lewis), or resection via combined abdominal, right transthoracic and neck incision with cervical anastomosis (McKeown); and left thoracoabdominal resection. The last two can be accompanied by an extended en bloc lymphadenotomy, and all three have been performed with combined laparoscopic and thoracoscopic minimally invasive techniques.

Transhiatal esophagectomy (THE) is performed via an upper midline laparotomy and a left cervical incision. The patient is positioned supine with arms tucked. Via the upper midline laparotomy, the left lateral segment of the liver is mobilized and retracted to the patient's right, and the esophagus is dissected at the hiatus. After entering the lesser sac, the stomach is mobilized and the short gastric vessels are ligated, with attention to preserving the right gastroepiploic artery and vein as the pedicle for the gastric graft. The left gastric artery and vein are dissected, and celiac nodal tissue is taken with the specimen. A Penrose drain is placed around the esophagus for traction and further mobilization. The lower third of the esophagus is dissected under direct vision via retraction of the hiatus. Both vagal nerves are cut, and the proximal two thirds of the esophagus are dissected bluntly via a hand through the hiatus. The posterior and anterior aspects are dissected first, followed by the right and left lateral portions. A 4-cm left-sided cervical incision is made paralleling the anterior border of the sternocleidomastoid muscle (SCM). After the SCM and carotid sheath are retracted laterally, the cervical esophagus is dissected. A Penrose drain is placed around the cervical esophagus to aid in further dissection along the esophageal wall. With traction on both the abdominal and cervical esophageal segments, final dissection of the thoracic esophagus is performed from both directions. The mobilized esophagus is divided, leaving a 3- to 4-cm cervical esophageal remnant, and the specimen is brought out of the laparotomy incision.

The stomach is divided in a vertical fashion via several firings of a 75-mm GIA stapler, taking a generous portion of the lesser curve with the specimen. Maintaining orientation, the gastric conduit is

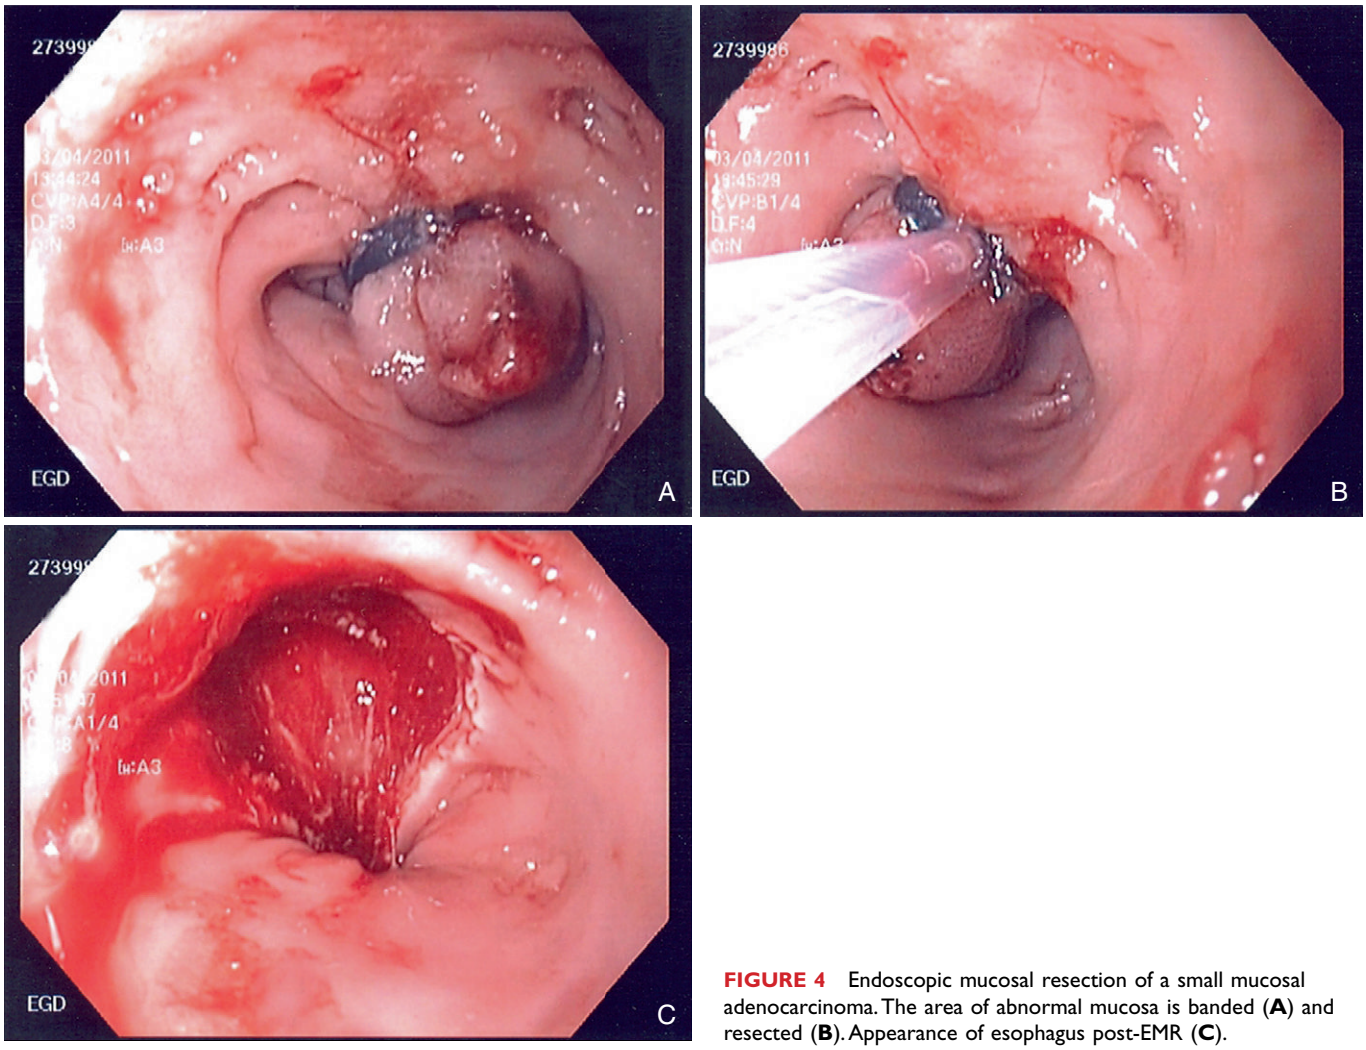

FIGURE 4 Endoscopic mucosal resection of a small mucosal adenocarcinoma. The area of abnormal mucosa is banded (**A**) and resected (**B**). Appearance of esophagus post-EMR (**C**).

sutured to a chest tube and is passed though the thorax to the cervical stump. A stapled or hand-sewn anastomosis is then performed via the cervical approach. A nasogastric tube is placed, and a J-tube is left in place for postoperative nutrition. The limitations of THE include a limited thoracic lymph node dissection and lack of direct visualization in the thoracic cavity. THE is preferable in distal esophageal cancer and is most appropriate in patients with a high likelihood of systemic disease and those with other underlying comorbidities. In patients with transmural tumors above the carina, the authors favor a transthoracic approach.

An Ivor Lewis esophagectomy includes a combined upper midline laparotomy and right thoracotomy and a high intrathoracic anastomosis. After an upper midline laparotomy incision is made, the hiatal dissection and mobilization of the stomach and distal esophagus are performed in the same fashion as in THE. We prefer to divide the stomach prior to pulling it into the chest. Upon completion of the abdominal mobilization, the patient is repositioned and a right posterolateral thoracotomy is made in the fifth intercostal space. The right lung is deflated and retracted, and the distal third of the esophagus is dissected and circled with a Penrose drain. The esophageal dissection can then be taken toward the neck and abdomen. A subcarinal lymphadenectomy is generally performed, and the thoracic duct may be ligated as it enters the thoracic cavity to minimize the risk of a chyle leak. The stomach is pulled into the chest through the hiatus and positioned into the thoracic inlet. An end (esophagus) to side (stomach) anastomosis is performed above the azygous vein. The anastomosis is generally 3 to 5 cm lower when performed through the chest, which has the advantage of allowing better gastric blood supply at the level of the anastomosis and the disadvantage of a higher incidence of postoperative reflux. Ivor Lewis esophagectomy is preferable in patients with middle or distal esophageal tumors.

A three-incision esophagectomy incorporates characteristics of the previous two approaches. The patient is placed in the left lateral decubitus position, and a right posterolateral thoracotomy is made as in the Ivor Lewis technique. The esophagus is mobilized from the diaphragm to the cervical inlet. A chest tube is left in place, and the thorax is closed. The patient is then placed in the supine position. An upper midline laparotomy is performed, and the hiatus, esophagus, and stomach are mobilized as in the previous two techniques. A left cervical incision is made to mobilize the cervical esophagus where it is divided. The gastric conduit is brought up to the cervical incision, where the anastomosis is fashioned. This technique may be preferable for mid- to upper-esophageal cancers because it allows for visual inspection of the thoracic esophagus.

An en bloc lymphadenectomy can be performed via either of the transthoracic approaches. The aim is to resect the esophagus en bloc with all surrounding lymphatic tissue from the carina to the celiac axis. The thoracic resection field is bound by the carina superiorly, esophageal hiatus inferiorly, hilum of lung and pericardium anteriorly, and the descending aorta and spine posteriorly (Figure 5). The pleura is initially incised along the azygous vein. The dissection proceeds toward the aortic adventitia with identification of the thoracic duct, which is ligated as it enters the chest. The left pleura is incised from the left mainstem bronchus to the diaphragm, and the azygous

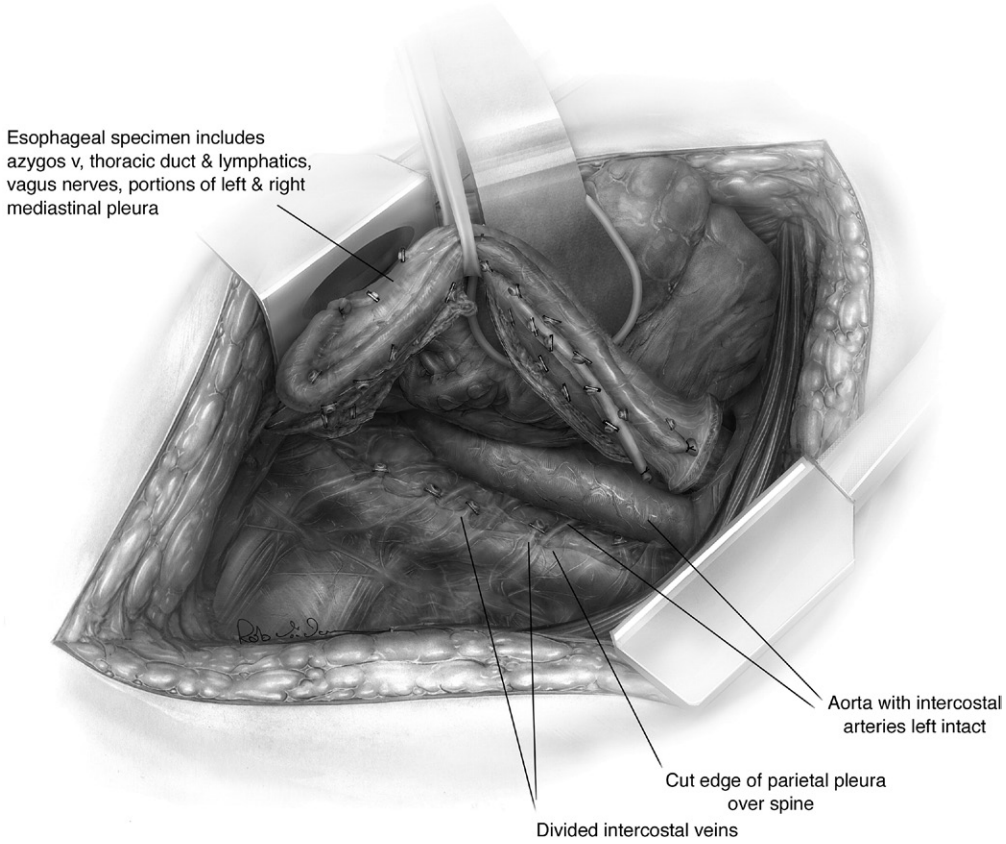

FIGURE 5 Extent of dissection at completion of mediastinal lymphadenectomy and esophageal mobilization during en bloc esophagectomy. *(From Peters JH: En-bloc esophagectomy,* Operative Techniques in General Surgery Journal *8(3):150–155, 2006.)*

vein is divided at the vena cava. The resection specimen contains the subcarinal lymph node basins. An abdominal incision is then made, and a celiac lymph node dissection is also carried out. The abdominal resection field is bound by the hiatus superiorly, pancreas inferiorly, splenic hilum laterally, and the inferior vena cava and common hepatic artery medially. A gastric conduit is constructed, and a thoracic or cervical anastomosis is constructed.

Minimally invasive esophagectomy (MIE) has been slow to be adopted and currently accounts for approximately 15% of esophagectomies performed. This technique can be performed via combinations of laparoscopy and thoracoscopy with the same basic principles of thoracic and abdominal dissection as in open techniques. The most common version begins with placing the patient in a left lateral decubitus position, after which a four-port entry technique is utilized to dissect the esophagus via the right thoracic cavity. The right lung is deflated and retracted, exposing the posterior mediastinum. The esophageal dissection proceeds in a caudad to cephalad direction, with concurrent dissection of the paraesophageal and subcarinal lymph nodes. The azygous vein is ligated with an endoscopic linear stapler to aid in cephalad dissection into the thoracic inlet. After the esophagus is mobilized from the diaphragm to the thoracic inlet, Penrose drains can be tied around the mobilized esophagus distally and proximally to aid in retrieval during the abdominal and cervical phases, respectively. A chest tube is left in the right pleural cavity, and the incisions are closed. The abdominal phase begins with placing the patient in a supine position and involves the placement of five ports. The dissection involves the hiatus, mobilization of the stomach with preservation of the right gastroepiploic artery, and creation of a gastric conduit with several deployments of a linear endoscopic stapler. A cervical anastomosis can then be fashioned via a hand-sewn or stapled technique through a cervical incision. Although a standardized MIE technique has not yet emerged, MIE may be optimal for patients with small tumors and limited nodal involvement.

Outcomes after MIE compared to open resection have been similar as far as mortality and 30-day morbidity; however, MIE may result in less respiratory complications, albeit with higher rates of reintervention and reoperation. The only randomized controlled trial of MIE versus open esophagectomy concluded that the incidence of pulmonary complications is lower in the MIE group (12% vs 34%). The extent of lymphadenectomy in MIE appears to be comparable to open esophagectomy; however, there are no studies to assess the long-term oncologic outcomes of patients undergoing MIE.

Perioperative Care: Morbidity and Mortality of Esophageal Resection

A 7-day to 14-day hospital stay is common following esophagectomy for cancer. Clinical care plans and standardized protocols have been shown to decrease stay and associated costs. Most surgeons, including the authors, continue to place a nasogastric tube for the first 5 to 7 days postoperatively to allow for decompression of the gastric conduit and to minimize aspiration risk, although its benefit has not been shown in prospective, randomized trials. Most also place a feeding jejunostomy at the time of surgery and begin daily tube feed on postoperative day 2 or 3. This allows not only for early enteral feeding but also for complete nutrition and discharge home in the case of an anastomotic leak and prolonged NPO. A clinical assessment of the integrity of the anastomosis is often helpful 5 to 7 days postoperatively. The authors prefer to do this via routine upper endoscopy. This has several advantages over barium contrast studies, including an accurate assessment of the size and location of any potential anastomotic disruption, an assessment of the mucosal blood supply of the upper gastric conduit, and the avoidance of potential oral contrast leakage and contamination. Furthermore, barium studies have been

well documented to have a high prevalence of false negative and occasionally false positive interpretation.

Complications occur in 50% to 75% of patients. Esophagogastric anastomotic leak rates average 15% for a cervical and 5% for an intrathoracic anastomosis. Most patients can and should be managed without the need for transfusion, allowing postoperative hematocrit levels to drift into the low 20s if necessary. Pulmonary complications predominate. Common complications include atrial fibrillation (17%), delirium (13%), pneumonia (9%), urinary infection (6%), ileus (5%), pleural effusion requiring treatment (4%), chyle leak (3%), pulmonary embolism (3%), pneumothorax (3%), and wound infection (2%-3%). Less common are myocardial infarction, deep venous thrombosis, stroke, reoperation for bleeding, recurrent laryngeal nerve paralysis, and sepsis. Esophageal resection is among the surgical procedures in which mortality is significantly affected by both surgeon and hospital volume. In high-volume centers, defined as those performing more than 20 esophagectomies per year, 30-day esophagectomy-related mortality is approximately 2% to 4%. This compares to 15% to 25% mortality in low-volume centers. It is no surprise, however, that many esophagectomies are still being performed in low-volume centers across the United States.

Management of Complications

Optimization of postoperative analgesia and implementation of proper pulmonary toilet are paramount to the prevention of respiratory failure, pneumonia, and reintubation. The interplay of the surgeon, respiratory therapists, and nursing staff is critical in preventing respiratory complications. Should respiratory complications arise, patients are supported with antibiotics and mechanical ventilation, if necessary.

Atrial fibrillation most commonly occurs on postoperative days 2 through 5. Due to the decreased cardiac output and perfusion of the gastric conduit in atrial fibrillation, it is essential to establish rate-control with beta-blockade and amiodarone. In the case of hypotension, occasional cardioversion may be necessary. As a whole, atrial fibrillation usually resolves spontaneously. If medical intervention is utilized, treatment should be maintained for 6 weeks.

An anastomotic leak is usually heralded by new onset fever, tachycardia, and increasing leukocytosis around postoperative days 5 through 7. It is of utmost importance to assess the surgical drains daily and to identify new pleural effusions on chest x-ray. Should a leak arise, it is managed by early broad-spectrum antibiotics (piperacillin/tazobactam plus or minus vancomycin), NPO, and appropriate drainage if there is a collection either via chest tube or by opening the cervical wound. A determination of the size and location of the leak can be established via EGD, and reassessment should be done on a weekly basis. If the leak is large with systemic compromise, the placement of a plastic anastomotic stent may be utilized. Anastomotic leaks that are well managed are not as lethal as in the past, and many can be managed without ICU transfer if anticipated and treated early.

Chyle leaks are most often identified by milky drain output. The management of a chyle leak depends largely on the volume and duration of the leak. As a general rule, drain outputs of less than 500 mL per day that are trending downward can be managed expectantly with NPO status and total parenteral nutrition. Chyle leaks of greater than 1 L per day with continued high output should be addressed surgically with exploration of the thoracic cavity either through a minimally invasive or open approach, with the goal to ligate the thoracic duct at its entrance into the thoracic cavity at the level of the diaphragm.

Survival

Five-year survival after esophagectomy alone is well documented to average 25% to 30%. This can be improved to 40% to 50% with the combination of neoadjuvant therapy and selective use of en bloc lymphadenectomy. Both a higher number of removed nodes and the use of en bloc resection have been shown to be independent predictors of improved survival. Stage-specific survival is shown in Figure 6. Overall, outcomes are better after neoadjuvant chemoradiotherapy, which seems in large part due to increasing R0 resection rates to approximately 95%. Most recurrences occur within 12 to 18 months, and more than 90% by 3 years. Surveillance after treatment should include clinical follow-up every 3 to 4 months for the first 2 years, every 6 months up to 5 years, and then annually. Blood sampling and repeat imaging are utilized as clinically indicated. CT is the preferred imaging modality for detecting recurrence after esophagectomy.

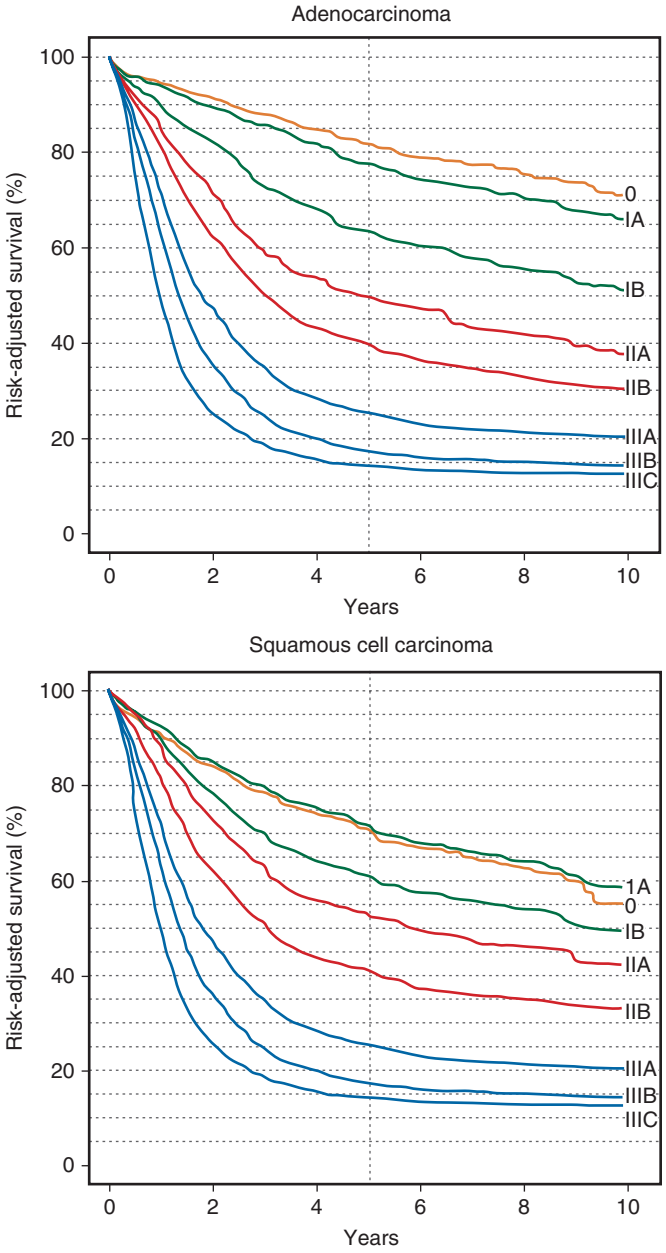

FIGURE 6 Risk-adjusted survival curves for adenocarcinoma and squamous cell carcinoma. *(Adapted from* AJCC cancer staging manual, *ed 7, 2010.)*

Functional Outcomes

Despite a wide range of postsurgical recovery time, functional outcomes after esophagectomy are generally good. Most patients are eventually either asymptomatic or have minor symptoms that do not require intervention. Less than 50% have dysphagia, regurgitation, or other gastrointestinal symptoms that may require intervention. Patients who survive more than 2 years regain their preop quality of life (QOL) within 6 to 9 months. In contrast, most patients who die within 2 years never regain their preop QOL.

CONCLUSIONS

The treatment paradigms of both esophageal adenocarcinoma and SCC currently include multimodal therapy tailored to each patient's specific clinical circumstances. Patients with early-stage adenocarcinoma (T1a, intramucosal) are ideally treated with endoscopic resection rather than traditional esophagectomy. Patients with T1b to T4a disease benefit from combinations of neoadjuvant and adjuvant chemotherapy and CRT in addition to surgical resection. Patients with T4b staging do not benefit from resection and are palliated with systemic chemotherapy often in combination with other procedures such as esophageal stenting. With the increasing incidence of esophageal adenocarcinoma, current and future efforts must be focused on optimizing treatment regimens to optimize survival in patients with this all too lethal disease.

Neoadjuvant and Adjuvant Therapy of Esophageal Cancer

Nabil P. Rizk, MD

INTRODUCTION

A few skeptics still remain regarding the benefits of multimodality therapy in esophageal cancer. However, with recent advances in the understanding of the disease (including a new staging system, better clinical staging capabilities, better algorithms for combined chemotherapy and radiation, and better tolerated therapeutic options) and the culmination of the recent publication of the Chemoradiotherapy for Oesophageal Cancer Followed by Surgery Study (CROSS) Group trial in which many of these new developments are accounted for, most investigators now agree that a subset of patients with esophageal cancer benefits from multimodality therapy. This is a marked departure from a previous era in which evidence cited as support for multimodality therapy was scarce and in which reliance on meta-analyses of flawed data was necessary to support the approach. Our current, more nuanced understanding of the treatment of esophageal cancer incorporates a better appreciation of the different stages of disease and the variable outcomes of the different histology. Consequently, although in the past all esophageal cancers were treated uniformly, current standards of care represent a marked evolution in treatment and outcomes. In the present era, a near consensus exists that early stage esophageal cancers (T1aN0 tumors) are most appropriately treated with either endoscopic means or surgery alone and that the only tumors considered appropriate for multimodality therapy are those which are *local-regionally advanced*. In this chapter, part I provides a summary of the patients whose conditions are appropriate for multimodality therapy; part II discusses various aspects of multimodality therapy, including what is commonly accepted, what remains controversial, and what is unknown.

PART I: DEFINITION OF LOCAL-REGIONAL ADVANCED ESOPHAGEAL CANCER

Patients with local-regional advanced esophageal cancer are candidates for multimodality therapy. Local-regional advanced esophageal cancer includes T2-T4 tumors and tumors with nodal disease (N1-N2) that are M0. In these patients, positron emission tomography (PET scan) is considered to be the gold standard for exclusion of metastatic disease, and endoscopic ultrasound scan (EUS) is considered to be the gold standard for evaluation of depth of disease. Nodal status, both the presence and the number of nodes, is the least predictable of the staging variables.

Clinical T1 Tumors

The recently updated American Joint Committee on Cancer (AJCC) system for esophageal cancer recognizes but does not distinguish between superficial (T1a) and deep (T1b) T1 tumors. T1a tumors by definition invade the mucosa only; T1b tumors invade into the submucosa. Although the depth of invasion in T1 tumors has implications regarding the possibility of successful endoscopic management, an equally important distinction is the potential for nodal metastases; namely, T1a and superficial T1b tumors (<50 of the submucosa invaded) rarely metastasize to regional lymph nodes, and deep T1b tumors (>50% of the submucosa invasion) can metastasize to

regional lymph nodes more than 40% of the time. The clinical implication of this early propensity for development of regional nodal disease is that T1b tumors are often understaged clinically, both because EUS is not accurate at distinguishing T1a and superficial T1b tumors from deep T1b tumors and because nodal disease is not accurately detected in T1 tumors with standard EUS and PET techniques. Less commonly used adjuncts to these two studies, EUS fine needle aspiration (FNA) and the PET maximal standard uptake value (SUV-max) of the primary tumor, have both been shown to increase the accuracy of detection of nodal disease. In summary, a reasonable approach to clinical T1 tumors is an attempt of an endoscopic mucosal resection as a possible therapeutic or diagnostic modality; if the deep pathologic margin invades the submucosa, with or without an involved deep margin, the possibility exists that this tumor represents a "deep" T1b tumor with a reasonable potential for regional nodal involvement. In this situation, additional efforts should be made to establish nodal disease, including the use of PET SUV-max and EUS FNA. If nodal disease is confirmed with reasonable certainty, these patients should be considered to have local-regionally advanced disease and should receive multimodality therapy.

Clinical T2 Tumors

Pathologic T2 tumors treated with surgery alone are associated with poor long-term survival and have a high likelihood of nodal disease; therefore, all of these tumors should be considered for multimodality therapy. Clinical establishment of whether a patient has a pathologic T2 tumor remains a challenge, however. Although EUS is the only means of establishing depth of invasion with any accuracy, T2 tumors are commonly overstaged and most frequently pathologically are deep T1b tumors. Less frequently, these tumors are in fact T3 tumors. One clinical correlate that is helpful in deciding whether patients are overstaged or understaged with EUS T2 is the presence of dysphagia; T1b tumors are rarely associated with dysphagia, whereas T2 and T3 tumors frequently are. In summary, if a patient presents with a EUS T2 tumor without dysphagia, then the workup should proceed as for a T1 tumor. If the patient has dysphagia, then multimodality therapy should be considered.

Clinical T3 Tumors

Diagnosis of clinical T3 tumors is most reliably done with EUS with a high level of confidence. Establishing nodal status is less relevant in these tumors because invariably these tumors are also node positive (if an adequate lymphadenectomy is done).

Clinical N1-N2 Tumors

Establishment of nodal disease is most relevant in more superficial tumors because in these tumors the option of a local therapy is available. In patients with EUS T1b tumors and EUS T2 tumors without dysphagia, the nodal status must be established as definitively as possible before resection. EUS appearance is unreliable, especially in superficial tumors. Likewise, visual identification of nodal disease with PET and computed tomographic (CT) scan is unreliable in more superficial esophageal cancers. The most accurate diagnostic tool is EUS-guided FNA. PET SUV-max is also a useful tool when EUS FNA is unavailable or when no nodes are identified. Some studies indicate that a low PET SUV-max of the primary tumor is rarely associated with a nodal disease.

Restaging After Preoperative Therapy

After completion of preoperative therapy, restaging of patients before surgery usually incorporates a CT scan to evaluate the possibility of locally invasive and potentially unresectable disease and a PET scan to exclude metastatic disease. Repeat esophagoscopy should be used to evaluate the endoluminal extent of disease; it is not, however, predictive of the presence of persistent disease. Repeat EUS likewise has minimal utility in restaging of patients.

PART II: MANAGEMENT OF LOCAL-REGIONAL ADVANCED ESOPHAGEAL CANCERS

Near Consensus

Multimodality Therapy

Many previously cited publications that were used to either support or refute the advantages of multimodality therapy or surgery alone for esophageal cancer resulted from multiinstitutional prospective randomized trials. For various reasons, many of these trials have been rendered irrelevant with the current approach to staging and treating the disease. Most of these studies did not have the availability of current standard staging studies, including PET scan, EUS, or even CT scan. Furthermore, these trials often treated an undefined number of patients with early stage disease, with the presence of any non-metastatic disease as the sole trial cancer-related entry criteria (Tables 1 and 2). The potential benefit of adjuvant therapy can only be expected in: (1) patients at risk for metastatic disease, which is unlikely in T1a and in superficial T1b tumors; and (2) patients without overt metastatic disease, which was probably underestimated in a significant number of patients given the limited clinical staging capabilities of the era. Thus, that these older studies did not reliably inform management is not surprising. Another important limitation in these studies includes wide variations in the administration of multimodality therapy. Concurrent chemoradiation is now accepted to be better than sequential chemotherapy and radiation, and some of the newer chemotherapy agents are considered at least equally effective but more tolerable than prior regimens. Because of these many limitations, many of the relevant advances made to the current understanding of multimodality therapy resulted partly from single-institution phase II trials. These trials were able to consistently innovate and evolve as newer technologies and therapies became available. Likewise, over time, large institutional databases became available and were able to validate certain treatment approaches. Ultimately, information from such trials and datasets culminated in several recent prospective clinical trials, which have significantly increased the understanding of the management of local-regional advanced esophageal cancer.

Currently, a near consensus exists that surgery alone for local-regional advanced esophageal cancer is inadequate. Furthermore, although little data directly compare chemotherapy alone before surgery with chemoradiation before surgery, the relevant studies that individually evaluate each approach tend to favor chemoradiation over chemotherapy only; certainly that is the approach most commonly used in the United States.

In addition to the perception of the superiority of preoperative chemoradiation over chemotherapy, squamous cell cancer (SCC) of the esophagus is also increasingly recognized to be significantly more responsive to chemoradiation than adenocarcinoma. One obvious implication of this finding is that predicting a clinical complete response is more reliable in SCC given the underlying higher incidence of the event; but a broader question raised is whether surgery should only be used as salvage therapy in squamous cell cancers after definitive chemoradiotherapy. Lastly, another recognized pathologic feature after chemoradiation is the higher likelihood of uninvolved surgical radial margins when compared with chemotherapy followed by surgery.

TABLE 1: Prospective randomized trials comparing preoperative chemo-radiation to surgery alone

Trial	No. of patients	Tumor type	Clinical stage	Staging workup	Chemotherapy	Radiation	Median survival rate	Significance

Type of Chemotherapy

Before the CROSS trial, data from various studies strongly supported the use of a cisplatin-based two-drug regimen (used in most randomized trials since the 1980s). Over time, the second drug evolved from the more poorly tolerated fluorouracil to several other better-tolerated drugs such as paclitaxel and irinotecan. The CROSS trial used carboplatin and paclitaxel concurrently with 41.40 Gy and showed impressive benefits. Given the ease of administration and relatively lower toxicity, this regimen is rapidly being adopted as the default new standard of care.

Controversial

Definitive Chemoradiation

Although the use of chemoradiation therapy followed by esophagectomy for local-regional advanced esophageal cancers has become accepted by most surgeons as the standard of care, this acceptance is not necessarily true of all physicians; the perception exists among some that definitive chemoradiation is the most appropriate treatment for all esophageal cancers, with surgery relegated to salvage recurrent disease. One reason for this approach stems from a sense of nihilism concerning a cancer with such poor outcomes, and part stems from fear of an operation with historically high morbidity and mortality rates. A major reason for this approach, however, is the presence of conflicting data in the literature regarding the added benefit of surgery in patients after chemoradiotherapy. The most important study that evaluated the marginal benefit of surgery after chemoradiation (Stahl) did not show a survival advantage with the addition of surgery. In this study, patients were randomized to either chemoradiation followed by surgery or to chemoradiation alone. Although this study raises important questions about the added benefit of surgery in this patient population, it is also important to note that the large majority of the patients had squamous cell cancer, the mortality rate of the operative arms was high (11.3%), and the local recurrence rate was higher in the nonsurgical arm. The relevance of these points includes the fact that adenocarcinoma is far more common in the western hemisphere and that it is not possible to extrapolate results from this study given the known differences in treatment response between squamous cell carcinoma and adenocarcinoma.

Selective Definitive Chemoradiation

Selective definitive chemoradiation implies definitive treatment with evaluation of clinical response either during or at the completion of the therapy. Surgery is then offered only to patients with persistent disease after chemoradiation. Supporters of this approach point to the Bedenne trial as evidence that surgery provides no additional benefit in patients whose conditions respond to therapy. Most proponents of this approach reserve it specifically for squamous cell carcinoma. They point to the fact that both Stahl's and Bedenne's trials included predominantly squamous cell carcinomas and that in a subgroup analysis of the CROSS trial and the Burmeister trial, patients with squamous cell cancer seem to benefit relatively more from chemoradiation than those with adenocarcinoma. Further supporting this approach is the significantly higher rates of complete pathologic response in squamous cell carcinoma and the fact that this is the standard approach for cervical esophageal squamous cell carcinomas. Some concerns are raised by this approach, however, and have not been addressed in these trials. Most importantly is the consequence of a local-regional recurrence. How often a salvage esophagectomy is possible in these patients is unclear. What happens when salvage is not possible? And what were the complications when salvage was done? Although conflicting studies are found regarding the risks of salvage esophagectomy, some attribute significantly increased risks for complications and death. An additional concern is specific regarding squamous cell cancers: these tumors typically arise in the mid esophagus, and when they recur local-regionally, they are frequently unresectable with very few available palliative options. Lastly, the definition of achievement of an adequate clinical response is not yet clear.

Selective Chemoradiation Versus Chemotherapy in Adenocarcinoma

The data supporting the benefits of preoperative chemoradiotherapy are most convincing in squamous cell carcinoma, whereas the data in adenocarcinoma are more tenuous. This differential benefit is best seen in the CROSS and Burmeister trials. One question, which is raised as a result of this difference, is whether adenocarcinoma is better treated with preoperative chemotherapy instead of chemoradiotherapy. Proponents of this selective preoperative approach based on histologic type also extrapolate the results from the Cunningham trial, which included primarily gastric cancer trials but also 25% esophageal and gastroesophageal junction adenocarcinomas. Proponents of the addition of radiation to the management of adenocarcinoma, however, point to the higher likelihood of achieving R0 resections with the addition of radiation, with several studies showing a correlation between R0 resection and survival. No good clinical trials are found to compare these two approaches.

Added Risks to Surgery of Chemoradiation

A persistent concern about the use of preoperative chemoradiation has been the potential of increased postoperative complications. This concern should be addressed as two separate questions: (1) what are the added risks after preoperative chemoradiation? and (2) what are the added risks after definitive chemoradiation and salvage esophagectomy? Most of the data regarding the added risks of preoperative chemoradiation compared with surgery alone, culminating in the CROSS trial, do not support any added risks. The caveat in these data is that the average patient receiving preoperative therapy tends to be younger and healthier than the average esophageal cancer population. In this vein, some good data support increased postoperative morbidity in older patients who received preoperative therapy, defined variably as age greater than 70 years or 80 years. The data regarding increased morbidity after salvage esophagectomy are less consistent, with some studies showing significant added risks and others showing none. One likely reason for these inconsistencies is that these series tend to be in highly skewed populations, typically patients at high risk who were not initially good surgical candidates. The available randomized data do not inform us on this issue.

Optimal Radiation Dose

Concurrent chemoradiation was proven to be superior to radiation alone in an early Radiation Therapy Oncology Group (RTOG) trial (RTOG 85-01). A subsequent RTOG trial (RTOG 94-05) evaluated the optimal radiation dose and compared 50.4 Gy with 64.8 Gy as a definitive concurrent chemoradiation dose. This trial determined that the higher dose was associated with higher complication rates, including fistulae and deaths, without any survival benefit. These data were then extrapolated for use as preoperative therapy in deciding the optimal tolerable preoperative radiation dose. In reality, many of the complications seen in the higher radiation group in the RTOG trial occurred before even reaching the 50.4 Gy dose, so whether higher doses necessarily result in higher complications is unclear. What is more clear is that higher radiation doses can be associated with improved pathologic response rates, and in situations where definitive chemoradiation (such as in squamous cell carcinoma) is being considered, that higher dosing may be worth exploring.

Different Approach to Siewert II and Siewert III Tumors

Although the most recent AJCC staging recommendations have combined all gastroesophageal junction (GEJ) tumors into the same esophageal staging system, this change did not result in a consensus about the best management of GEJ tumors. Because gastric cancer multimodality trials include patients with GEJ tumors, notably Siewert II and III tumors, the tumors are frequently managed as gastric cancers. Alternatively, some make a distinction between Siewert II and III tumors and manage local-regional advanced Siewert III lesions as gastric cancers, typically with either preoperative and postoperative chemotherapy or with postoperative chemoradiation, and local-regional advanced Siewert II lesions with preoperative chemoradiotherapy.

PET-Directed Therapy

There are expanded indications for the use of PET scans to assist in directing multimodality treatment beyond excluding metastatic disease. The indications most supported by evidence stem from the Metabolic response evaluation for individualisation of neoadjuvant chemotherapy in esophageal and esophagogastric adenocarcinoma (MUNCON) trials, which prospectively showed that patients who have evidence of a PET response to induction chemotherapy have a better prognosis and that the lack of PET response might be an indication to alter the planned therapy. Use of PET scan at the completion of chemoradiotherapy to either establish the lack of residual disease or to estimate response to therapy is least supported by clinical data, likely because of the confounding effects of radiation.

Unknown

Very little data are found on what the optimal management is for patients initially managed surgically who subsequently are found to have a more advanced stage of disease for which multimodality therapy is appropriate. Options include observation, adjuvant chemotherapy, or adjuvant chemoradiation. Another area without clear guidelines is the management of patients with involved radial margins, especially in patients who did not receive preoperative radiation. Although radiation is frequently added in this situation, no evidence is found to support any particular treatment approach.

SUMMARY

Multimodality has become the standard of care for the management of local-regional advanced esophageal cancer, with concurrent chemoradiation as the most accepted preoperative therapy. In the future, further attempts will be seen to define which subset of patients are most appropriately treated with definitive chemoradiation, reserving surgery for palliation of either persistent or recurrent disease.

Esophageal Stents

Matthew J. Schuchert, MD, Catherine Go, and James D. Luketich, MD

The primary goals of palliation in patients with unresectable esophageal cancer include the relief of dysphagia, maintenance of oral intake, management of complications, relief of pain, and prevention of reflux, regurgitation, and aspiration, while minimizing the length of hospital stay and maximizing quality of life. Although a variety of treatment options exist (including photodynamic therapy [PDT], chemotherapy, radiation therapy, brachytherapy, and laser ablation), esophageal stenting appears to provide the most immediate and durable results. A combination of modalities can be employed to maximize the palliative effects.

Stenting of the esophagus is the most commonly used first-line modality to palliate dysphagia and prevent malnutrition secondary to esophageal and proximal gastric cancers (Figure 1). The repertoire of available devices includes rigid plastic conduits, self-expanding metal stents, and self-expanding plastic stents. Uncovered stents have the advantage of better purchase on the esophageal wall, thus limiting

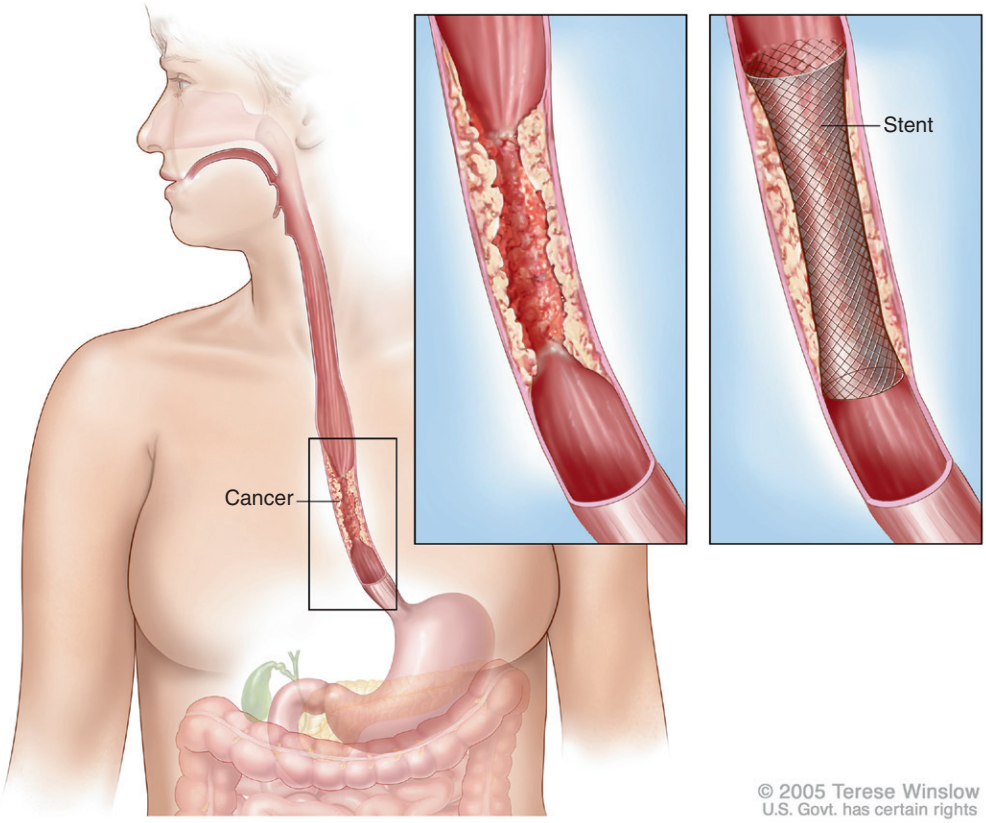

FIGURE 1 Esophageal stent insertion for malignant disease. *(© 2005 Terese Winslow, U.S. Government.)*

stent migration. However, they allow (and even stimulate) tumor and granulation tissue ingrowth. Expandable stents may be covered with a plastic coating to retard tissue ingrowth, but they have an increased risk of stent migration. Stent selection is tailored to the individual patient and is dependent on tumor length, bulk, and location. Deployment is achieved under fluoroscopic and/or endoscopic guidance. Stents are highly effective in palliating dysphagia in the setting of esophageal malignancy but can be associated with a substantial complication rate, predominantly due to the patient's poor functional and nutritional status as well as the extent of the underlying esophageal disease. In this chapter, we review the indications, techniques, and outcomes of esophageal stenting.

INDICATIONS

Current indications for stent placement approved by the Food and Drug Administration include the palliation of esophageal obstruction and tracheoesophageal fistulas secondary to malignancy. Other less common applications for esophageal stent placement include dysphagia secondary to external compression by benign neoplasms, benign strictures, and esophageal leak or perforation. Recently, stents have also found a role in management of esophageal varices.

The most common indication for esophageal stent insertion is relief of dysphagia in the setting of unresectable esophageal cancer. The significant majority of newly diagnosed cases have advanced disease at the time of diagnosis, with dismal five-year survival rates of approximately 20%. Palliation of dysphagia, therefore, becomes a paramount component of care. Stents provide safe and expeditious relief of dysphagia, thereby enhancing the patient's nutritional status and quality of life. Dysphagia can also result from obstructing lesions of the esophagus related to adjacent lung cancer or mediastinal lymphadenopathy due to extrinsic compression. Benign, refractory strictures related to peptic ulcer disease or prior caustic injury can be treated with stent insertion in select cases. Stent placement may be either temporary or permanent, depending on the clinical circumstances. In the setting of malignancy, temporary stents represent useful adjuncts before surgical resection by relieving dysphagia and enhancing nutrition during neoadjuvant therapy (chemotherapy, radiation therapy). Temporary stent placement may also be useful in the management of perforations, leaks, and benign strictures.

HISTORICAL ASPECTS

The first generation of endoluminal stents consisted of rigid plastic or rubber prostheses inserted at the time of rigid esophagoscopy. Dilation to 48F to 54F was commonly required to permit introduction of these devices. The bulky insertion techniques resulted in a higher risk of perioperative complications—perforation in particular. With the advent of flexible endoscopic techniques, a new generation of self-expanding metallic stents (SEMS) was introduced that greatly simplified stent insertion. In a seminal prospective, randomized trial by Knyrim and associates, SEMS were associated with significant reduction of perioperative complications, reduced perioperative 30-day mortality (29% vs 14%), and were found to be cost-effective when compared with rigid prostheses. Numerous studies have established that SEMS are superior to rigid prostheses in the management of patients with malignant esophageal obstruction. Self-expanding esophageal stents are now the most commonly used method of palliation in esophageal cancer. Over the last two decades, there has been a dramatic evolution in stenting technology

that has broadened its application in the management of a variety of esophageal conditions.

STENT DESIGN

With the introduction of SEMS, the use of rigid stent prostheses fell out of favor. SEMS are easier to deploy, achieve a wider luminal diameter, and are associated with a reduced periprocedural complication rate (including mortality). Though the cost of SEMS is greater than rigid prostheses, fewer repeat interventions are needed, leading to an overall reduced cost over the limited expected lifetime of a patient with advanced esophageal cancer.

Most SEMS that are currently available today are constructed with Nitinol (a composite of nickel and titanium), which is a highly elastic alloy with intrinsic properties of elasticity and shape memory that allow conformation to varying degrees of stenosis and angulation. The design of these pliable constructs allows the use of a lower-profile delivery system and efficient transmission of adequate radial force upon stent expansion. Initially, all SEMs were uncovered (Figure 2, *A*). Uncovered stents expand radially and incorporate into the wall of the esophagus with time, which dramatically reduces the potential for stent migration. However, the open spaces within the interstices of the uncovered metallic stent permit the ingrowth of granulation tissue or tumor, leading to recurrent symptoms of dysphagia in 13% to 26% of cases.

To minimize the occurrence of tumor ingrowth and the development of esophageal erosions or tracheoesophageal fistulas, stents were developed that were partially covered with silicone, polyurethane, or other polymers (Figure 2, *B*). Current designs maintain a 1 to 1.5 cm margin of exposed wire struts on the proximal and distal flanges of the stents that optimize stent purchase and permit integration into the esophageal wall. The use of a covered stents significantly decreases the severity of tumor ingrowth and consequent dysphagia, but it is associated with a slightly higher migration rate.

Completely covered self-expanding plastic stents (SEPS) were introduced into the market in 2001 and expanded the number of applications for stent usage, including benign conditions not readily treatable by SEMS due to their erosive tendencies. SEPS lack the ingrowth properties of metallic stents and are removable. Prospective randomized studies comparing SEMs with SEPS have demonstrated equivalent relief of dysphagia in the setting of esophageal cancer. Plastic stents are limited, however, by increased migration rates due to the mechanical characteristics of the plastic coating and decreased purchase upon the esophageal wall. Plastic stents do exert greater radial force than SEMS, which can lead to migration by "squirting" either proximally or distally with respect to the narrowed segment. The increased radial force can also lead to the subjective sense of discomfort or pain. Some of the plastic stent delivery systems are stiff and bulky, making deployment difficult in severely narrowed segments.

The most recent generation of stents includes fully covered SEMS that are designed to overcome the limitations of partially covered SEMS and SEPS. These stents may promote less granulation tissue and associated stenosis and may be removable after several weeks. However, an increased migration rate still may be expected as a result. Published data on the performance of fully covered stents are awaited.

CLINICAL EVALUATION AND TECHNIQUE

Preoperative assessment of clinical symptoms should be objectively recorded. Dysphagia scores are utilized to gauge the degree of symptomatic esophageal obstruction. The following dysphagia scoring system is commonly employed: 0—Tolerating a regular diet, no dysphagia; 1—Difficulty with solids; 2—Difficulty with soft foods; 3—Difficulty with liquids; 4—Difficulty managing saliva. Careful preoperative radiographic assessment is imperative in planning the optimal approach. Barium esophagography provides a road map of the esophagus and allows assessment of the extent of obstruction, the length of esophageal involvement, and the presence of other anatomic abnormalities such as leak, perforation, or fistula. Computed tomographic (CT) and positron emission tomography (PET) scanning are critical in the setting of malignancy in helping to stage the

extent of disease. Esophagogastroduodenoscopy allows confirmation of the underlying pathology and a real-time assessment of the extent of disease and whether the obstruction is intrinsic or extrinsic in nature. Flexible bronchoscopy is a useful adjunct in assessing patients with esophageal cancers of the proximal-mid esophagus and in those with suspected tracheoesophageal fistulas.

Esophageal stents may be inserted using endoscopic or fluoroscopic guidance under conscious sedation or general anesthesia. The authors prefer to employ a general anesthetic in most cases in an effort to minimize the risk of aspiration and to optimize stent positioning. During EGD, the degree of esophageal narrowing, the location and length of esophageal involvement, and the integrity of surrounding esophageal tissues are assessed. On occasion, significant narrowing may prevent the safe passage of the endoscope, and gentle dilation is performed to enable advancement of the scope beyond the distal extent of the lesion. Care should be taken to minimize the extent of dilation if anticipating the need for stent insertion. Overdilation of a malignant stricture might decrease stent purchase after deployment, leading to a higher risk of stent migration. Alternatively, a smaller-caliber endoscope can be used.

Once the lesion has been assessed, the appropriate length stent is selected—usually 2 cm longer than the lesion—and a guidewire is passed into the esophagus past the distal end of the stricture. The scope is withdrawn and the stent deployment device is passed over the wire, followed by reintubation with the scope. The stent can then be deployed under direct visualization.

Fluoroscopic guidance is the more traditional method of monitoring stent deployment. The proximal and distal extent of the lesion is mapped with radiopaque markers that are placed on the skin of the chest wall (Figure 3). A scope is then advanced into the duodenum, and a guidewire is inserted. The scope is withdrawn, and the distance between the two external markers is measured and an appropriate stent is selected. The stent delivery system (Figure 4) is then advanced over the wire under fluoroscopic guidance. The stent is identified by radiopaque proximal and distal markers that are aligned with the previously placed skin markers. Once adequate position is confirmed via fluoroscopy, the stent is deployed.

Delivery systems may employ a proximal release or distal release technique. Slight adjustments to stent position can be made during deployment to optimize stent position or after deployment using endoscopic graspers. Following deployment, the delivery system and guidewire are removed, and repeat endoscopy is performed to assess the adequacy of stent position and expansion. Stents should be slightly oversized to permit increased pressure of the stent against the esophageal wall so as to minimize the risk of stent migration. Care should be taken not to select a diameter that is too large, which can lead to incomplete stent expansion with residual infolding of the

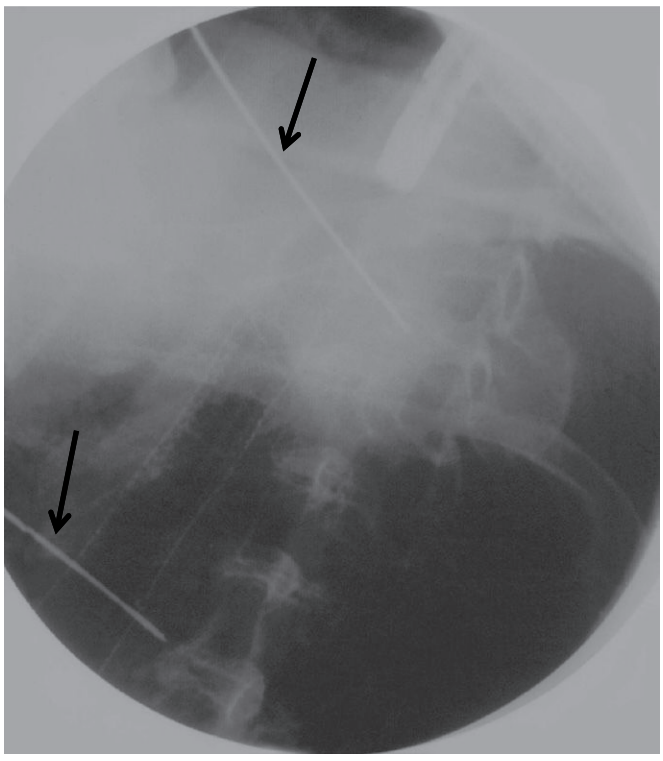

FIGURE 3 Deployment of esophageal stent. Note the proximal and distal skin markers that delineate the extent of obstructing tumor *(arrows)*. Fluoroscopy demonstrates good stent position and expansion.

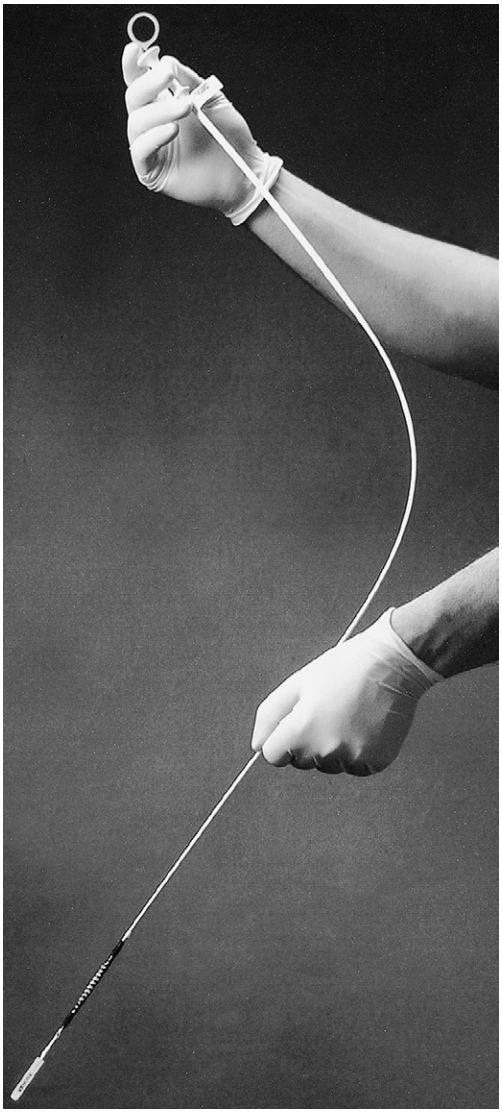

FIGURE 4 Esophageal stent delivery system. The Ultraflex stent is mounted on a plastic delivery vehicle and is advanced over a wire to the desired position. The stent is then deployed by pulling the release string while monitoring stent expansion under fluoroscopic guidance.

stent that will partially obstruct the stent lumen. Appropriate deployment will result in a stent that is well expanded with good purchase along the esophageal wall. Areas of incomplete expansion can be augmented with the assistance of a balloon dilator. Most stents are equipped with proximal and distal purse strings that permit stent repositioning as required after deployment. Utilizing careful technique, success rates of 90% to 100% for stent deployment can be expected.

COMPLICATIONS

Numerous complications related to stent placement have been documented and range from 30% to 50% in most series (Table 1). The most common complication encountered with SEMS placement is the development of exuberant granulation tissue or tumor ingrowth in the proximal and distal uncovered portions of the stent, which occurs in approximately half of patients within 2 to 3 months of stent placement and can result in recurring dysphagia. Stent migration is another common complication. Proximal stents are associated with a higher rate of airway compromise due to tracheal compression and migration, and distal stents (especially those that span the gastroesophageal junction) can lead to wide open reflux (10%-20%), regurgitation, and even aspiration (1%-2%). Stents can be associated with severe discomfort and/or nausea following placement that may be unremitting in nature and may require stent repositioning, revision, or removal (1%-2%). Procedure-related perforation is rare and has only been reported in 1% to 2% of cases. It has been reported that over half of patients require endoscopic reintervention for complications at a mean interval of 88 days. It is important to note, however, that despite numerous modifications in stent design over time, there has been no significant reduction in postprocedure complications, which is likely due to the generally poor medical and nutritional status of patients experiencing malignant esophageal obstruction.

Following stent insertion, patients should be carefully followed in an outpatient setting to ensure adequate symptomatic palliation and to monitor for any of the above-mentioned complications. Hospital admission is advisable if there are any intraoperative complications. Adequacy of stent position can be assessed with a standard chest x-ray in most cases or via chest CT. Objective assessment of swallowing function can be performed with a barium swallow (Figure 5).

TABLE 1: Complications arising from SEMS insertion

Chest pain or odynophagia	13%
Tumor ingrowth/overgrowth	10%
Stent migration	9%
Severe reflux	8%
Food impaction	6%
Nausea or vomiting	6%
Aspiration pneumonia	3%
Esophageal erosion/fistula	0.8%
Perforation	0.4%

SPECIAL CONSIDERATIONS

Bridge to surgery: Esophageal stents can be utilized as a temporary measure to enhance oral intake in preparation for definitive surgical resection. Uncovered stents are not usually recommended due to increased periesophageal desmoplastic reaction that can obscure tissue planes and make the planned surgery difficult. This is especially notable in the setting of neoadjuvant therapy (chemotherapy, chemoradiation). Fully covered stents can be placed preoperatively and removed before surgery during the course of neoadjuvant therapy to minimize the risk of complications.

Long-term usage: Recent data suggest that long-term placement of stents is safe (13.5 months in one study). Over time, patients should be monitored for signs of recurring dysphagia, which could be due to stent migration or tumor ingrowth.

Proximal esophageal cancer: Esophageal stents can be employed in the proximal esophagus to relieve esophageal obstruction and control fistulae. The use of stents in this setting can be limited due to patient intolerance secondary to pain and globus sensation, as well as airway compression. Stent positioning distal to the cricopharyngeus is critical in minimizing the risk of these symptoms.

Antireflux valves: For tumors involving the GE junction, stent placement can lead to the development of severe reflux symptoms due to compromise of the lower esophageal sphincter valve mechanism. Several stent modifications have been developed in an attempt to create an antireflux valve mechanism. Results from randomized studies, however, are mixed, and as a result, the use of reflux valves has not entered the mainstream during esophageal stenting in the setting of malignancy.

Radioactive stents: Stents covered with iodine-125 have been studied in the setting of malignant dysphagia and have shown some survival benefit, but they are still in nascent stages.

CONCLUSIONS

The use of expandable stents represents a safe and expeditious approach in the palliation of malignant dysphagia. Changes in stent design have simplified stent insertion and have broadened its application to a variety of benign conditions. SEMs have emerged as a superior construct when compared with rigid prostheses in terms of ease of insertion and procedure-related morbidity. Partially covered SEMs are associated with reduced tissue ingrowth and recurrent dysphagia when compared with uncovered stents. Among partially covered SEMS, there are no proven advantages of one design versus another. Although SEPS have demonstrated equivalent relief of dysphagia when compared with SEMS, SEPS have been associated with increased difficulty of insertion and complication rates (migration, hemorrhage, food impaction) in the management of patients with malignant dysphagia. The use of temporary SEMS or SEPS for the management of esophageal perforation and anastomotic leaks is promising but will need to be validated in larger studies with more detailed follow-up. Careful patient selection and postoperative follow-up are required to enhance patient outcomes. As technology improves, and as surgeons gain experience in employing an individualized multimodality approach in the treatment of malignant obstruction of the esophagus (stenting, dilation, laser ablation, photodynamic therapy, radiotherapy, chemotherapy), the palliative benefits of these approaches will be optimized.

Esophageal Perforation

Charles M. Ferguson, MD

Esophageal perforation is a life-threatening condition that requires early accurate diagnosis, superb judgment in choice of method of repair, meticulous technique in repair, and conscientious and comprehensive postoperative care to ensure a good result. Thus, a good result in management of esophageal perforation is generally a marker for superb clinical care. The mortality rate for esophageal perforation continues to range from 10% to 40% and is associated with the cause of the perforation, the location of the perforation, the underlying pathology, delay in diagnosis, and the method of treatment of the perforation. Most perforations today follow instrumentation of the esophagus, after esophagoscopy, transesophageal echocardiography, pneumatic dilation, placement of intraesophageal tubes, and traumatic intubation. Spontaneous perforations (Boerhaave's syndrome), foreign body perforations, and caustic ingestion are less common causes, as are postsurgical perforations (from mediastinoscopy, antireflux surgery, anterior spinal surgery, and even thyroidectomy). Finally, both blunt and penetrating trauma may result in esophageal trauma. The key to early diagnosis is suspicion of perforation in any patient with pain, cervical crepitation or swelling, and fever after any of the previously mentioned events (Figure 1). An esophagogram with water-soluble contrast generally reveals the perforation, although barium has greater sensitivity and specificity, despite the risk of local contamination with barium (Figure 2). Computed tomographic (CT) scan is helpful in determination of the presence or absence of a contained perforation, which may change the treatment plan.

INITIAL THERAPY

Once the diagnosis of esophageal perforation is made, therapy must be directed at resuscitation. All patients with esophageal perforation should be started on broad-spectrum antibiotics that cover upper gastrointestinal (UGI) pathogens (the author favors coverage of gram-positive and gram-negative organisms and fungi). A nasogastric (NG) tube should generally be placed just above the perforation at the time of the water-soluble swallow and placed to suction to prevent further contamination. Patients with uncontained intrathoracic or intraabdominal perforations usually have development of an immediate chemical pleuritis or peritonitis with third spacing of fluid and thus should be started on vigorous intravenous (IV) fluid resuscitation with monitoring of urine output. Any significant pleural effusion should be drained via chest tube.

MANAGEMENT DECISIONS

The decision on how to manage an esophageal perforation can be quite difficult, and the wrong decision can be costly and painful to the patient and surgeon. The only easy management decision is the cervical esophagus—if the perforation is large enough to see on the UGI swallow, it should be drained, unless it is well contained and drains back into the esophagus.

Cervical Perforation

The preferred method is a left-sided neck incision at the anterior border of the sternocleidomastoid muscle, retracting it and the carotid sheath laterally (Figure 3). The retroesophageal space is then entered bluntly along the prevertebral fascia, with care taken to preserve the recurrent laryngeal nerve. Blunt dissection should be carried down to the posterior mediastinum to drain all collections, and if the perforation is identified, the defect is closed with absorbable sutures. Oftentimes, the actual defect in the esophagus is not identifiable; if so, simple draining of the space generally results in healing of the defect.

Thoracic Perforations

Patients with uncontained thoracic perforation generally need surgery (operative or endoscopic) to ensure healing; the sooner it is performed, the better the outcome. An algorithm (Figure 4) is helpful in the decision on how to manage thoracic perforations with an otherwise normal esophagus. It should be noted that any underlying pathology may well affect the ability to repair a perforation. Thus, patients with a perforation through a malignancy should undergo resection, and patients with perforation and achalasia need myotomy to ensure the ability of the perforation to heal.

Endoscopic clips and stents seem to be most effective for small perforations, and stents can be particularly useful for anastomotic leaks after esophagogastrectomy, provided the gastric tube conduit has adequate blood supply (this can generally be determined at the time of endoscopy). If the gastric tube is necrotic, then therapy necessitates resection and diversion with cervical esophagostomy, reduction of viable stomach into the abdomen, and feeding jejunostomy

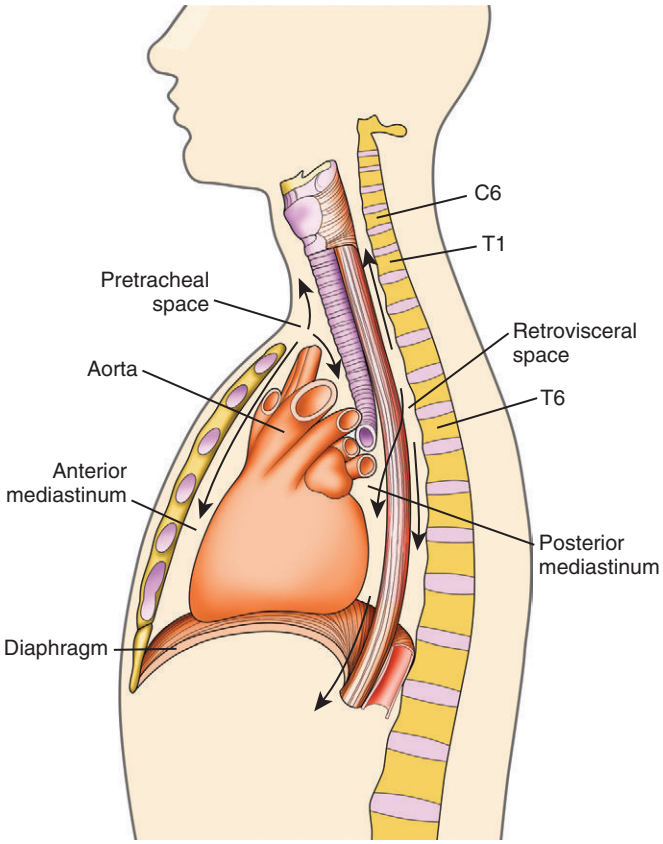

FIGURE 1 Direction of descent of mediastinal infections. *(From Patterson A, Cooper JD, Deslauriers J, et al:* Pearson's thoracic and esophageal surgery, *ed 3, Philadelphia, 2008, Churchill Livingstone.)*

with plan for later reconstruction with colonic interposition. For patients in whom endoscopic stents are chosen, any associated collections must be adequately drained. This can usually be done via chest tube, although some authors recommend thoracoscopic débridement of the pleura and drain placement.

Perforations of the upper two thirds of the esophagus for which operative therapy are chosen are best approached through a right thoracotomy via the fifth interspace. The pleura is opened in the area of the perforation and the esophagus dissected out such that the perforation can be clearly identified. The edges of the perforation should be débrided, and the mucosa and muscularis closed in layers with absorbable suture material, with a 40F to 48F bougie in place to prevent narrowing (Figures 5 and 6). Surrounding tissue should be used as a buttress over the repair; pleura or pericardial fat pad are described, but the author prefers a vascularized intercostal muscle flap, harvested from the fifth interspace. The wound should be copiously irrigated and drained with large chest tubes adjacent to the injury. If any concern exists about the repair, the patient is generally turned supine at the conclusion of the repair and a feeding tube placed (gastrostomy or jejunostomy). In the rare case with delayed presentation of a perforation, one should consider cervical esophagoscopy and gastrostomy with feeding jejunostomy. The cervical esophagostomy can be performed through an incision along the anterior border of the sternocleidomastoid, with the carotid sheath retracted laterally. The esophagus is easily dissected out bluntly with an index finger. Once it is dissected bluntly from the prevertebral fascia down to the posterior mediastinum, it is brought up to the skin, where a bridge can be placed beneath it, and opened longitudinally as a loop esophagostomy. Alternatively, it can be divided and an end esophagostomy created, but this complicates subsequent reconstruction.

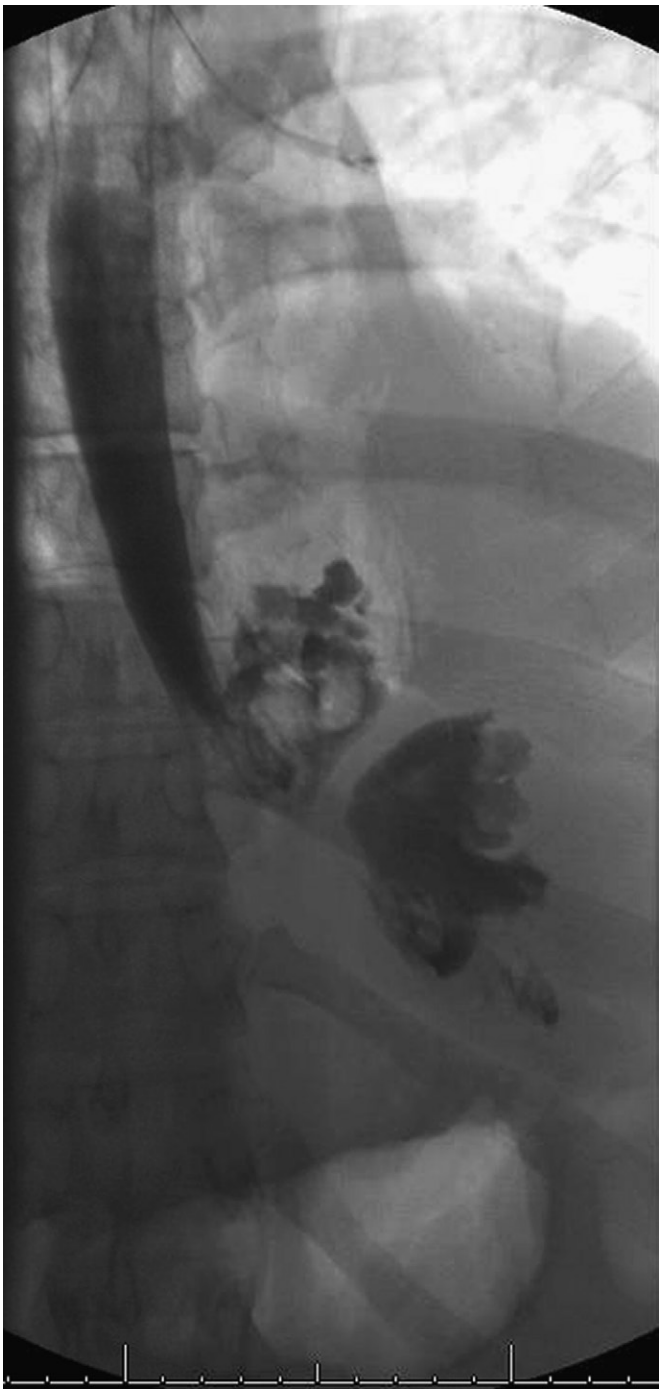

FIGURE 2 Barium swallow showing a lower esophageal perforation.

Perforations of the lower third of the esophagus should be approached through the left seventh interspace. Again, primary repair is preferred and should be buttressed with an intercostal muscle flap.

Abdominal Perforations

Perforations of the abdominal esophagus can usually be approached via an upper midline incision. In the occasional heavy patient with a large hiatus hernia and perforation of the abdominal esophagus, exposure may be better through a low left thoracotomy; this situation is rare. Once exposed and débrided, the perforation should be closed

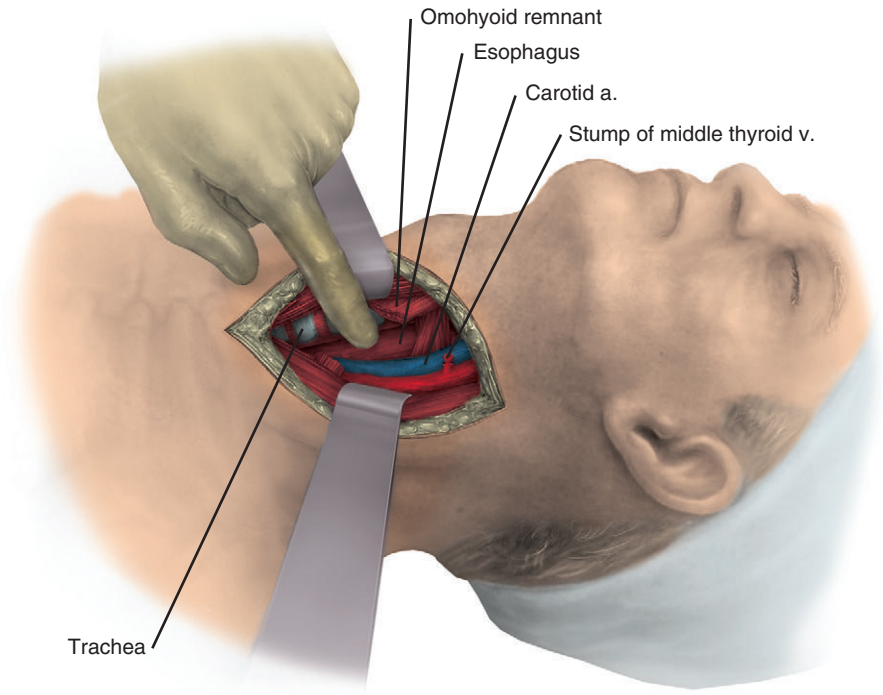

FIGURE 3 Make an incision over the anterior border of the sternocleidomastoid muscle. If necessary, ligate the middle thyroid vein and inferior thyroid artery. Retract the trachea and thyroid gland medially to help expose the esophagus. *(From Cooke DT, Lau CL: Primary repair of esophageal perforation,* Op Tech Thor Cardiovasc Surg *13(2):126–137, 2008.)*

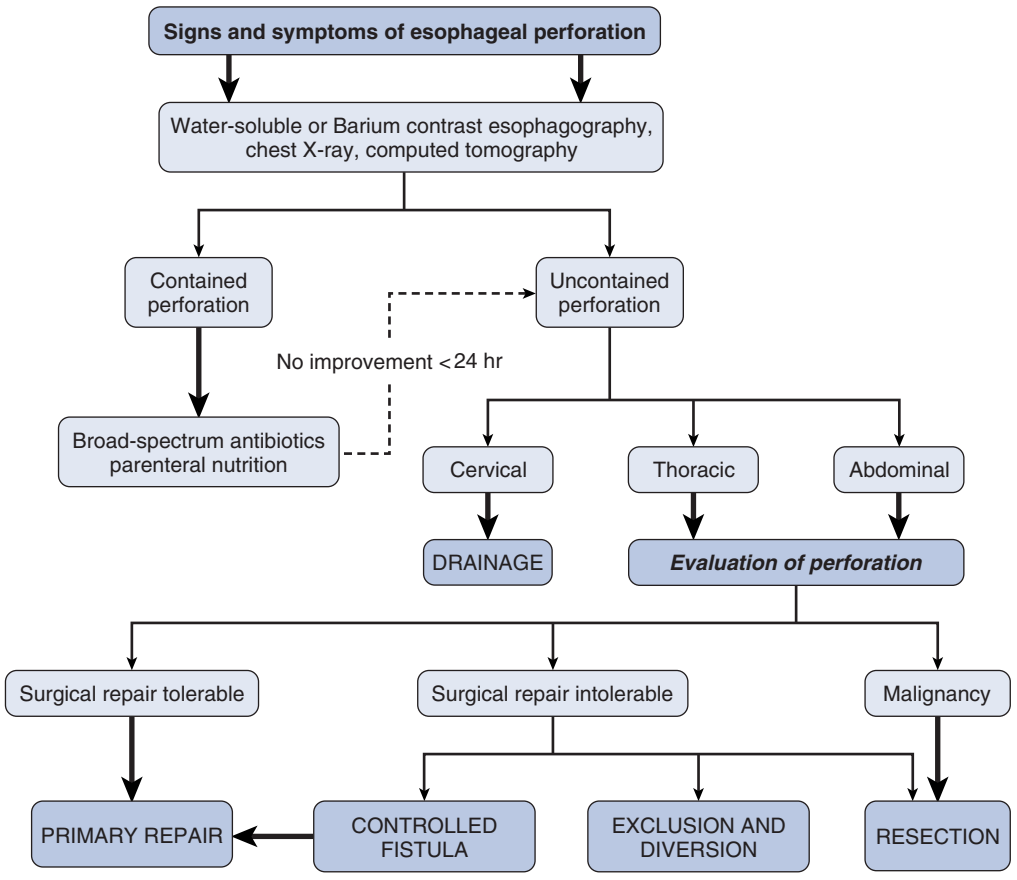

FIGURE 4 Algorithm for the management of thoracic perforations.

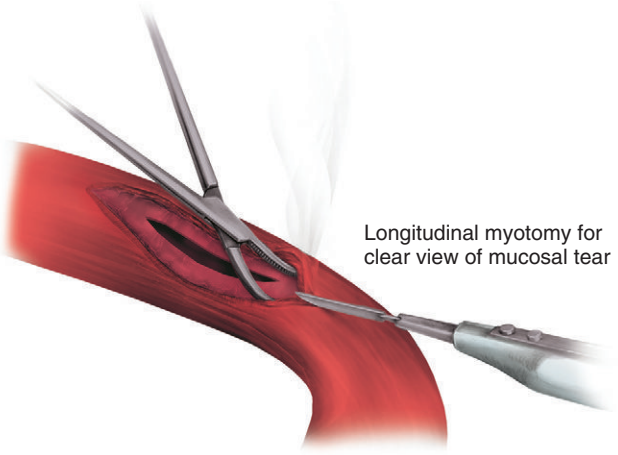

FIGURE 5 Mucosal injury is usually more extensive than the apparent muscular defect. A longitudinal myotomy is performed until the full extent of the mucosal tear is apparent. The mucosa is débrided as necessary to freshen edges. *(From Cooke DT, Lau CL: Primary repair of esophageal perforation,* Op Tech Thor Cardiovasc Surg *13(2):126–137, 2008.)*

as previously mentioned and the repair buttressed. Omentum works well for a buttress, as does the fundus of the stomach as a Nissen or Thal-type fundoplication.

SPECIAL SITUATIONS

Perforation Through a Malignancy

When one is faced with a perforation through a malignancy, the question is whether one can treat both problems. If the contamination can be adequately drained with chest tubes, the better part of valor in this situation is probably to place an endoscopic stent to control contamination and to place chest tubes to control the pleuritis, leaving the oncologic problem for another day. If this is not possible, then resection is necessary. Ideally, a resection and anastomosis appropriate to the site should be performed. However, in the setting of massive contamination, this may not be possible, and resection with cervical esophagostomy and gastrostomy for feeding should be considered. The resection can be performed via a right thoracotomy and then the patient turned supine for the cervical esophagostomy and gastrostomy.

Perforation With Achalasia

When an esophagus with achalasia is perforated (either via pneumatic dilation, at the time of myotomy, or via some other mechanism), the problem is that if the perforation is above the lower esophageal sphincter, the intraluminal esophageal pressure may preclude healing of the repair. Thus, a myotomy must be performed at the time of the repair. Generally, this is best performed through a left thoracotomy through the seventh interspace. The esophagus is bluntly dissected out circumferentially, with care taken to avoid injury to the vagi. The myotomy should be performed on the opposite side of the esophagus from the perforation, and the perforation closed in layers with absorbable suture, buttressed with omentum. A NG tube can be left above the repair to suction for a week.

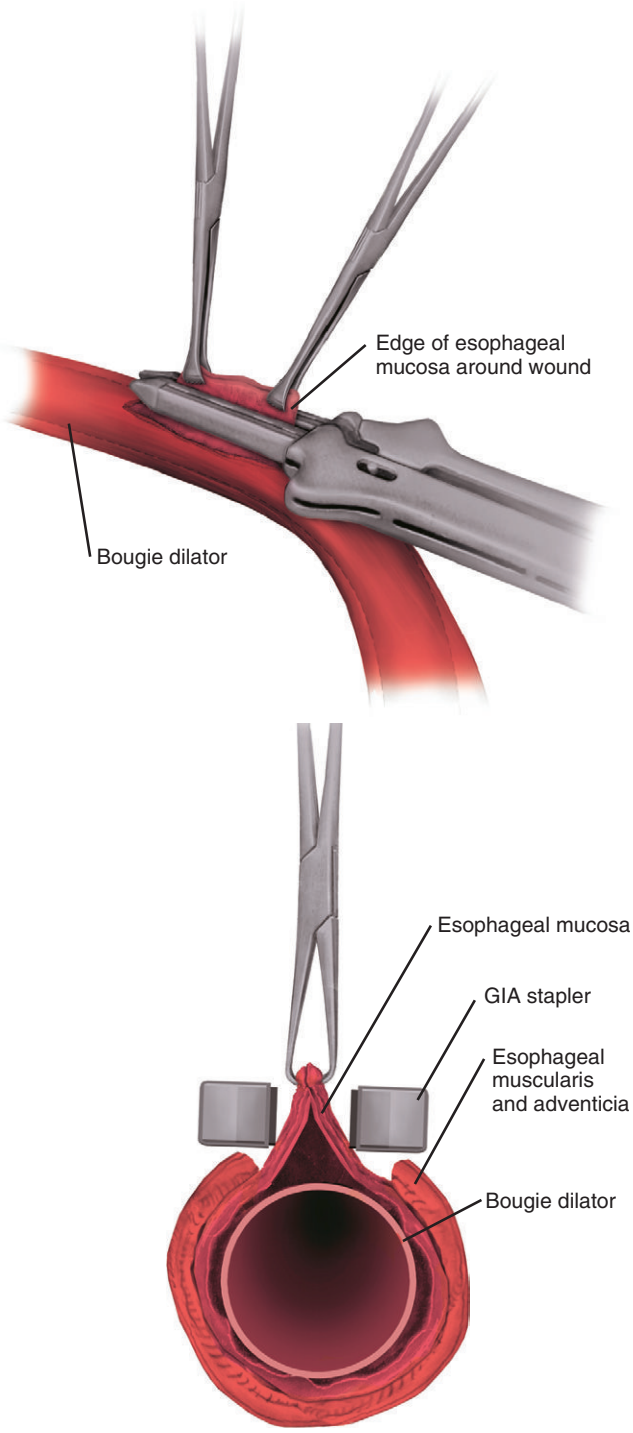

FIGURE 6 A 40F or 46F Maloney bougie is inserted into the lumen, the esophageal mucosal edges are grasped and approximated with Allis clamps or interrupted sutures, and the mucosa is closed with a 3.5-mm load. *GIA,* Gastrointestinal anastomosis. *(From Cooke DT, Lau CL: Primary repair of esophageal perforation,* Op Tech Thor Cardiovasc Surg *13(2):126–137, 2008.)*

Perforation of the Esophagus After Nissen Fundoplication

Occasionally, patients present 3 or 4 days after Nissen fundoplication with upper abdominal pain, fever, tachycardia, and leukocytosis and are found on barium swallow or CT scan to have a perforation of the

esophagus. These perforations can generally be cured with immediate laparotomy, dismantling of the fundoplication, direct repair of the esophagotomy in layers (with 40F bougie in place to prevent narrowing), and rewrap of the Nissen. Temporary endoscopic stenting is tempting to try in this situation, although no reports are found of this as yet.

Leakage of Esophagogastrostomy After Esophagectomy

Anastomotic leak is a dreaded complication of Ivor Lewis esophagectomy. Management of this leak is dependent on the size of the leak, degree of contamination, and viability of the gastric conduit. In patients with necrosis of the gastric conduit, clearly the anastomosis needs to be dismantled and a cervical esophagostomy and gastrostomy performed. On the other hand, in patients with a viable conduit and contamination that can be handled with chest tube drainage, an endoscopic stent often solves the problem. The author recommends endoscopy in the operating room after stabilization of the patient's condition. If the conduit appears viable at endoscopy, then placement of stent and chest tube drainage or thoracoscopy is recommended, or even thoracotomy and drainage of the pleural and mediastinal spaces. If the gastric conduit appears gangrenous, then a thoracotomy is performed to resect the gangrenous stomach. The gastric remnant is reduced into the abdomen with gastrostomy for feeding, and an esophagostomy is performed as described previously. Once the patient has recovered from this critical illness, one can contemplate reconstruction of the esophagus.

The Management of Benign Gastric Ulcer

Raafat Z. Abdel-Misih, MD, FRCS Edin, FRCS Eng, FACS, James D. Larson, MD, and Sherif R. Abdel-Misih, MD

INTRODUCTION

The number of elective operations for benign gastric ulcer disease has decreased dramatically over recent decades. As generations of surgeons with less direct experience encounter this disease, the significance of proper patient selection and appropriate intervention becomes of increasing importance. Overall, the annual incidence rate of peptic ulcer disease (PUD) is 0.1% to 0.3%, resulting in nearly 300,000 new cases diagnosed each year; approximately one third of these are gastric ulcers. The advent of pharmacologic therapy to address acid hypersecretion and treat *Helicobacter pylori* infection is the primary reason for reduction in the need for elective surgical intervention.

ETIOLOGY

The etiology of benign gastric ulceration is multifactorial and is best described in the context of each ulcer type. *H. pylori* infection and nonsteroidal antiinflammatory drug (NSAID) usage contribute to a great majority of cases; thus, nonoperative management of the disease is indicated in nearly all cases, with the exceptions of hemorrhage, perforation, obstruction, and refractory disease. Direct *Helicobacter* treatment and eradication is paramount because complete mucosal healing occurs less than 0.5% of the time with persistent infection. Other notable sources implicated in benign disease include smoking, steroid usage, and Zollinger-Ellison syndrome.

PRESENTATION AND DIAGNOSIS

The hallmark symptom of ulcer disease is epigastric pain. Most often, this pain is relieved with the ingestion of food or antacids and recurs after a short interval. Evaluation of the patient generally involves multiple modalities, given the broad differential diagnosis of epigastric discomfort, but ultimately, the diagnosis rests with endoscopy. Esophagogastroduodenoscopy provides definitive diagnosis, allows for characterization of the lesion's location and extent, and provides tissue for detection of microorganisms and malignant disease.

In the setting of appropriate conservative management, a failure of medical therapy is typically considered persistence of disease beyond 12 weeks. Many patients are given considerably longer periods of time, however, before surgical evaluation. The amount of time given to each patient is dependent on several factors. The treating physician may prefer a longer wait before evaluation by a surgeon, and patients with multiple comorbidities who are generally poor surgical candidates typically receive longer trial periods. Ulcers along the greater curvature tend to prompt earlier intervention given the association of disease in this location with malignancy.

GASTRIC ULCER TYPES AND LOCATION

The location of a gastric ulcer determines the preferred treatment modality, with the classification system proposed by Johnson (Figure 1) typically used to define each type. Type I ulcers, located along the lesser curvature, are the most common. Ulcer types II and III are associated with acid hypersecretion, and thus, vagotomy is recommended when surgical intervention is necessary. Lesions along the lesser curvature near the gastroesophageal junction are type IV. Type V disease is diffuse and associated with NSAID usage. Giant ulcers, often located along the greater curve, have a greater tendency to harbor malignant disease. Only 10% of benign ulcers are located on the greater curvature. The surgical management is described in detail for each ulcer type.

Type I

Located near the incisura on the lesser curvature, type I disease is the most common and comprises approximately 60% of benign gastric ulcers. The etiology of type I ulcers is not fully understood; these lesions are not associated with acid hypersecretion and, in some cases, are noted in the setting of low levels of gastric acid production. *H. pylori* infection can be found in most patients with type I disease, but it also occurs in those whose infections have been eradicated or who have no history of infection. As with other gastric ulcers, most are treated successfully with conservative therapy. For refractory disease, antrectomy and vagotomy with Billroth I reconstruction is the procedure of choice when possible. Despite the lack of definitive association with acid production, the rationale for vagotomy arises from the unclear nature of these ulcers and in general the addition of minimal, if any, morbidity. A Billroth II or Roux-en-Y technique may prove necessary when the anatomy is such that gastroduodenostomy is not feasible; however, this is often possible with good gastric mobilization and wide Kocher's maneuver.

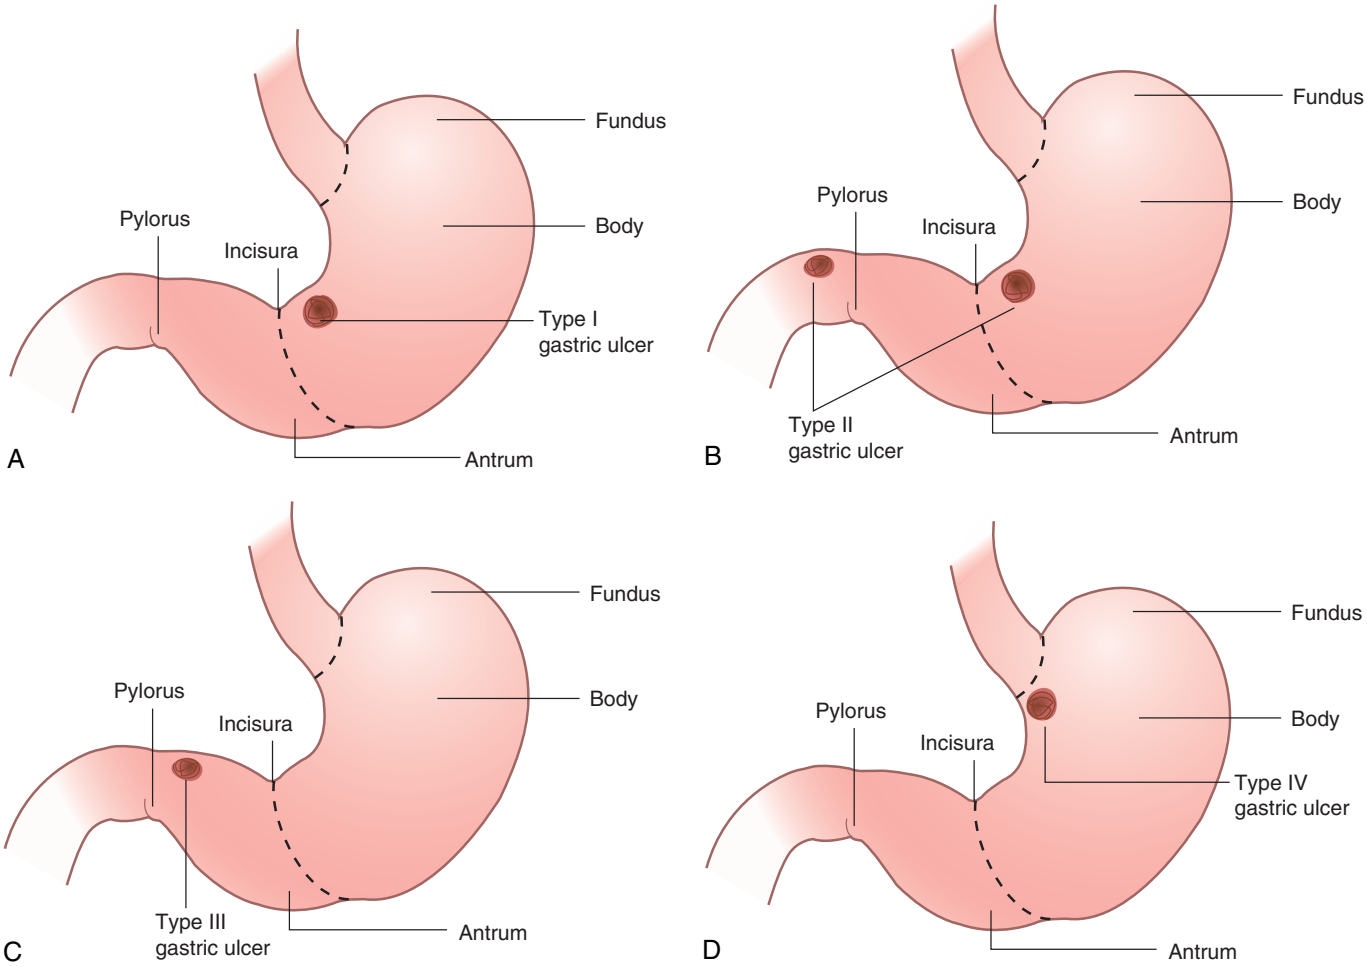

FIGURE 1 **A** to **D,** Johnson classification of gastric ulcers. *(From Townsend CM, Beauchamp RD, Evers BM, Mattox KL:* Sabiston textbook of surgery, *ed 18, Philadelphia, 2007, Saunders, Fig. 47-10.)*

Types II and III

Type II disease involves concomitant ulcers along the lesser curvature near the incisura and a duodenal ulcer, and type III ulcerations are prepyloric. Distal gastrectomy that includes the ulcer is the preferred surgical resection, again with Billroth I reconstruction when possible. Because of the duodenal involvement in the type II and the distal location of type III ulcers, sufficient mobilization of the duodenum may prove difficult, if not impossible, necessitating Billroth II or Roux-en-Y creation. These ulcers *are* associated with acid hypersecretion; as such, when resection is performed, a vagotomy is recommended because conservative acid reduction therapy has already failed. Depending on the comfort of the surgeon with the various techniques, type III ulcers are occasionally amenable to full-thickness excision combined with highly selective vagotomy; this is not recommended unless the surgeon has considerable experience because the gastrin-secreting tissue is left in place and recurrence rates are higher with incomplete vagotomy.

Type IV

Although type IV ulcers are not related to acid hypersecretion, they do pose a particular surgical challenge because of their proximal location along the lesser curvature near the gastroesophageal junction. Resection is directed at preserving a maximal length of healthy stomach such that a gastroduodenostomy may be possible even after such a proximal ulcer is removed. The Pauchet's and Csendes' techniques described subsequently (Figure 2) facilitate this goal. A Kelling-Madlener resection, in which total gastrectomy is avoided for very proximal locations with the ulcer left in place and an antrectomy with vagotomy performed, is not recommended given the unclear etiology of these ulcers and lack of association with acid production. In general, total gastrectomy is rarely necessary for gastroesophageal junction ulcers.

Type V

The diffuse nature of type V ulceration makes surgical intervention difficult; fortunately, the need for operation is rare. The use of NSAIDs or steroids is the primary etiology, and resolution is generally facilitated simply with cessation of the offending agent and the addition of a proton pump inhibitor (PPI) or histamine blocker. Bleeding is the most common indication for operation in this setting. Should intervention become necessary, the initial therapy is endoscopic with injection or cautery of significant points of hemorrhage. Unfortunately, because of the diffuse nature of the disease, endoscopic treatment may be inadequate. The localization of bleeding vessels and subsequent coiling or embolization via interventional radiology can be attempted next. Surgical approaches should be reserved for cases refractory to other measures. In that situation, an anterior gastrostomy facilitates inspection of the gastric mucosa with

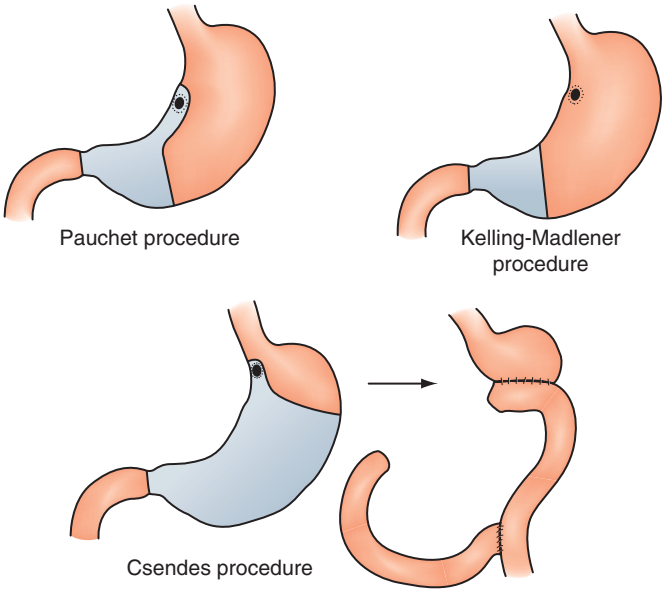

FIGURE 2 Special surgical procedures for gastric ulcers. *(From Townsend CM, Beauchamp RD, Evers BM, Mattox KL:* Sabiston textbook of surgery, *ed 18, Philadelphia, 2007, Saunders, Fig. 47-16.)*

the goal of oversewing major sites of bleeding. If this is unsuccessful, one should be prepared to perform a total gastrectomy because it may prove to be a life-saving measure. Gastric devascularization has been described in small studies in the past, whereby the major vessels are ligated and the short gastric vessels remain as the primary blood supply. This approach has been virtually replaced with interventional radiology and is uncommon.

Stress-Related Mucosal Disease

Stress-related mucosal disease, or stress gastritis, is generally encountered in the critical care setting and can occur as early as 12 hours after admission. Relative mucosal ischemia appears to play a principal role, with acid secretion likely a secondary association. Many clinical factors are associated with the risk of stress gastritis, including acute respiratory distress syndrome, multiple long bone fractures, transfusion requirements greater than 6 units, sepsis, acute renal failure, and specific associated trauma, such as central nervous system (CNS) injury (Cushing's ulcer) and extensive burns over 35% body surface area (Curling's ulcer). Patients at particular risk of clinically significant hemorrhage seem to be those who need mechanical ventilation for greater than 48 hours or with coagulopathy, defined as a platelet count less than 50,000/mm^3 or international normalized ratio (INR) of more than 1.5. Prevention of gastritis with addition of pharmaceutical prophylaxis is paramount. However, should further intervention become necessary, then treatment parallels that for type V ulceration; endoscopic and interventional techniques are generally applied first, with surgical involvement reserved for refractory cases.

Cancer Risk After Resection

Data regarding the risk of gastric malignant disease after partial resection are conflicting, in regards to both the time course and the actual (if any) extent of increase. Malignant disease usually appears 15 to 30 years after surgery and may in fact be less common than in the general population during the first 10 years. Significant variability in the literature is also present as to the ultimate risk conferred by resection, anywhere from no additional risk to five times that of normal. On the basis of the largely inconsistent information, no strong recommendations can be made for routine surveillance of these patients. Rather, a strong suspicion and low threshold for workup of upper gastrointestinal symptoms should be maintained, particularly as time from resection elapses.

Giant Ulcer

Giant ulcers are those that are more than 3 cm in diameter. These ulcers have an increased association with cancer: 30% of those larger than 3 cm harbor malignant disease. Earlier surgical intervention is generally warranted given this association. Endoscopy with multiple biopsies (at least four with jumbo forceps and eight with regular) to include both the ulcer base and edge usually provide sufficient tissue for diagnosis to guide therapy, with treatment of nonmalignant ulcers adhering to guidelines as outlined previously, depending on the location.

Obstruction

Obstruction is the least common complication of gastric ulcer disease. It is not an emergency, and initial management involves nasogastric decompression and fluid and electrolyte replacement. This nonoperative therapy can result in at least temporary resolution of a significant percentage of obstructions, which may be the result of edema or acute inflammation. Subsequent definitive management usually rests with resection and reconstruction, ideally as a Billroth I procedure. If chronic scarring and local derangement of tissues prevents safe resection or a tension-free gastroduodenostomy, then vagotomy and diversion with gastrojejunostomy is appropriate. Endoscopic dilation with or without stenting has yielded some favorable short-term results, but recurrence rates are much higher than with resection. Dilation may be preferable in those patients who are poor surgical candidates.

Perforation

Perforation is the most common complication of gastric ulcers, and the patients tend to be older and have more debilitated conditions than those with perforated duodenal ulcers. Surgical intervention is usually necessary, ideally with a partial gastrectomy to include the ulcer and reconstruction. Rarely, in the setting of a patient with a hemodynamically stable condition without signs of peritonitis, nonoperative treatment may be considered. If the patient cannot tolerate a resection, then full-thickness excision of the ulcer is appropriate, with care to send that tissue as a specimen to rule out malignant disease. Redundancy of the gastric walls generally allows for reapproximation of healthy tissue edges, without the need for an omental patch. In the case of a perforated type II or III ulcer, a vagotomy and drainage procedure can be considered. If before the perforation, however, the patient has never had a period of medical management to include eradication of *H. pylori,* if present, and PPI or H2 antagonist medications, it is reasonable to attempt these first, assuming close follow-up evaluation is possible.

SURGICAL TECHNIQUE

Vagotomy and Drainage

For those patients whose ulcers are associated with acid hypersecretion and are refractory to medical management, a vagotomy is recommended at the time of definitive surgical therapy. Although many variations in description and technique exist, in general, three approaches to vagotomy are recognized (Figure 3); it is important to

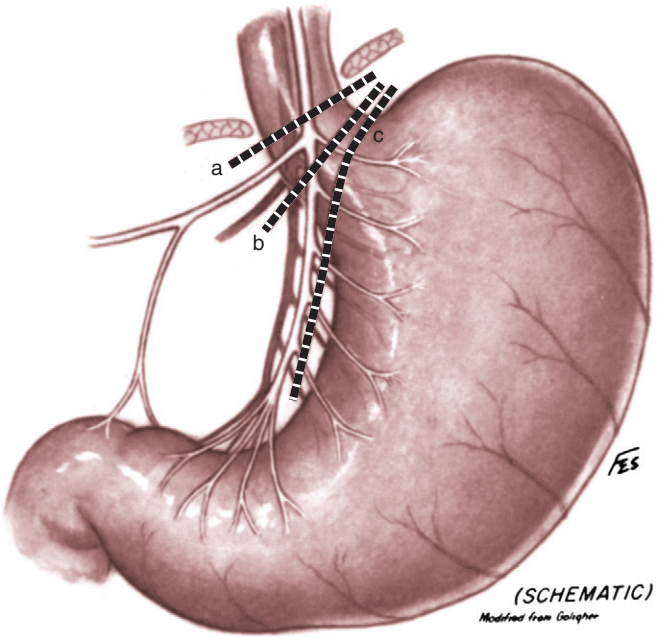

FIGURE 3 Vagotomy: Truncal vagotomy *(a);* selective vagotomy *(b);* highly selective vagotomy *(c). (From Zuidema GD, Yeo CJ:* Shackelford's surgery of the alimentary tract, *ed 5, Philadelphia, 2001, Saunders, Fig. 11-1.)*

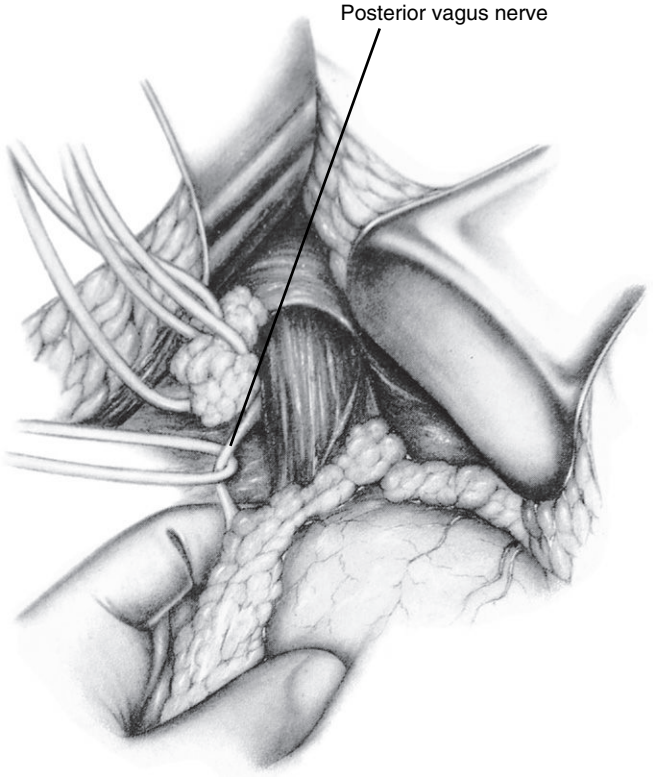

FIGURE 4 Exposure of posterior vagus. *(From Malt R:* Surgical techniques illustrated: a comparative atlas, *Boston, 1985, Saunders.)*

be acquainted with each method and the rationale behind it. Keep in mind that the ultimate goal is parasympathetic denervation of any remaining acid-producing stomach tissue, a feat best accomplished with the technique the operating surgeon is most familiar with and comfortable pursuing.

The first, and usually most straightforward from a technical standpoint, is truncal vagotomy. The anterior and posterior nerves are divided at the level of the distal esophagus, ideally approximately 4 cm proximal to the gastroesophageal junction. At this level, one has the best chance of finding a single trunk for both branches: 90% of anterior and 75% of posterior vagi. This requires mobilization of approximately 5 to 6 cm of the esophagus to provide adequate exposure for complete nerve identification because those that are branching by this point form several smaller cords. Clips are placed proximally and distally on each vagal trunk and then transected, with the segment sent for pathologic confirmation. The so-called "criminal" nerve of Grassi, the first gastric branch of the posterior vagus, is of particular importance because its separation point can be proximal to the celiac division of the posterior nerve. It travels to the posterior fundus, running past the angle of His, and failure to identify and divide it can result in a higher rate of failure; two thirds of cases with ulcer recurrence after an initial antisecretory operation have evidence of incomplete vagotomy.

Several points can be made that facilitate identification of the posterior vagus nerve. Place downward traction by grasping the proximal stomach with the left hand, keeping the gastroesophageal junction between the index and middle fingers. This pull allows the esophageal muscular layers to stretch and puts the posterior nerve under tension such that it can be palpated as an identifiable and relatively isolated cord toward the right side of the esophagus (Figure 4). Unlike the anterior vagus, which is running directly on the esophagus, the posterior nerve is generally located approximately a centimeter away from the wall itself.

A second approach is a selective vagotomy. This method spares the posterior branches that innervate the pancreas and small intestine, and the anterior branches that course to the liver and gallbladder. Preservation of these distal sites of innervation is directed at decreasing the potential morbidity of vagotomy; the incidence of postoperative diarrhea and dumping has in some cases proven to be less with a properly performed selective versus truncal vagotomy, and the recurrence rate of ulceration is equivalent. Selective vagotomy is performed more frequently for refractory duodenal ulcers in the setting of a concomitant drainage procedure; when used after a gastric resection for benign ulcer disease, its benefit over truncal vagotomy is less clear.

A third approach is a highly selective (parietal cell) vagotomy that seeks to preserve Latarjet's nerves that terminate on, and provide motor function to, the pylorus. This makes it distinct from the other denervation techniques in that no drainage procedure is necessary. Successful completion requires substantial familiarity with the technique; in most cases of refractory benign gastric ulcer, it is unnecessary because a resection of the pylorus is often a part of the procedure. Highly selective vagotomy involves identification of the terminal fronds of both the anterior and the posterior branches; these are located at the junction of the corpus and antrum and have a characteristic "crow's foot" configuration with three divisions. This point is generally 6 cm proximal to the pylorus, and these terminal branches are left intact. The individual neurovascular bundles originating from the vagal trunks and running within the anterior and posterior leaves of the lesser omentum to the stomach are divided up to and including the distal esophagus for approximately 5 cm, with the integrity of the trunks preserved. An alternative method of dealing with the anterior row of vagal fibers is to perform a running anterior seromyotomy at the level of their junction with the stomach; because of its location, this technique is difficult to perform on the posterior row, which is dealt with as described previously.

In those cases in which a truncal or selective vagotomy is executed but no resection is done, usually because of extensive scar tissue or an emergent situation, a procedure to allow drainage through the pylorus is warranted. Most commonly, a pyloroplasty (Figure 5) is performed in the manner described by Heineke-Mikulicz, whereby a longitudinal incision is created through the pylorus and closed

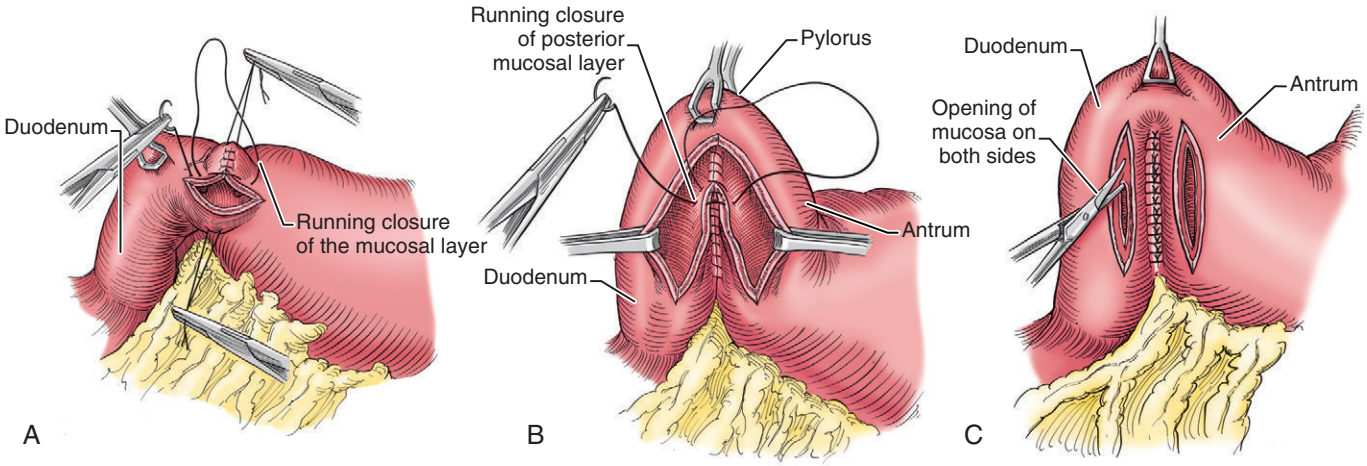

FIGURE 5 **A,** Heineke-Mikulicz pyloroplasty; **B,** Finney pyloroplasty; **C,** Jaboulay gastroduodenostomy. *(From Townsend CM, Evers BM:* Atlas of general surgical techniques, *ed 1, Philadelphia, 2010, Saunders, Figs. 23-3, 24-3, 25-4.)*

transversely. In cases in which the duodenum is heavily scarred, the Finney and Jaboulay techniques may afford more mobility to allow closure. If a pyloroplasty is not possible via these methods, then a gastrojejunostomy is appropriate.

Extent of Resection

In general, an antrectomy with resection of less than 50% of the stomach is suitable for most benign gastric ulcer disease treatment. Minor variations usually enable the surgeon to remove the ulcer itself and all of the gastrin-secreting tissue without significantly compromising the remaining gastric volume. Although arbitrary, some gross anatomic landmarks help delineate the approximate area of removal. The antrum-body physiologic junction is estimated by a line drawn from 2/5 the distance from pylorus to the cardia on the lesser curvature to 1/8 the same distance on the greater curve. This corresponds to about 7 cm on the lesser curve (2 to 3 cm from the aforementioned crow's foot) and 5 cm on the greater curve, although it becomes more proximal with advancing age. If the resources are available, intraoperative frozen section to determine the presence of antral glands containing G cells in remaining tissue can be obtained, thus directing further resection.

As the ulcer location (or proximal extent of a large ulcer) moves progressively more proximal, principally on the lesser curve, the ability to preserve enough length to create a tension-free gastroduodenostomy becomes challenging. Pauchet's procedure (see Figure 2) addresses this issue by starting proximal to the ulcer on the lesser curve and extending distally to increase the distance along the greater curve. Those ulcers within approximately 2 cm of the esophagus are particularly difficult and may necessitate a subtotal gastrectomy with Roux-en-Y reconstruction, even when saving as much stomach as possible (Csendes' procedure). The need for a total gastrectomy, however, is rare and should be avoided.

The distal extent of resection is usually straightforward with a transection through healthy duodenal tissue just distal to the pylorus. When the local inflammatory reaction of a gastric ulcer or the ulcer itself creates an ill-defined margin, determination of the point at which to stop can be difficult. This is particularly troubling when the ulcer is posterior and involves the surface of the pancreas. It is best to avoid attempting complete resection of the ulcer base; perform the antrectomy as usual, leaving the base in place (Figure 6), and reconstruct overtop the area. With the source of inflammation removed, the area heals without adversely affecting the anastomosis, which generally lies just proximal to the ulcer base.

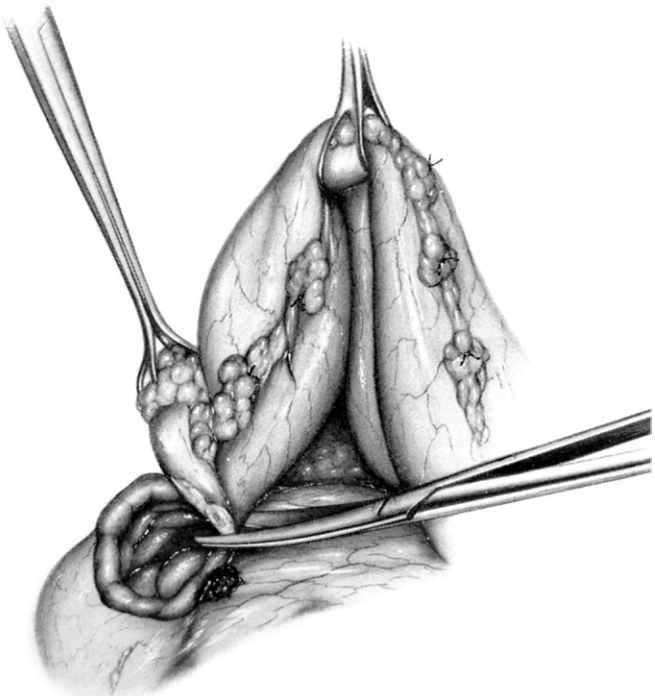

FIGURE 6 In the setting of an ulcer closely associated with the pancreas, the resection is performed while the base is left undisturbed. *(From Malt R:* Surgical techniques illustrated: a comparative atlas, *Boston, 1985, Saunders.)*

RECONSTRUCTION TECHNIQUES

Billroth I

Gastroduodenostomy has taken many forms since its inception well over a century ago and persists today most commonly as one of the early modifications performed by Billroth (Figure 7). The reconstruction via anastomosis of the end of the duodenum to the distal greater curvature of the stomach is the preferred technique for most benign gastric ulcer disease.

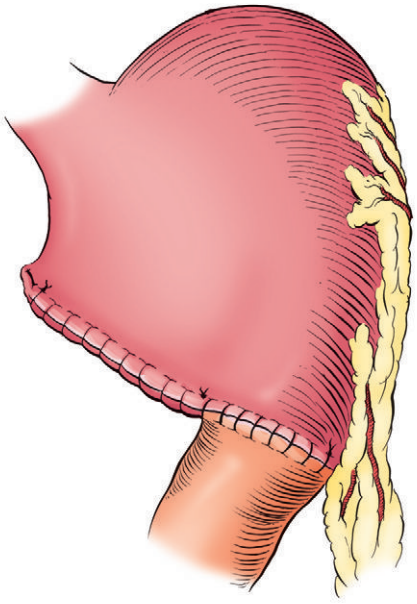

FIGURE 7 Billroth I. *(From Townsend CM, Evers BM:* Atlas of general surgical techniques, *ed 1, Philadelphia, 2010, Saunders, Fig. 26-13.)*

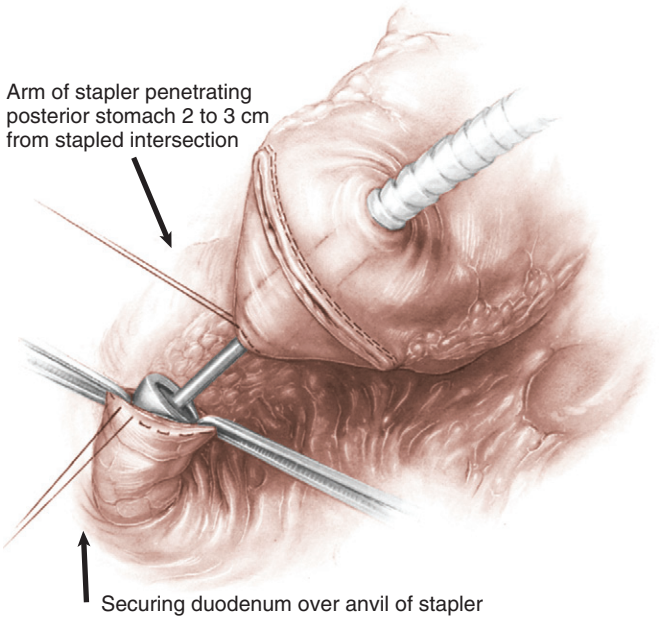

FIGURE 8 Stapled Billroth I. *(From Zuidema GD, Yeo CJ:* Shackelford's surgery of the alimentary tract, *ed 5, Philadelphia, 2001, Saunders, Fig. 11-56.)*

The authors perform the anastomosis in a single layer with simple sutures of 3-0 silk. Much attention is given in the literature to the point where the reconstructed lesser curve meets the gastroduodenal suture line (the "angle of sorrow"), with many variations on closing this defect. The authors' practice is to simply place an incorporating u-stitch that involves all three lines—the presence of healthy, well-vascularized tissue and lack of tension are likely of much greater importance than the specific technique used to place this particular suture. Performing Kocher's maneuver does not always prove necessary but can provide added length when the anastomosis is otherwise placed under tension. The use of an end-to-end anastomosis (EEA) stapler placed through an anterior gastrotomy to create the anastomosis is also acceptable (Figure 8). The gastrotomy can then be closed with another staple line or be hand sewn. With the exception of somewhat increased cost, stapling seems to afford equivalent operative experience and outcomes.

After surgery, a nasogastric tube is left in place to monitor for bleeding and is removed on postoperative day 1. A liquid diet is then started and maintained until bowel recovery, at which point the patient is discharged after tolerating a regular diet.

Billroth II

The authors reserve the use of a Billroth II gastroenterostomy for those patients in whom a Billroth I is not feasible, most often because of an inability of the duodenum and greater curvature to approximate without tension. As with gastroduodenostomy, many amendments to this reconstruction exist. A combination of the Reichel-Polya and Hofmeister-Finsterer modifications, first described in the early 20th century, is the preferred technique (Figure 9). Globally, this involves creation of a wide-mouthed gastroenterostomy with extension of the afferent limb along the closed portion of stomach nearest the lesser curve. Many aspects of the variation in this reconstruction have been, and still remain, points of debate with no clear superiority identified. The following are several topics that have generated much discussion and the authors' general approach to them.

- The ideal afferent limb should be as short as possible (no longer than 20 cm and less if the anatomy allows) to decrease the incidence of afferent loop syndrome. Mobilization of the ligament of Treitz can be performed to provide an even shorter limb.
- The authors' preference has been for a one-layered hand-sewn anastomosis, performed with 3-0 silk suture. Stapled techniques appear to be equivalent.
- The gastroenterostomy is performed in a retrocolic position, with the anastomosis placed through and lying below the colonic mesentery. This infracolic location helps prevent kinking of both the afferent and the efferent jejunal limbs and thus their respective obstructive pathologies; placement of sutures from the gastric wall to the transverse colon mesentery is important to maintain this setting.
- Use of a retrogastric location facilitates drainage of the stomach.
- An isoperistaltic orientation takes advantage of the natural course of the small intestine and permits a shorter afferent limb.
- The creation of a Braun's enteroenterostomy distally during the initial operation is acceptable but not routinely necessary.

Management of the duodenal stump with a Billroth II reconstruction is a subject that merits attention because of the potential for great morbidity. As a result of marked advances in intensive care, the mortality of duodenal stump leaks has improved from the historic reports of greater than 50% to around 10%, and in some accounts, even less. Stump leak rates are approximately 1% to 3%; postoperative leaks occur most frequently on postoperative day 6 to 10, but late stump "blow-out" can happen years after the initial surgery. Accordingly, a drain should be used near the stump; it can be removed in the office if the patient has been discharged before passage of the critical early time period.

Closure of the stump can be accomplished in many ways. If the tissue is well vascularized and healthy, it can be stapled or hand-sewn closed in a single layer and no further reinforcement is needed. Dissection of the duodenum away from the pancreas is not necessary,

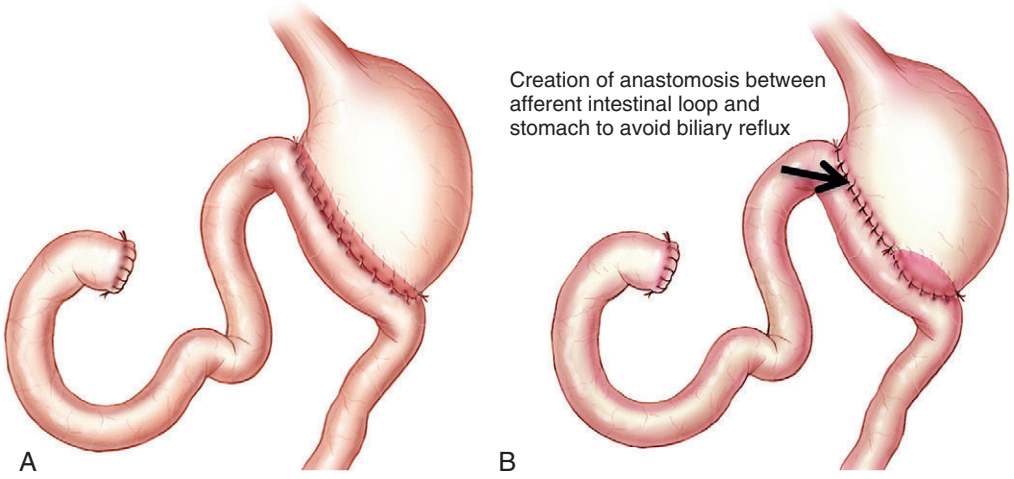

FIGURE 9 Gastrojejunostomy: **A,** Along entire length of gastric division (Polya); **B,** along part of the gastric division (Finsterer). *(From Piessen G: Reconstruction after gastrectomy: which technique is best,* J Visceral Surg *147(5):e273–e283, 2010.)*

and in fact, should be avoided, to obtain closure. An extensive review regarding the management of the difficult duodenal stump is beyond the scope of this chapter, but end or lateral stump drains, technically demanding techniques such as those described by Nissen and Bancroft, multiple layer closures, and omental patches are not routinely necessary.

Roux-en-Y

Several aspects appear to be important in creation of a successful Roux-en-Y reconstruction (Figure 10). A Roux limb length of at least 40 cm helps prevent bile reflux. When performed during an open procedure, both retrocolic and antecolic positions for the Roux limb appear to be equivalent in terms of outcome, but more length can generally be gained with the retrocolic version. Variations on the standard reconstruction such as an uncut Roux-en-Y or the creation of a rho-shaped Roux limb are acceptable but likely unnecessary, and both hand-sewn and stapled anastomoses are acceptable. Some comparisons of Roux-en-Y have shown it to be superior to Billroth II in terms of untoward subjective symptoms and objective endoscopic evidence of bile reflux. The choice between the two depends primarily on the operator's experience and comfort with each technique and its potential morbidities.

Minimally Invasive Approach

As previously mentioned, surgical indications for PUD include hemorrhage, obstruction, perforation, and refractory ulcer disease. As minimally invasive surgery has become more pervasive and widely accepted for surgery for both benign and malignant disease, increasing use of laparoscopy for PUD has been seen but still remains uncommon.

Like all minimally invasive approaches, patient selection and surgeon experience are paramount to success. Patient factors such as previous surgery, comorbidities, and body habitus must be considered because they may often make laparoscopy difficult, necessitating conversion to laparotomy. However, more important in the case of PUD is the patient's medical condition. Patients with any degree of hemodynamic instability or long-standing peritonitis are best managed with a traditional open approach, whereas patients with stable conditions may be considered.

Laparoscopic techniques used in foregut operations as in antireflux and bariatric surgery have made many surgeons facile with techniques that can similarly be used for laparoscopic PUD operations. Most commonly, this involves a four-port or five-port technique

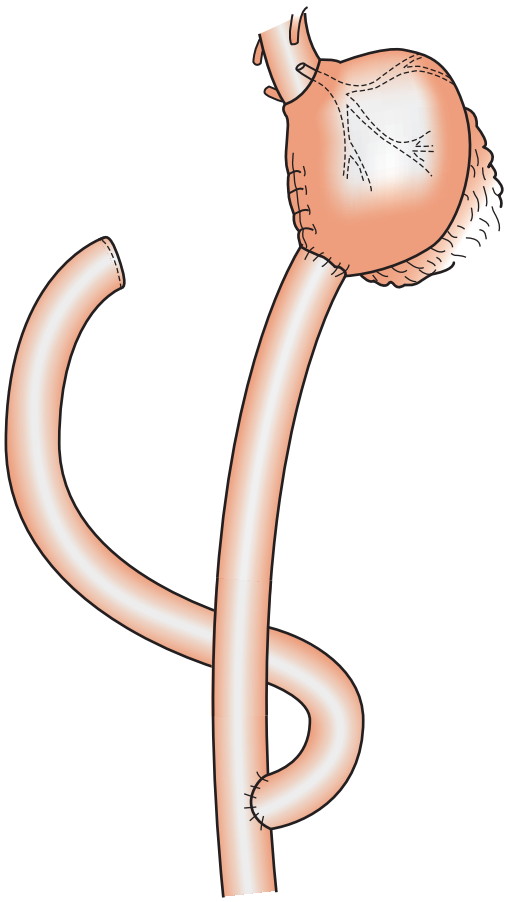

FIGURE 10 Roux-en-Y reconstruction. *(From Cameron JL:* Current surgical therapy, *ed 5, St Louis, 1995, Mosby.)*

(Figure 11), depending on the complexity of the operation, as it is sometimes necessary to have a retractor for the left hepatic lobe or an additional assistant port. As in many minimally invasive foregut operations, patients are positioned with the legs abducted in a split-leg position. Patients need to be well secured for safety because the table is typically placed into a reverse Trendelenburg's position with the surgeon operating between the patient's legs and assistants at the sides.

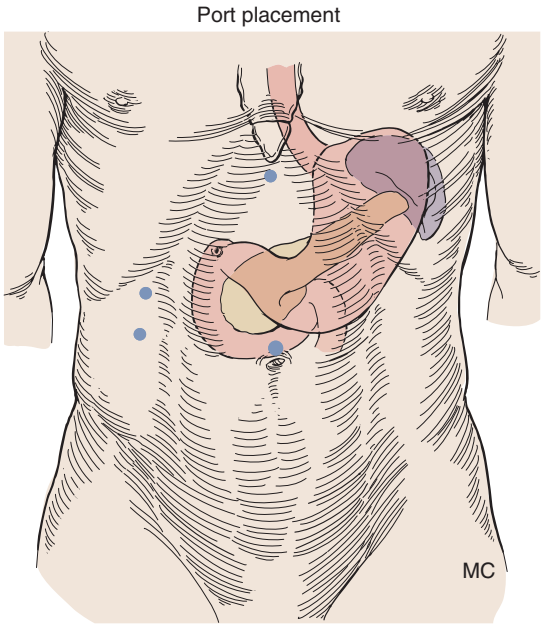

FIGURE 11 Possible port arrangement for laparoscopic approach to foregut surgery, showing port placement in relation to an ulcer. *(From Townsend CM, Evers BM:* Atlas of general surgical techniques, *ed 1, Philadelphia, 2010, Saunders, Fig. 29-6.)*

With the advent and efficacy of PPIs, current surgical management of perforated peptic ulcers most commonly involves omental patch repair with vigilant pharmacotherapy afterwards. Omental patch repair has been pursued with the use of laparoscopy for some time and has accumulated good data including several randomized controlled clinical trials that support its use and equivalency to traditional open approach.

A minimally invasive approach is not generally advocated for active hemorrhage associated with a peptic ulcer; however, a minimally invasive approach is not unreasonable to pursue for definitive operation when hemorrhage has been temporarily controlled with medical, endoscopic, or interventional radiology management. In those cases of controlled hemorrhage that have a high risk of rebleeding (such as adherent clot, a visible vessel, or active bleeding at the time of endoscopy), definitive surgical intervention may be reasonable to pursue in experienced, skilled hands.

In patients with disease refractory to PPI pharmacotherapy, elective laparoscopic approaches similar to the open approaches previously discussed may be pursued. Again, a surgeon's expertise and experience with laparoscopy may allow for operations like truncal vagotomy, pyloroplasty, gastric resections, and reconstructions.

Robotic surgery continues to evolve within all fields of surgery, including general surgery, although its role and benefits remain somewhat uncertain. The robotic system offers high-definition, three-dimensional visual quality with the enhanced range of motion and dexterity that may be useful in more complex operations as in selective vagotomies or gastric resections with reconstructions. However, the caveat, as with laparoscopy, is that surgeon experience is of utmost importance in optimization of said benefits and outcomes in these patients.

THE MANAGEMENT OF DUODENAL ULCERS

Robert J. Beaulieu, MD, and
Frederic E. Eckhauser, MD, FACS

INTRODUCTION

With the improvement in medical management of peptic ulcer disease, the incidence of hospitalization for duodenal ulcer (DU) disease has declined dramatically since 1990. The two improvements in care largely responsible for the reduction in surgeries for DU are antisecretory medications, such as proton pump inhibitors (PPIs) and histamine-receptor blockers, and therapy targeting the eradication of *Helicobacter pylori*. However, surgery remains an important element in the care of DUs because of the high rate of morbidity and mortality as a result of associated complications, such as bleeding, perforation, or obstruction.

Approximately 60,000 patients are hospitalized annually for DU disease, with an in-hospital mortality of 3.7%, a rate significantly higher than that of gastric ulceration (2.1%). Of patients hospitalized for duodenal ulceration, 10% will require surgery for progression to complicated ulceration, most commonly hemorrhage, and the overall operatively mortality rate may be as high as 10%. The two most common causes of duodenal ulceration are *H. pylori* infection and recent use of nonsteroidal antiinflammatory drugs (NSAIDs), accounting for more than 90% of cases of DU disease. Other important factors include gastrinoma (Zollinger-Ellison syndrome), smoking, steroid or cocaine use, and, likely, gastroduodenal dysmotility. The underlying pathophysiology involves dysregulation of acid secretion and impaired mucosal defense. Patients with DU disease usually have normal fasting gastrin levels but exhibit a higher acid load secretion when exposed to gastrin stimulus than do healthy patients. Further, duodenal mucosa demonstrates gastric metaplasia as a response to damage, allowing for *H. pylori* colonization and infection. *H. pylori* infection disrupts mucosal integrity and stimulates increased acid secretion through excretion of histamine N-methyltransferase.

Duodenal ulceration is marked by sudden onset epigastric pain that is commonly described as gnawing, burning, or stabbing in nature. Patients particularly complain of onset of pain between midnight and 3:00 AM. Although uncommon, pain of duodenal ulceration may be referred elsewhere, typically the back, if the ulcer has extended into the pancreatic head or free perforation has occurred. More than 90% of ulcers are visualized in the first portion of the duodenum on endoscopic evaluation. Ulceration in the more distal portions should raise concern for gastrinoma, which accounts for

only 1% to 2% of patients with newly diagnosed duodenal ulceration. DUs have a characteristic appearance with sharply demarcated, clean edges with exposed submucosa. In the case of recent hemorrhage, an eschar or clot may be adherent to the ulcer bed. If duodenal ulceration is visualized on upper endoscopy, gastric mucosal biopsies should be taken to demonstrate the presence of *H. pylori* as a causative agent.

MEDICAL MANAGEMENT OF DUODENAL ULCERS

The majority of regimens for medical management of DUs are focused on eradication of *H. pylori* infection. After the initial diagnosis of active infection by serology, antral biopsy, and/or breath test with carbon-labeled urea, combined therapy with antibiotics active toward *H. pylori* (clarithromycin and amoxicillin typically) and an antisecretory agent should be initiated (Table 1). In this setting, eradication of *H. pylori* significantly reduces rates of ulcer recurrence and ulcer complications, such as bleeding. NSAIDs or aspirin should be avoided, and smoking cessation is essential. In a large meta-analysis examining eradication therapy compared to none, the number of patients that needed to be treated to avoid recurrence was only two. Patients who have uncomplicated DU disease should take antisecretory drugs such as PPIs for 2 to 4 weeks, whereas patients with complicated DU disease should probably receive indefinite PPI therapy.

SURGICAL MANAGEMENT OF DUODENAL ULCERS

Operative management of DUs is indicated when there are complications such as perforation, hemorrhage, and obstruction. Most surgery is performed emergently for the treatment of bleeding or perforation. Because of the effectiveness of medical management, surgery for intractable disease has become rare. Increasingly, surgical techniques focus on repairing the primary defect as in simple closure and oversewing, with subsequent medical eradication of *H. pylori.* However, in some cases, it may be necessary to induce gastric denervation by highly selective vagotomy (HSV), vagotomy and drainage (pyloroplasty or gastrojejunostomy), or vagotomy and antrectomy.

TABLE 1: Medical management regimens for eradication of *H. pylori*

Agent	Length of treatment
PPI (omeprazole 20 mg OR lansoprazole 30 mg) + Amoxicillin 1000 mg + Clarithromycin 500 mg	Orally, twice daily for 14 days
PPI (omeprazole 20 mg OR lansoprazole 30 mg) + Metronidazole 500 mg + Clarithromycin 500 mg	Orally, twice daily for 14 days
Alternative regimen: Bismuth subsalicylate 525 mg qid + Metronidazole 500 mg tid + Tetracycline 500 mg qid + PPI (omeprazole 20 mg OR lansoprazole 30 mg daily)	Orally, given as indicated for 14 days

PPI, Proton pump inhibitor; *qid,* four times daily; *tid,* three times daily.

Operations tailored toward reduction of acid secretion, either by truncal vagotomy or more selective approaches, must be measured against the effectiveness of medical therapy with antisecretory agents. Truncal vagotomy results in 60% to 70% reduction in acid secretion with liquid meal stimulation when compared with normal subjects but is associated with 10% risk of postoperative dumping, diarrhea, or gastroparesis. Inclusion of an antrectomy may further decrease acid secretion by 85% compared with normal individuals. However, PPI therapy allows for nearly 100% acid reduction at 6 hours after dosing yet falls to 60% to 70% reduction by 24 hours (most are doses on a once-daily schedule). It is no surprise, therefore, that the rates of operation for intractability have fallen dramatically since the introduction of these agents in the 1990s. However, early operative management remains essential for the treatment of bleeding, perforation, and obstruction associated with DUs.

Perforated Duodenal Ulcers

Perforation is the most common fatal complication of DUs. The vast majority of patients (>90%) with perforation of a DU experience sudden onset of severe, diffuse abdominal pain and/or demonstrate pneumoperitoneum on plain radiograph. However, up to 20% of patients do not show free intraperitoneal air on plain radiography and may require computed tomography for diagnosis. Early diagnosis is paramount, as delay beyond 12 hours increases the risk of cardiovascular collapse and subsequent risk for morbidity and mortality. Initial management of a perforated DU consists of insertion of a nasogastric tube, fluid resuscitation, intravenous PPI, and broad-spectrum intravenous antibiotics. The patient should then be taken to the operating room emergently for closure and peritoneal washout.

Most perforations are located on the anterior surface of the first portion of the duodenum, immediately distal to the pylorus, and are less than 5 mm in diameter. In younger patients, patients with preexistent anemia, and patients whose time-to-operation was less than 24 hours, simple closure and peritoneal irrigation are as effective as more extensive gastric resection. Typically, the peritoneal cavity is washed with 5 to 10 liters of warm saline before repair of perforation is attempted. For perforations larger than 5 mm, a patch of omentum is secured in a tension-free fashion over the defect, with absorbable sutures placed into the seromuscular layer adjacent to the ulcer, provided it appears to be healthy, viable tissue. The integrity of the repair is tested by insufflating air through the nasogastric tube under low pressure. To prevent fluid collections and monitor for ongoing leakage, a Jackson-Pratt drain is left in the hepatorenal recess. The anesthesia team should be made aware that the nasogastric tube should be left in place at the cessation of the procedure.

Postoperatively, repair of perforated DU should be followed by PPI and antibiotic therapy to reduce the risk of recurrence. If the suspected cause of perforation is NSAID use, these agents should be discontinued in the postoperative period. However, in patients who require continued postoperative NSAID use or those unlikely to comply with anti–*H. pylori* and antisecretory regimens, HSV or truncal vagotomy and drainage should be considered instead of patch closure. Patients who have previously failed medical management—namely, those who have developed perforation while on antibiotics and antisecretory drugs—should be considered for acid reduction surgery as well. Patients with ongoing shock, delayed presentation beyond 48 hours, marked comorbid disease, and significant peritoneal contamination are poor candidates for definitive surgery, and patch closure should be used in these patients.

There is growing evidence that laparoscopic approaches, especially the Graham patch or vagotomy, to repair DUs are safe and effective in experienced hands. Patients with ongoing hemodynamic stability, multiple medical comorbidities, or peritonitis lasting longer than 24 hours are best served with an open approach. Patients with radiographic evidence of large duodenal defects or complex locations may preclude use of a laparoscopic approach and should probably

be managed openly initially. Multiple trials report improved rates of wound infection and pain control among patients treated laparoscopically. However, there appears to be no difference in the length of hospital stay or rates of postoperative complications between the open and laparoscopic approaches. Therefore, for the stable patient with minimal risk factors, it is reasonable to consider laparoscopic HSV or the Taylor procedure (posterior truncal vagotomy and anterior seromyotomy or anterior parietal cell vagotomy). However, patients with large or complex duodenal perforations are best served with an open surgical approach.

Postoperatively, we perform an upper gastrointestinal (GI) study on every patient on the second or third day. If there is no evidence of leakage and the stomach is emptying appropriately, the patient is started on a clear liquid diet. Perioperative antibiotics are not required unless there was peritoneal purulence noted at time of operation. All patients receive intravenous PPIs, and patients for whom serologic findings showed the presence of *H. pylori* are initiated on appropriate treatment immediately. Drain outputs are collected routinely to observe for bilious drainage to suggest postoperative leakage, especially at the initiation of oral diet. Postoperative leak in the stable patient, without signs of peritonitis or clinical decompensation, can be managed conservatively. On discharge, all patients who did not undergo definitive acid suppression surgery are placed on PPI. A carbon-labeled breath test is scheduled in one month for patients undergoing treatment for *H. pylori* to confirm eradication.

Perforations due to DU are typically small and anteriorly placed. However, large or even "giant" perforations (>2.5 cm) and those that are inconveniently placed may be better treated by definitive surgery such as vagotomy and pyloroplasty or duodenal intubation and serosal jejunal packing. Omental patching may still be successful in the case of large perforation in the emergent setting and may be recommended for the inexperienced technician because of the ease of performance (Figure 1). Total gastrectomy is rarely indicated because it often creates more technical difficulty in the repair and because omental and serosal patching have such high success rates.

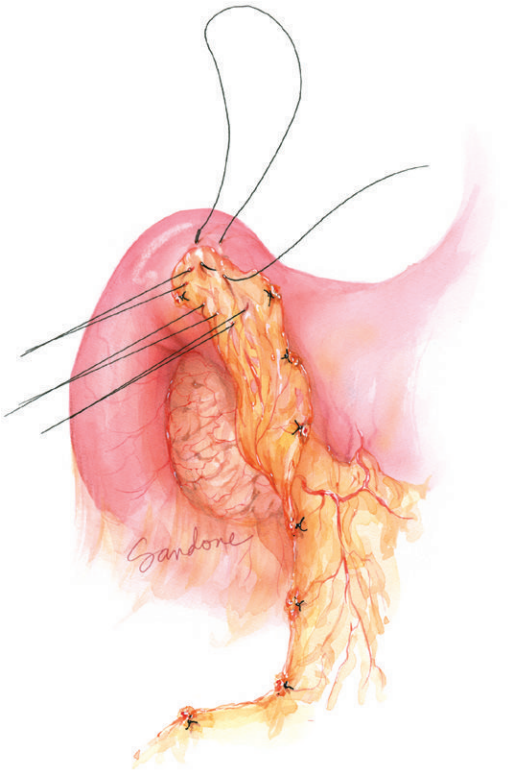

FIGURE 1 Omental patch. *(Illustration by Corinne Sandone, from Cameron JL:* Atlas of surgery, *vol 2, St. Louis, 1994, Mosby-Year Book. Reprinted with permission.)*

Bleeding Duodenal Ulcers

Bleeding DUs are a common initial presentation for DU disease and carry a significant mortality rate. Approximately 2.5% of patients hospitalized with bleeding ulceration will die of this complication. There is a 15% risk at 5 years for hemorrhage in patients with DUs who have not had surgery and who have not received continuing maintenance therapy. For patients treated with H2 blockers, PPIs, or therapy for *H. pylori*, the risk of hemorrhage has not changed significantly since the introduction of these agents. Patients with history of hemorrhage from duodenal ulceration are at an increased risk of bleeding again, in which the rebleeding rate may be as high as 30% to 40% and the mortality rate 10% to 40%. However, the rates of surgery for bleeding ulcer have steadily declined as endoscopic management has become more popular and has been shown to achieve excellent results in initial management of acute GI bleed. Patients older than age 65 also appear to be at an increased risk of experiencing hemorrhage associated with their DUs than do younger patients.

Patients should be placed on a PPI drip immediately on suspicion of a bleeding DU. Endoscopic management has largely surpassed surgery as the initial approach in acute GI hemorrhage and can correctly identify the source of bleeding in approximately 90% of patients. Clipping, cautery, and epinephrine injection are often employed techniques for endoscopic hemorrhage control and are commonly used in conjunction with one another. There is some evidence that, after successful treatment of bleeding, an endoscopic "second look" procedure the following day may decrease the risk of rebleeding. Endoscopic management is less likely to be successful in patients who experience hemodynamic instability at presentation, who have an ulcer base greater than 2 cm, a deep posterior location of the DU, and a transfusion requirement greater than 4 units in a 24-hour period. Endoscopic management should be performed in tandem with surgical consultation to allow for timely identification of patients for whom surgery is required.

Patients with bleeding DUs are typically referred to surgery if bleeding continues after conservative management or if there is evidence of recurrent bleeding after two attempts at endoscopic therapy. Many of these lesions are in the posterior proximal duodenum. In patients demonstrating hemodynamic instability at the time of evaluation, simple oversewing of the ulcer is the procedure of choice. After a midline or upper midline laparotomy, anterolateral duodenectomy is performed, allowing for visualization of the posterior ulcer. Heavy permanent sutures and a u-stitch are used to oversew any visible bleeding vessel in the ulcer base. If bleeding is vigorous, especially to the point of obstructing the view of the ulcer base, a Kocher maneuver may be performed to mobilize the proximal duodenum and allow for manual compressing of the ulcer between the thumb and finger of the surgeon. Multiple u-stitches may be required and care should be taken to avoid unintentional involvement of the common bile duct in the stitch because of its close approximation with the posterior duodenum. A two-layer closure technique is used to repair the duodenectomy and the operation is completed. Postoperatively, the patient should be maintained on intravenous PPI infusion.

Definitive ulcer management with truncal vagotomy or HSV should be reserved for patients at low risk who are hemodynamically stable. In this case, the initial approach is the same. However, the duodenectomy may then be carried through the pylorus, which will be later closed in a Heineke-Mikulicz or Finney pyloroplasty. Until recently, vagotomy with antrectomy was considered the gold-standard definitive ulcer surgery for patients with recurrent DU bleeding. However, recent studies have placed its position as such in question. Yet, vagotomy with antrectomy and subsequent Billroth II

reconstruction is still a reasonable option in stable patients with chronic ulcer diathesis (Figure 2). In patients for whom a partial gastrectomy results in more than 50% of the gastric area removed, reconstruction should be performed using a Roux method. Closure of the DU is essential regardless of the method of reconstruction. The ulcer may be oversewn through an anterior duodenectomy, as previously described, or through the open end of the duodenum. Lesions that are within the proximal duodenum can create difficulty with closure of the duodenum stump and may preclude this method of treatment.

Postoperatively, the patient should be continued on intravenous PPI infusion. If *H. pylori* status was not determined preoperatively, operative biopsy of the gastric mucosa may prove helpful in determining this diagnosis. The role of definitive ulcer therapy, such as truncal vagotomy and antrectomy or HSV, in patients who have not been adequately treated for *H. pylori* has not yet been examined. In such cases, oversewing of the ulcer bed alone with postoperative therapy for *H. pylori* eradication may be reasonable. In patients with sources of duodenal bleeding that are difficult to identify, angiographic embolization may be helpful. Recent series, although small, report high success rates and low risks of recurrent bleeding in patients treated by angiography. Patients who experience recurrent bleeding after definitive surgery may be initially managed by antisecretory agents, but up to 50% require reoperation.

Obstruction Duodenal Ulcers

Acute and chronic gastric outlet obstruction may occur as a result of a large, edematous DU. Patients with untreated duodenal ulceration have a lifetime risk of 10% for pyloric stenosis. Acute obstruction is often successfully managed with conservative treatment involving nasogastric decompression with nasogastric intubation, fluid resuscitation, and intravenous PPI administration. Symptoms of acute disease typically include early satiety, bloating, nausea, and vomiting. Laboratory examinations reveal hypochloremic alkalosis due to the loss of gastric secretions. These patients rarely require operative intervention. Upper endoscopy is indicated to rule out malignancy, a far more common cause of gastric outlet obstruction, and will demonstrate active ulceration with significant edema.

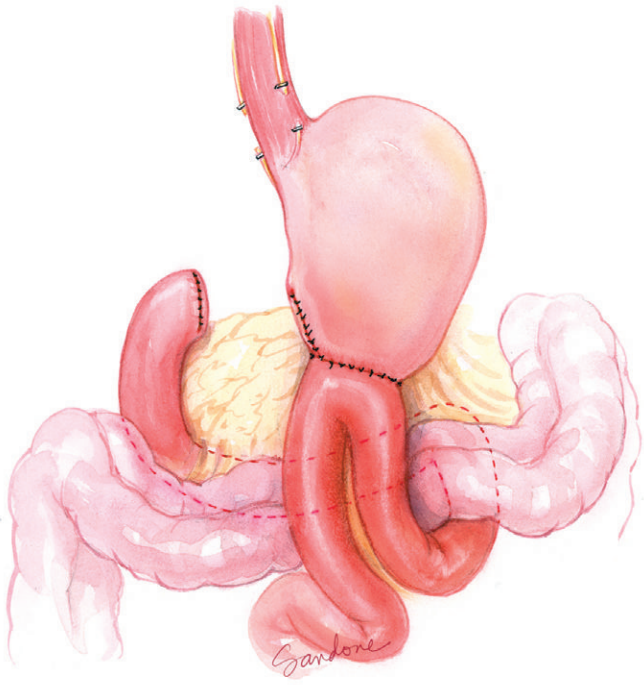

FIGURE 2 Billroth II reconstruction. *(Illustration by Corinne Sandone, from Cameron JL:* Atlas of surgery, *vol 2, St. Louis, 1994, Mosby-Year Book. Reprinted with permission.)*

Chronic outlet obstruction due to DU differs from acute in both the length of the settings (typically weeks to months) and the severity of the weight loss. Diagnostic tests, including an upper GI series, will reveal a distended stomach and significant narrowing of the pylorus, secondary to stenosis due to chronic edema and inflammation. The resulting scar and fibrosis may prevent the progression of an endoscope beyond the pylorus. Patients with chronic outlet obstruction do not experience durable relief of symptoms with gastric decompression and PPI infusion. As such, operative intervention is often required (>90% of patients).

After confirmation that the pyloric stenosis and subsequent obstruction are due to duodenal ulceration and not malignancy, relief of the anatomic abnormality is the focus of intervention. Upper endoscopy with balloon dilatation of the pyloric cicatrix is the first-line therapy in most instances. Success rates are high with initial relief achieved in 80% of patients and sustained improvement in 50% to 70% of those treated, but many patients will have to undergo multiple dilatations. Patients who require more than two dilatations should be considered for operative intervention, as they are at a high risk for failure of endoscopic treatment. Yet another consideration for the progression to surgery is the fact that an estimated 67% of patients treated for gastric outlet obstruction due to duodenal ulceration do not have *H. pylori* infection, and early acid-reducing surgery is warranted.

The surgical options for treatment of gastric outlet obstruction are primarily laparoscopic or open HSV with gastrojejunostomy (HSV/GJ) or vagotomy and antrectomy. Although both treatments are equally effective clinically, several other factors are helpful in determining the appropriate therapy. Surgeons adept in laparoscopic techniques may prefer the HSV/GJ because of its minimally invasive nature. However, malignancy is by far the most common cause of gastric outlet obstruction in the adult population, and this may be difficult to diagnose by laparoscopic techniques. Biopsy of the ulcer should be performed when the patient is undergoing laparoscopic repair for gastric outlet obstruction. When HSV is performed, gastrojejunostomy is the preferred drainage procedure compared with pyloroplasty. Some centers recommend the placement of a feeding jejunostomy tube at the time of surgery to minimize the risk of postoperative malnutrition and delayed gastric emptying, which may be complications for 10% to 50% of postoperative patients.

Intractable Duodenal Ulcers

The number of patients affected by intractable DUs has decreased since the advent of PPI therapy. Much of the literature regarding treatment of intractable DUs relies on patients undergoing therapy before the widespread use of antisecretory agents. Therefore, patients afflicted with intractable ulcers today may represent a population different from those previously described, including atypical pathophysiology that is largely as yet unrecognized. Intractable ulcers should also prompt a workup for gastrinoma. A history of noncompliance with medications complicates both the acute and postoperative management of many of these patients. Acid-reducing surgery, particularly HSV, serves as the mainstay of therapy, although the surgeon should strongly judge the ability of large resections to address the underlying etiology, which may be unknown, of the duodenal disease and the likelihood of patient adherence to a strict postoperative regimen. Gastrojejunostomy may also be performed in conjunction with HSV. Prior to either operation, many patients are treated empirically for *H. pylori* infection. Factors that increase the risk of developing duodenal ulceration, including smoking and aspirin or other NSAID use, should be stopped. Postoperatively, the patient should be placed on PPIs indefinitely.

Atypical Indications

Giant DUs are those measuring greater than 2 cm. Given their size, they represent a surgical challenge and leakage following repair with typical patch methods is a common complication. No consensus management exists regarding the care of these patients. Patients that present with hemodynamic instability warrant immediate operative intervention with attempted repair or patch of the perforation and identification of any sites of bleeding. In the low risk patient, more definitive ulcer operation may be indicated, including vagotomy and antrectomy. An innovative approach using placement of gastrostomy and jejunostomy tubes at the time of repair, to drain the gastric contents without the use of a nasogastric tube, decompress the duodenum, and allow for early enteral feeding has also been suggested in these patients.

Marginal ulcerations are those that affect the perianastomotic region following a gastrojejunostomy, most commonly seen after gastric bypass operations for morbid obesity. Factors that may affect the risk of marginal ulcer include ischemia, aspirin or other NSAID use, gastrinoma, smoking, and excluded antrum following revisional gastric bypass surgery. In the setting of recurrent marginal ulcer following previous vagotomy or acid-reduction surgery, further differential diagnosis includes incomplete vagotomy, retained antrum, long afferent limb (after Billroth II), and ongoing *H. pylori* infection. Retained or excluded antrum causes the antrum to no longer be exposed to gastric acidification and, therefore, hypergastrinemia results, causing further gastric acid creation. Pancreatic polypeptide levels and gastric acid output after feeding are used to assess completeness of the vagotomy, as they are both mediated through vagal stimulation.

Initial evaluation with upper endoscopy will help to make the diagnosis and allows for control of bleeding from the ulceration site. It is recommended that insufflation during the procedure be kept to a minimum to reduce gastric distention and tension on the anastomosis. Patients with recurrent or persistent *H. pylori* infection should receive an appropriate regimen. For persistent marginal ulcer, operative intervention may be warranted. The goal of the surgeon should be to remove the affected mucosa with reanastomosis and reduction in the acid-secreting capabilities of the stomach. Incomplete truncal vagotomy is often addressed through thoracoscopic truncal vagotomy. Open or laparoscopic approach is performed by resection of the distal gastric remnant, including the gastrojejunostomy, and reanastomosis. Simple conversion of a gastroduodenostomy or gastrojejunostomy to a Roux-en-Y gastrojejunostomy must be done in conjunction with acid reducing surgery.

Duodenal Closure

The posterior location of many DUs increases the complexity of duodenal stump closure following partial gastrectomy and subsequent gastrojejunostomy. The duodenal stump is most easily closed with a GI anastomosis or thoracoabdominal stapler (blue cartridge). Not uncommonly, stapler use is precluded because of grossly friable tissue in the posterior duodenal wall, an already challenging location for closure. In these cases, the anterior wall of the duodenum may be sewn to the most proximal aspect of the distal ulcer lip demonstrating a healthy seromuscular layer. Repair is usually carried out with an absorbable suture in interrupted fashion. An omental patch can be then oversewn to the closure site. Air may be insufflated with a nasogastric tube to allow for inspection of the integrity of the closure. If possible, end duodenostomy, with closure of the duodenal stump around a tube to allow for decompression, should be avoided because of the high likelihood for leakage. Instead, duodenal decompression should be accomplished by a retrograde placed jejunostomy tube. Placement of a gastrostomy and jejunal feeding tube should be considered as at initial intervention.

Zollinger-Ellison Syndrome

Haggi Mazeh, MD, and Herbert Chen, MD, FACS

INTRODUCTION

In 1955, Zollinger and Ellison described a syndrome characterized by ulceration of the upper jejunum, hypersecretion of gastric acid (gastrinoma), and non-beta islet cell tumors of the pancreas. Since their first description, more than 1000 patients have been diagnosed with Zollinger-Ellison syndrome (ZES) and more than 3400 papers have been published on this rare disease. ZES differs from typical peptic ulcer disease in nearly every aspect and therefore requires special consideration. Despite its rarity, surgeons should be aware of the current available diagnostic tools and the different management aspects of ZES because an increasing number of patients are diagnosed with ZES and appropriate management should be tailored to each one. The purpose of this chapter is to review the epidemiology, pathogenesis, presentation, diagnosis, and management of ZES. Management controversies are highlighted.

EPIDEMIOLOGY

Zollinger-Ellison syndrome is a very rare entity, and its incidence rate in the United States is estimated at 1 to 3 per million per year. ZES is also estimated to constitute 0.1% to 1% of all patients with peptic ulcer disease; however, the actual number may be higher because some of the patients with entitled peptic ulcer disease may have undiagnosed ZES. Most ZES cases are sporadic (80%), but 20% are associated with multiple endocrine neoplasia type 1 (MEN 1). Only approximately 25% of the patients with MEN 1 have ZES. The mean age of symptom onset is 41 years, and up to 90% of the patients are diagnosed between ages 20 and 60 years. Nevertheless, patients as

young as 7 years and as old as 90 years have been identified. Patients with MEN 1 are more likely to present younger (at the third decade of life). A slight male predominance is seen, with a male : female ratio of 1.5-2 : 1.

PATHOGENESIS

Gastrinomas are derived from the enteroendocrine cells that are multipotential endodermal stem cells and are found mainly in the pancreas and small intestine. Tumors that arise from these cells are considered neuroendocrine tumors and are entitled gastrinomas when these cells secrete gastrin that results in the typical clinical manifestation. Recent advances identified several genetic mutations that are involved in ZES. These include the oncogenes *c-myc* and *HER-2/neu* and the tumor suppressor genes *MEN-1, p16INK4a,* and *DPC4/Smad.*

The result of excessive gastrin secretion is high gastric acid output. Gastrin has a trophic effect on parietal cells that secrete acid and enterochromaffin-like cells that secrete histamine, a potent acid secretion stimulant.

CLINICAL PRESENTATION

- Peptic ulcers. More than 90% of the patients with ZES have development of peptic ulcers. The ulcers are most commonly solitary and less than 1 cm in diameter. Ulcer location may vary; 75% occur in the first part of the duodenum, 14% in the distal duodenum, and 11% in the jejunum. Ulcers in patients with ZES are more often persistent and tend to recur.
- Diarrhea. More than 70% of the patients with ZES have diarrhea that results from the high rate of acid secretion, inactivation of pancreatic enzymes by low pH, and the inhibition of sodium and water absorption in the small bowel.
- Other symptoms include abdominal pain (90%), heartburn (44%), nausea/emesis (30%), gastrointestinal bleeding (25%), and weight loss (17%).
- Metastatic disease to the liver and bone is present in up to 33% of the patients with ZES and may cause local symptoms.

DIAGNOSIS

The diagnosis of ZES is based on clinical evaluation, laboratory testing, and imaging.

Clinical Evaluation

Despite increased awareness to ZES, the mean delay between symptom onset and correct diagnosis is 5 to 6 years. Correct diagnosis at the time of presentation is made in only 5% of patients with MEN 1 ZES and in only 2% of the patients with sporadic disease. This can partially be explained by the high prevalence of proton pump inhibitor (PPI) usage that may mask symptoms by providing very effective acid secretion suppression. A high index of suspicion should be maintained in patients with: 1, a combination of diarrhea, abdominal pain, and weight loss; 2, refractory or recurrent ulcers; 3, any symptoms of acid hypersecretion that are associated with diarrhea; 4, prominent gastric folds on endoscopy (caused by trophic gastrin effect); and 5, any gastrointestinal symptoms in patients with MEN 1. Family history and pituitary and parathyroid disease should be assessed to evaluate the possibility of MEN 1.

Laboratory Testing

- Fasting serum gastrin. This test should be routinely performed in all patients with suspected ZES. Patients should be off PPIs for 72 hours and fasting for 12 hours. A serum gastrin level greater than 1000 pg/mL (normal limits <110 pg/mL) is virtually diagnostic; however, multiple circumstances may cause gastrin elevation (Table 1). Specifically, achlorhydria with elevated gastric pH should be considered. Up to 60% of patients with ZES have gastrin levels less than 500 pg/mL, and additional testing should be obtained when ZES is suspected.
- Secretin stimulation test. This test can be used to differentiate between patients with ZES and patients with other causes of hypergastrinemia and should be performed routinely. Secretin (intravenous [IV], 0.4 μg/kg) is administered, and gastrin levels are measured at 0, 2, 5, 10, 15, and 30 minutes. Patients with ZES have a dramatic increase in gastrin levels, and an increment greater than 110 pg/mL is considered positive. A rise of 200 pg/mL above baseline has a sensitivity of 83% to 93% and a specificity of 100% for the detection of ZES.
- Ruling out of MEN 1. Serum calcium, parathyroid hormone, prolactin, and fasting insulin levels should be measured. Patients with suspected MEN 1 should undergo genetic testing.
- Other tests. Gastric acid secretion studies have been largely abandoned because of their invasiveness, and serum chromogranin A level is not as specific and sensitive as the previous tests and therefore is not routinely used. Selective arterial stimulation with calcium gluconate (calcium infusion study) followed by venous sampling is another test that is not routinely used because of decreased sensitivity.

Imaging Modalities

As many as 70% of the gastrinomas form in the duodenum, and the remainder arise in the pancreas (20%) and in adjacent lymph nodes (10%). Although up to 80% of the gastrinomas are located in the gastrinoma triangle (Figure 1), 20% may occur at different sites; because of their small size, accurate preoperative localization is of utter importance. Another purpose of the imaging modalities is assessment of local extension and identification of metastatic disease. Such studies include ultrasound scan, computed tomographic (CT) scan, magnetic resonance imaging (MRI), somatostatin receptor scintigraphy (SRS), fluorodeoxyglucose positron emission tomography (FDG-PET), endoscopic ultrasound scan (EUS), and angiography.

Because 80% of the gastrinomas express type 2 somatostatin receptors, SRS is the modality of choice with a sensitivity of 85% and specificity close to 100%. EUS has a sensitivity that reaches 70% and is particularly useful for intrapancreatic primary tumors. The

hypervascularity of gastrinomas can be used with contrast CT scan (50% sensitivity), MRI (30% to 50% sensitivity), and angiography (60% sensitivity). Gastrinomas located within the duodenal wall appear to be particularly resistant to detection with these modalities. Intraoperative ultrasound scan may be used to facilitate localization of small lesions that were not readily visible on preoperative studies. Arterial secretin stimulation and gastrin measurement at specific locations may also aid in intraoperative localization.

MANAGEMENT

The management of patients with ZES has evolved over the years. Before the development of effective acid-reducing medications, the morbidity and mortality associated with ZES was mainly the result of hypersecretion complications, and the only effective treatment was total gastrectomy. With the introduction of H2 antagonist and PPI medications, the mortality associated with hypersecretory complications has been, for all intents and purposes, eliminated. Estimates are that 60% to 90% of the gastrinomas are malignant, and therefore current management of ZES includes medical therapy to control the symptoms and complications of gastrin hypersecretion and surgery for selected patients to control the tumor.

Medical Management

Patients with ZES should be started on a high dose of PPIs (omeprazole, 60 mg daily; pantoprazole, 120 mg daily) to control acid secretion. Half the patients without MEN 1 are able to titrate down to a maintenance dose of 20 mg daily. Long-term treatment with PPIs has been generally safe, even in high doses.

Systemic therapy with somatostatin receptor analogs such as octreotide reduces gastrin secretion. Such therapies have been used with variable results and are not considered first-line agents. Systemic chemotherapies such as cisplatin and doxorubicin have also been tried with limited success.

Surgical Management

The effective use of PPIs to control acid secretion has dramatically altered the surgical management of ZES. The current role of surgery is to manage the long-term outcome of patients because of the malignant potential of the primary tumor.

Sporadic Disease

Because gastrinoma resection results in excellent prognosis and because the importance of malignancy control is increasingly appreciated, all patients at good risk with sporadic gastrinoma and no evidence of metastatic spread should be offered resection with curative intent. Such resection may eliminate or decrease the need for PPIs and prevent the morbidity and mortality associated with future metastatic spread. Patient selection and preferably preoperative localization are of utter importance as the medical treatment enables elective surgery that must be performed safely with specific goals and weighed against effective expectant management and excellent long-term prognosis of these patients.

The surgical goal is to detect and resect the primary tumor and to identify local spread to lymph nodes or distant metastasis to the liver. At laparotomy, abdominal exploration to identify peritoneal spread and liver palpation should be performed in every patient. This should be followed by a wide Kocher's mobilization of the duodenum and the pancreas head. The entire pancreas and duodenum should be exposed and mobilized to permit bimanual palpation. Intraoperative ultrasound scan, duodenal transillumination, and duodenotomy are advocated in all patients. For lesions not identifiable with other imaging modalities, palpation may identify 50% to 65% of duodenal gastrinomas, endoscopic transillumination may detect an additional 15% to 20%, and duodenotomy another 15%. Routine duodenotomy resulted in doubling the surgical cure rate from 30% to 60%. The use of intraoperative ultrasound scan may facilitate lesion localization and assess the relation of the tumor to pancreatic duct. Single lesions identified on exploration should be resected, including in the liver. Pancreatic head and neck gastrinomas should be enucleated when possible or resected with pancreaticoduodenectomy (Whipple's procedure) in selected patients. Distal pancreatectomy should be performed for pancreatic tail lesions. If the gastrinoma is not found in surgery, blind distal pancreatectomy should be avoided as different ectopic locations include small bowel mesentery, liver, and ovary. The resection of pancreatic or duodenal gastrinoma should be accompanied by regional lymph node dissection.

Because of the trophic effect of gastrin and excess of gastric parietal cells, gastric secretion may not return to normal after surgical gastrinoma resection. Up to 40% of the patients need long-term PPI treatment as a result of increased acid secretion for a mean of 8 years.

Multiple Endocrine Neoplasia Type 1

In patients with MEN 1 ZES, diagnosis and treatment of hyperparathyroidism before the gastrinoma surgical management is considered is important. The correction of hyperparathyroidism reduces the fasting serum gastrin concentration by eliminating the hypercalcemia as a contributing factor and decreases the basal acid secretion. Total parathyroidectomy with autotransplantation or subtotal parathyroidectomy is generally advocated for patients with hyperparathyroidism and MEN 1.

The surgical management of patients with MEN 1 ZES is challenging, and surgical recommendations are in evolution. Short of pancreaticoduodenectomy, cure is uniformly not possible in MEN 1 ZES because 30% of the patients have more than 20 duodenal tumors and 86% have positive lymph nodes. Biochemical relapse occurs in more than 95% of the patients within 3 to 5 years of surgery, and liver metastases develop rarely and in correlation to tumor size. In contrast, acid secretion can be managed medically in these patients; therefore, current recommendations include surgery only for patients

TABLE 2: Differences between sporadic Zollinger-Ellison syndrome (ZES) and multiple endocrine neoplasia type 1 (MEN 1) ZES

	Sporadic ZES	MEN 1 ZES
Prevalence rate	80%	20%
Family history	–	+
Other endocrinopathies	–	+
Gastrinoma size	>2 cm	<2 cm
Number of tumors	Single	Multiple
Most common tumor location	Pancreas	Duodenum
Lymph node primary	10%	–
Surgical cure rate	60%	Rare
Malignant potential	High	Low

with a tumor greater than 2 to 2.5 cm in size. Table 2 summarizes the differences between sporadic and MEN 1 ZES.

Metastatic Disease

Metastatic gastrinoma is currently the most common cause of morbidity and mortality in patients with ZES, but unfortunately, current therapy is limited. Liver resection is indicated in resectable disease and in the absence of compromised liver function and extrahepatic metastasis. The effect of somatostatin analogs (octreotide) in controlling gastrinoma symptoms is not predictable and has shown inconclusive results in metastatic disease. Hepatic artery embolization with or without selective artery chemotherapy infusion is used in patients who are symptomatic but are not surgical candidates with an approximately 50% response rate. Radiofrequency ablation or cryoablation may be used for small liver lesions. Liver transplantation is reserved for patients with isolated metastases to the liver, and most clinicians consider it an investigational approach. Chemotherapy and radiotherapy have limited effect in gastrinomas, which resulted in the development of novel therapeutic approaches that include molecular targeted therapy such as tyrosine kinase and mTOR inhibitors. These therapies are under clinical trials.

Reoperation

Because 70% of the patients with sporadic ZES have persistent or recurrent disease, the role of reoperation is important. Reoperation may prove beneficial in cases where cure can be achieved. Unfortunately, such cure intent cannot be accomplished in most patients; therefore, the increased potential risk should be weighed against the cure odds in every patient.

OUTCOMES AND PROGNOSIS

Surgery results in cure of ZES in 60% of the patients with sporadic disease, but MEN 1 ZES is rarely cured. Benign gastrinomas rarely cause mortality, and the prognosis of patients with ZES largely depends on the presence of malignant disease (60% to 90%) and the extent of disease. The staging of gastrinomas is dictated by tumor size, lymph node involvement, and presence of distant metastases (tumor node metastasis [TNM]) and is detailed in Table 3. Up to one fourth of the patients have liver metastases at the time of diagnosis, and patients with liver metastases have only a 30% 10-year survival rate as compared with a more than 80% rate in those without. Patients with MEN 1 ZES have as low as a 6% rate of metastases at the time of diagnosis, which translates to an excellent survival rate (100% at 20 years). The 10-year survival rate with or without surgery for patients with sporadic ZES is detailed in Table 3.

TABLE 3: Gastrinoma staging and prognosis with or without surgery

Stage	TNM	10-Year survival rate with surgery	10-Year survival rate without surgery
I	T < 2 cm	94%-96%	68%-82%
II	T > 2 cm	86%-91%	40%-55%
III	Any T, any N, M1	65%-90%	7%-50%

TNM, Tumor node metastasis.

Clear association between gastrin level at the time of diagnosis and the prognosis has been shown. Patients with mildly elevated gastrin levels (0 to 499 pg/mL) had 94% and 86% 5-year and 10-year survival rates, respectively. Patients with moderate elevation (500 to 1000 pg/mL) had 92% and 87% 5-year and 10-year survival rates, respectively. Lastly, patients with severe elevations (>1000 pg/mL) had 86% and 73% 5-year and 10-year survival rates, respectively.

POSTOPERATIVE SURVEILLANCE

Current surveillance guidelines include history and physical examination, serum gastrin values, and abdominal imaging (CT scan or MRI) at 3 and 6 months after resection. Thereafter, history, physical examination, and serum gastrin values are recommended every 6 to 12 months for 1 to 3 years and then as clinically indicated. Imaging studies are recommended only as clinically indicated.

AREAS OF CONTROVERSIES

- Vagotomy during laparotomy. Despite effective medical management of acid hypersecretion, parietal cell vagotomy decreases the need for long-term PPIs and avoids the side effects that include achlorhydria that may lead to vitamin B_{12} and iron deficiency. Long-term use of PPIs may also result in the development of gastric carcinoid tumors, and for these reasons, selective vagotomy may be considered when laparotomy is performed for gastrinoma.
- Pancreaticoduodenectomy. Given the good prognosis of patients with ZES, pancreaticoduodenectomy should be carefully weighed against the risks. Whipple's procedure also modifies the anatomy and may affect future interventional methods for liver metastases. Because most gastrinomas in MEN 1 ZES are located in the duodenum, Whipple's procedure may increase the cure rates in these patients; however, this should be offered only to patients in whom gastrin source is localized to the pancreatic head.
- Lymph nodes. Lymph node primary gastrinomas do occur in up to 10% of the cases, and lymph nodes may be involved with tumor from another primary. The extent of lymph node

dissection is controversial and should be tailored to each patient as the routine lymph node removal may increase surgical cure rates.

- Liver metastases resection. Patients with liver metastases who undergo removal of all known disease have a 5-year survival rate of up to 85%. Patients with tumor burden that is unresectable may still benefit from cytoreduction surgery that may affect symptoms that result from tumor endocrine function. Surgical liver metastases resection should probably be offered only to patients in whom at least 90% of the tumor could be removed.
- Laparoscopy. Despite increased technical laparoscopic capabilities and experience, gastrinomas present several challenges. Duodenotomy and palpation of duodenal wall is an essential part of the exploration of all patients with ZES gastrinoma, and the tumors tend to be large and often present with liver metastases. These factors make laparoscopy unappealing for the treatment of gastrinomas.

CONCLUSION

The surgical management of ZES has evolved since its first introduction. At present, gastric acid reducing medications can control symptoms, and the current role of surgery is to manage the long-term outcome of patients because of the malignant potential of the primary tumor. Because of the rarity of this syndrome, areas of controversy exist and future studies with larger cohorts are needed to shed light on the optimal management of these complicated cases.

MALLORY-WEISS SYNDROME

Brian D. Shames, MD, and David W. McFadden, MD

HISTORY

In 1879, Heinrich Quincke described three cases of gastrointestinal (GI) bleeding caused by ulcers of the esophagus. Subsequently, in 1929, G. Kenneth Mallory and Soma Weiss, described a syndrome of massive upper GI (UGI) hemorrhage from fissure-like lesions of the esophageal mucosa. These lesions developed at the junction of the esophagus and gastric cardia and were caused by alcohol-induced retching or vomiting. For the next 40 years, reports of Mallory-Weiss syndrome were sporadic and numbered less than 250 in total. Treatment was equally divided between supportive observation and surgical hemostasis. The introduction of flexible endoscopy in the early 1970s revolutionized the diagnosis and management of UGI hemorrhage. Mallory-Weiss syndrome has since become a more commonly diagnosed cause of UGI hemorrhage, and a myriad of associated causal factors for the development of Mallory-Weiss tears have been described. The syndrome that bears their names now encompasses all causes of linear mucosal lacerations of the gastroesophageal junction (GEJ) that lead to UGI bleeding. The syndrome should not be confused with Boerhaave's syndrome, which is distal esophageal perforation as a result of vomiting.

INCIDENCE, PATHOPHYSIOLOGY, AND ASSOCIATED CONDITIONS

Although the syndrome was once thought to be a rare cause of UGI bleeding, multiple large studies with flexible endoscopy have shown a 5% to 15% incidence rate of Mallory-Weiss syndrome in patients with acute UGI hemorrhage. Mallory-Weiss tears are the second most common etiology of upper GI nonvariceal bleeding after ulcer disease. How frequently a Mallory-Weiss tear occurs without bleeding cannot be determined with any certainty. It is highly likely that the condition occurs in a less severe form more often than is clinically recognized.

The pathophysiology of Mallory-Weiss tears has not been completely defined. A factor common to most causes of Mallory-Weiss tear is an acute increase in intraabdominal pressure. The most common symptoms before the development of hemorrhage are vomiting and retching. During emesis, the pylorus closes, the abdominal wall and diaphragm contract, the gastric cardia relaxes as the distal stomach contracts, and intragastric contents are forcefully expelled in a cephalad direction. Mucosal tears are thought to be the result of the rapid development of a large gradient between the intragastric pressure and the intrathoracic pressure at the GEJ, which occurs in actions like vomiting and retching. The forceful elevation of the GEJ above the diaphragm leads to the dilation and subsequent tearing of the gastroesophageal mucosa.

Reported risks factors for the development of a Mallory-Weiss tear include hiatal hernia, chronic alcoholism, and increasing age. Mallory-Weiss syndrome usually occurs in the fifth and sixth decades of life. In one report, 44% of cases were associated with alcohol use, but no risk factor was documented in 23%. Any disorder that initiates vomiting or retching may result in the development of a Mallory-Weiss tear. This includes reports of Mallory-Weiss tears associated with hyperemesis gravidarum, pancreatitis-related emesis, eating disorders such as bulimia, cardiopulmonary resuscitation, primal scream therapy, blunt abdominal trauma, chemotherapy-associated emesis, paroxysms of coughing, childbirth, straining for bowel movement, seizures, scuba barotrauma, and endoscopy. In women of childbearing age, the most common cause of these tears is hyperemesis gravidarum, which usually occurs in the first trimester and causes severe persistent nausea and vomiting.

Alcohol use and liver disease have long been associated with Mallory-Weiss syndrome. However, Mallory-Weiss tears represent a cause of UGI bleeding in only 3% to 10% of patients with cirrhosis, which is similar to the prevalence rate of this condition in the general

population. The frequency of bleeding from a Mallory-Weiss tear has been reported to be significantly higher in patients with advanced liver disease, especially in patients with Child-Pugh grades B and C. In a second study, 14 of 42 patients (33%) with acute esophageal bleeding related to Mallory-Weiss tears had liver disease. The severity of bleeding was significantly worse in patients with liver disease, but it was not correlated with portal hypertension or Child-Pugh classification.

Hiatal hernia has been found in 40% to 100% of patients with Mallory-Weiss tears and has been considered by some to be a necessary predisposing factor. It has been proposed that, in hiatus hernia, a higher pressure gradient develops in the hernia compared with that in the rest of the stomach during retching, thereby increasing the potential for mucosal laceration. Mallory-Weiss tears may also be more likely to occur when the upper esophageal sphincter does not relax during vomiting. However, the presence of a hiatal hernia is found in a minority of patients with Mallory-Weiss syndrome, which makes its relevance questionable.

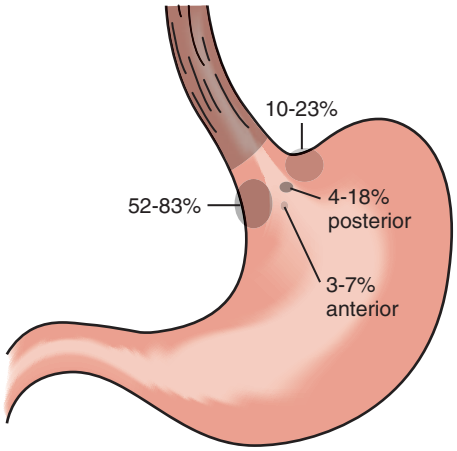

FIGURE 1 Distribution of mucosal tears in Mallory-Weiss syndrome. Data compiled from multiple series.

DIAGNOSES AND OUTCOMES

Hematemesis is the presenting symptom in 80% to 90% of patients with Mallory-Weiss syndrome, although 10% may have melena as the first sign of bleeding. The triad of retching and vomiting followed by hematemesis varies in occurrence, ranging from 30% to 80% of cases. A history of recent alcohol ingestion is common but not invariable. The use of aspirin or nonsteroidal antiinflammatory medications before Mallory-Weiss hemorrhage has been found in up to 30% of cases. Abdominal pain is not a common presenting symptom because most episodes of bleeding from Mallory-Weiss tears are painless. As many as 50% of patients may not have a history of vomiting preceding hematemesis, and 25% may have no identifiable risk factor. Because the history and symptoms of Mallory-Weiss syndrome can be indistinguishable from those of other common causes of UGI bleeding, differentiation of Mallory-Weiss tears from other causes of UGI hemorrhage without invasive diagnostic studies is difficult.

Before diagnostic interventions are undertaken, as with all patients with GI bleeding, the patient needs to have appropriate intravenous access and the severity of the bleeding assessed. Hemodynamic instability and shock are present in up to 10% of patients with Mallory-Weiss tears. Volume resuscitation should consist of crystalloids and blood products when deemed necessary. Initial laboratory studies should include measures of hematocrit, blood type and crossmatch, and coagulation parameters. Any defects in coagulation should be corrected, and this effort should be considered part of the initial resuscitation. Serial assessments of the hematocrit and hemodynamic monitoring should be used to judge the efficacy of resuscitation and any therapeutic maneuvers. Nasogastric tube placement and gastric lavage with 250 mL of room temperature saline solution can be used to assess for the presence of active hemorrhage and to clear the stomach of blood that may obscure subsequent endoscopy. Once resuscitative efforts have been instituted and the patient's condition has been stabilized, diagnostic interventions should be considered.

Flexible endoscopy is the current standard of evaluation of UGI bleeding. A complete evaluation of the esophagus, stomach, and proximal duodenum should be performed. A retroflexion view of the GEJ is essential in the evaluation. Mallory-Weiss tears appear as linear lacerations of the mucosa of the gastric cardia, GEJ, or distal esophagus. Tears that involve only esophageal mucosa are uncommon. Most Mallory-Weiss tears (52% to 83%) occur below the GEJ along the lesser curve of the stomach; 10% to 23% occur along the greater curvature below the GEJ. Anterior and posterior tears range between 3% and 7% and 4% and 18%, respectively (Figure 1). Most tears average 0.5 to 2.5 cm, but they may be up to 5 cm in length. Endoscopy reveals a single tear in 76% to 90% of cases. Two lacerations have been described in 8% to 15%, and three tears have been found in 1% to 8%. The coexistence of other sources of UGI bleeding, such as esophageal varices, gastritis, duodenitis, and peptic ulcerations has been seen in 32% to 82% of patients.

Bleeding from Mallory-Weiss tears is self limited in 90% of patients, and therapeutic action is not needed. Healing of the tears occurs in 48 to 72 hours. When no active bleeding is seen at the initial endoscopy, which occurs in 50% to 75% of cases, cases can be managed with supportive care only. Recurrent bleeding is unusual but has been described in up to 10% of cases. In one retrospective study of 159 patients with Mallory-Weiss syndrome, 17 patients (10.7%) presented with recurrent bleeding. These patients were compared with 142 patients who had a benign course. The demographics of the patient and initial general physical status were not associated with the risk of recurrent bleeding. In addition, no significant differences were seen in the risk of recurrent bleeding for those patients with comorbid diseases, including diabetes and cardiovascular disease. A history of peptic ulcer or alcohol abuse had no influence on the risk of recurrent bleeding. However, the proportion of patients with comorbid liver cirrhosis was higher (41% vs 18%; $P = 0.028$) in those patients with recurrent bleeding.

Active bleeding, such as spurting or active oozing from the tear, is associated with recurrent bleeding. Active bleeding was seen during endoscopy in 88% of patients (15 of 17) with recurrent bleeding as opposed to 38% of patients (55 of 142) without ($P < 0.001$) in a retrospective study. The risk of recurrent bleeding was not associated with the number and location of the tear, the length of the tear, the presence of hiatal hernia, or waiting time for endoscopy. Additional studies have suggested that an initial hematocrit value less than 30%, the presence of a nonbleeding visible vessel, coagulopathy, or the presence of liver dysfunction predict recurrent bleeding. The presence of any one of these factors requires more aggressive treatment and monitoring.

Reported mortality rates related to Mallory-Weiss syndrome range from a low of 1.5% to a high of 10%. Identified risk factors for mortality in a retrospective study that analyzed 93 patients with Mallory-Weiss syndrome included advanced age, very low hemoglobin levels, elevated aspartate aminotransferase (AST) level, and the presence of the clinical sign of tarry stool. A separate study revealed the following significant risk factors for mortality: the presence of liver cirrhosis or shock, low hemoglobin levels and platelet counts, low blood pressure and a high pulse rate at admission, and an endoscopic finding of active bleeding.

TREATMENT

Endoscopic therapy is the mainstay for treatment of Mallory-Weiss syndrome. The need for surgical or alternative therapies such as angiographic techniques or the use of a Sengstaken-Blakemore tube is increasingly rare given the success of endoscopic techniques. In modern studies, surgery is necessary in less than 1% of patients. Endoscopic hemostasis is accomplished with various techniques, including injection therapy, multipolar electrocoagulation, band ligation, and hemoclipping. Combinations of the various techniques have also been reported. Unfortunately, no definitive randomized trials have been performed to determine which therapy is most effective.

Lessons learned from treatment of other more common causes of GI bleeding have been applied to the treatment of Mallory-Weiss tears. Mechanical hemostasis (hemoclip, banding) has been effectively used in patients with peptic ulcer bleeding or Dieulafoy's-like lesions. The advantages of a mechanical technique include greater patient safety, fewer associated complications, and a less expert technique needed. Endoscopic band ligation is commonly used to treat variceal bleeding and is indicated for nonfibrotic bleeding lesions that can be aspirated into the hood of the ligation device. Band ligation has some advantages, including ease of deployment, even if the bleeding site must be approached tangentially. Furthermore, the hood of the device fixes the bleeding site, which minimizes motion, and the visible vessel is ligated in its deeper aspect. Hemoclips have a similar ease of use and are highly effective. Band ligation and clip application appear to be equivalent treatment for primary hemostasis (100%) and have a similar incidence rate of rebleeding (6% vs 10%).

Endoscopic injection therapy has been shown to be an effective and safe treatment of UGI hemorrhage. Injection therapy has varied from the use of purely vasoconstricting agents like epinephrine to sclerosing agents like polidocanol and dehydrated ethanol or combinations thereof. Epinephrine injection is most commonly used to treat Mallory-Weiss tears; reported rates of primary hemostasis range from 93% to 100%. However, several series have suggested that the use of epinephrine injection alone could lead to an increased risk of recurrent bleeding as compared with mechanical techniques. However, epinephrine injection in combination with hemoclip placement has been used extensively in bleeding peptic ulcer and has also been used with Mallory-Weiss tears in an attempt to decrease recurrent bleeding.

Which endoscopic therapy is best? Although no definitive studies are found, some data from prospective studies, case series, and retrospective studies do exist. In 2004, a prospective, randomized trial compared the effectiveness of endoscopic band ligation with epinephrine injection for actively bleeding Mallory-Weiss tears. Although the study was small (17 patients per group), the authors showed no difference in the efficacy or safety of band ligation versus epinephrine injection for the treatment of actively bleeding Mallory-Weiss tears. No reoccurrence of bleeding was seen in either group. A 2009 retrospective trial compared the efficacy of band ligation (29 patients) with hemoclip placement associated with epinephrine injection (27 patients). This study found that both techniques are safe and effective in primary hemostasis. However, recurrent bleeding occurred significantly more often in patients treated with hemoclip placement and epinephrine injection versus treatment with band ligation (18% vs 0%; $P = 0.02$). One explanation for this finding is that treatment of Mallory-Weiss tears at the GEJ is probably more technically demanding when a hemoclip is used compared with band ligation at this site. Furthermore, clip placement is quite superficial, and esophageal and gastric motility may result in the clip falling off. In contrast, band ligation is much easier to perform, even when the scope is tangential to the lesion, and it results in a much deeper ligation. The authors of this study suggest that the first-line treatment of bleeding Mallory-Weiss tears should be endoscopic band ligation. However, in practice, the choice of endoscopic therapy depends on local expertise.

Angiographic techniques for control of UGI bleeding consist of intraarterial infusion of vasopressin and transcatheter embolization. The use of intraarterial vasopressin at rates of 0.2 to 0.5 U/min over varying lengths of time has yielded rates of hemostasis of 50% to 100% in small studies of Mallory-Weiss syndrome. Selective embolization of the left gastric artery or its branches has also been reported to be effective in the cessation of bleeding from Mallory-Weiss tears. In general, intra-arterial therapy should be reserved for those patients with failed endoscopic therapy and who are poor surgical candidates.

The use of Sengstaken-Blakemore tubes for control of Mallory-Weiss bleeding has been reported with varying degrees of success. Their use is controversial and considered an act of desperation. Concern about their usage in patients with Mallory-Weiss syndrome centers on the risk of extending the mucosal tears into full-thickness tears of the esophagus or stomach. The presence of hiatal hernia is also a contraindication to the use of such tubes because the asymmetric pressure gradient generated by the gastric balloon may lead to necrosis and perforation of the herniated portion of the stomach.

SURGERY

Before the widespread use of flexible fiberoptic endoscopy, surgery was needed to control hemorrhage from Mallory-Weiss tears in approximately half of all cases. Today, surgery for Mallory-Weiss syndrome is uncommon and rare, even at many tertiary referral centers. Surgical rates have declined from a high of 50% in the preendoscopy era to 0 to 3% in the most recent published series. Surgery is usually reserved for those patients with failed endoscopic therapy. In general, if patients have rebleeding after initial endoscopic therapy, a repeat endoscopy is indicated. A suggested treatment algorithm is shown in Figure 2.

Surgical control of bleeding from Malloy-Weiss tears has classically been performed through open surgery with a high anterior longitudinal gastrotomy to gain visualization of the mucosa at the GEJ. Localization of the site of bleeding before laparotomy is important. Subserosal staining of blood near the GEJ is characteristic of Mallory-Weiss bleeding and can be used as a clue to the location of the mucosal tear. This sign, however, is present in only a minority of patients. Simple oversewing of the tear with absorbable sutures suffices. When localization of the site of bleeding has not occurred or when visualization is impaired by ongoing hemorrhage, packing the stomach with laparotomy pads and sequential inspection of all of the gastric mucosa can help in locating the source of bleeding. Intraoperative endoscopy is also a technique that may aide in the identification of the source of bleeding. Inspection for other sources of hemorrhage is wise because 32% to 82% of the Mallory-Weiss tears coexist with other common causes of UGI bleeding.

A combined laparoscopic and endoscopic technique for oversewing Mallory-Weiss tears has been described. Laparoscopy was performed with port placement as is customary for foregut surgery. Endoscopy was then used to localize the site of the tear. Full-thickness absorbable sutures were then placed with endoscopic guidance to occlude the site of hemorrhage. Patients who come to surgery are typically at higher risk for complications and mortality. This is more a reflection of the contribution of comorbid conditions and the sequelae of severe hemorrhage rather than the complexity of surgery.

SUMMARY

Mallory-Weiss tear is a linear mucosal laceration of the GEJ that leads to UGI bleeding. It is caused by any condition associated with forceful vomiting or retching. The bleeding is self limited in 90% of patients, and when treatment is mandated, endoscopic therapy is successful 99% of the time. Surgery, which consists of a simple

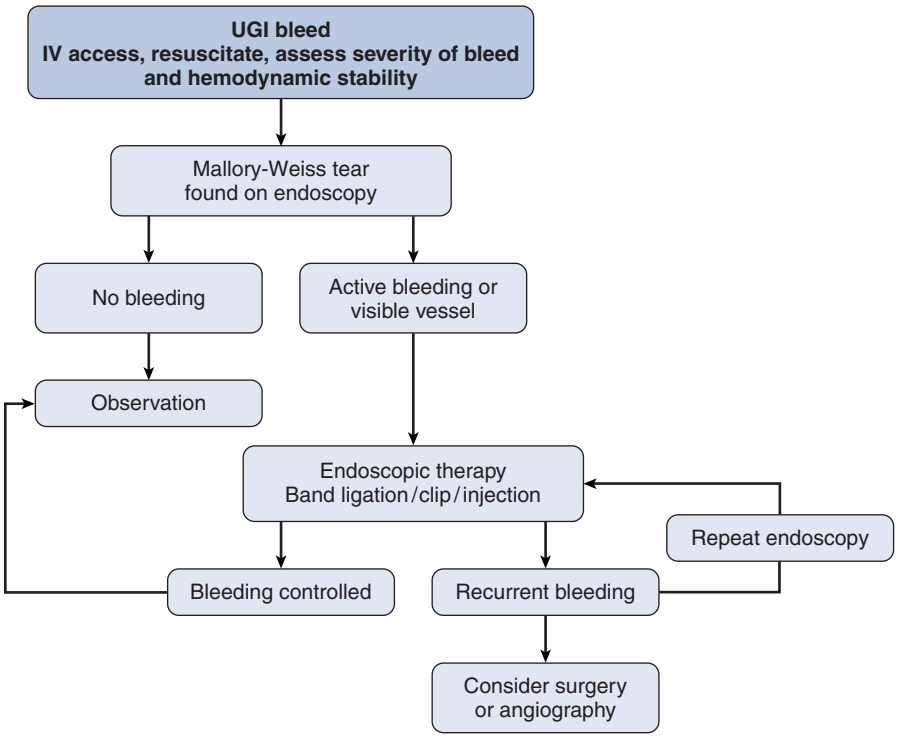

FIGURE 2 Treatment algorithm for Mallory-Weiss syndrome. *IV,* Intravenous; *UGI,* upper gastrointestinal.

oversewing of the bleeding mucosa, is reserved for patients with failed endoscopic therapy.

Gastric Adenocarcinoma

Sam S. Yoon, MD, and Do Joong Park, MD, PhD

INTRODUCTION

Epidemiology and Presentation

More than 1 million cases of gastric cancer are estimated to occur worldwide per year, with more than 700,000 deaths each year. Thus, gastric cancer is the fourth most common cancer and the second leading cause of cancer death. Gastric adenocarcinoma accounts for about 95% of gastric cancer cases. The incidence rate of gastric adenocarcinoma varies tremendously throughout the world and country by country. Nearly three quarters of cases occur in developing countries, and the countries with the highest incidence rates are in Eastern Asia (e.g., Korea, Japan, and China). The incidence rate of gastric cancer in the United States and Western Europe has been steadily declining and is currently only about one sixth that of Eastern Asia. Despite this, the incidence rate of proximal gastric cancer in Western countries is rising. Overall, males are affected twice as frequently as females, and the average age of presentation is between 60 and 70 years old.

Risk factors for gastric adenocarcinoma include *Helicobacter pylori* infection, diets high in smoked or salty foods, pernicious anemia, prior gastric surgery, chronic atrophic gastritis, and intestinal metaplasia. Genetic cancer syndromes that increase the risk of

gastric cancer include hereditary nonpolyposis colon cancer (HNPCC), Li-Fraumeni syndrome, Peutz-Jeghers syndrome, and hereditary diffuse gastric cancer (HDGC) syndrome.

Gastric adenocarcinoma is often asymptomatic in its early stages and in later stages causes weight loss, epigastric pain or discomfort, gastrointestinal bleeding, vomiting, and anorexia. In Japan and Korea, high awareness and common endoscopic screening for gastric cancer has led to the proportion of patients with early gastric cancer (i.e., T1 tumors) to reach about 50%. Unfortunately, in other countries, gastric cancer is found most frequently in advanced stages.

Pathology

Gastric adenocarcinoma arises in the inner mucosal lining of the stomach in the epithelial cell layer. As tumors grow deeper into the wall of the stomach (i.e., submucosa and muscularis propria), they can spread via lymphatics to regional lymph nodes and hematogenously to distant sites, most commonly to the liver. For T1b tumors (invading the submucosa), lymph node metastases are found in about 20% of patients. For T2 tumors (invading the muscularis propria), the lymph node metastasis rate increases to more than 50%. Tumors that penetrate the subserosa (T3) or serosa (T4a) of the stomach can progress to invade adjacent structures such as the pancreas, spleen, and colon (T4b) or disseminate via the peritoneal cavity, leading to carcinomatosis.

Several systems have been developed to classify gastric adenocarcinomas by macroscopic or histologic appearance. The most widely used histologic classification is the Lauren classification. The Lauren intestinal type exhibits components of glandular, solid, or intestinal architecture and tubular structures. This type is more common in men and older patients, is associated with environmental exposures such as *H. pylori* infection, and arises often from precancerous areas, such as chronic atrophic gastritis or intestinal metaplasia. The Lauren diffuse type shows single cells or poorly cohesive cells infiltrating the gastric wall, and progressive disease can ultimately lead to linitis plastica (also known as leather bottle stomach). The diffuse type does not typically arise from precancerous areas, is slightly more common in women and in younger patients, and is more associated with familial occurrence, thus suggesting a more genetic etiology. The incidence rate of the intestinal type has been declining, but the incidence rate of the diffuse type has remained either stable or increased.

Signet ring cells are neoplastic cells that contain a large amount of mucin, which pushes the nucleus to the periphery. The general perception is that the presence of these cells is a poor prognostic factor. However, signet ring cells can be found in early T1 tumors and may be associated with *improved* survival compared with T1 tumors without signet ring cells. Furthermore, for T2 or greater tumors, the presence of signet ring cells may not be an independent prognostic factor when patients are stratified by stage.

Preoperative Evaluation

The preoperative evaluation of patients with gastric adenocarcinoma involves establishing the diagnosis, assessing the extent of local disease, ruling out distant metastases, and assessing the patient's general medical condition. All patients should have an upper endoscopy, and information should be obtained as to the location, size, and degree of infiltration of the tumor. If endoscopic ultrasound (EUS) is available, this modality can give additional information, especially regarding T stage. An abdominal computed tomographic (CT) scan should be performed to identify possible regional and distant nodal disease, local extension of tumor to adjacent organs, liver metastases, and peritoneal metastases. The role of chest CT scan to rule out lung metastases or mediastinal nodal disease is controversial because the yield is low in the absence of intraabdominal metastases. Positron emission tomography (PET) or PET/CT scans are not generally obtained for staging given the low yield, but PET scans may be useful in the assessment of response of tumors to neoadjuvant treatment.

Small volume peritoneal carcinomatosis can be missed on abdominal CT scans, and so diagnostic laparoscopy can be performed. Furthermore, patients without overt peritoneal carcinomatosis may have microscopic free peritoneal tumor cells when peritoneal washings are performed. In one study from Memorial Sloan-Kettering Cancer Center, radiologically occult metastatic disease was identified with laparoscopy in 25% of patients who were determined with EUS to have T3-T4 or N+ disease and in only 4% of patient who were determined with EUS to have T1-T2 and N0 disease. The survival of patients without peritoneal carcinomatosis but with free peritoneal tumor cells in peritoneal washings may be similar to that of those with overt peritoneal carcinomatosis, although the increased efficacy of more recent chemotherapy regimens has called this into question.

Staging

The American Joint Committee on Cancer (AJCC) changed T and N definitions and the overall staging classifications of gastric adenocarcinoma in the seventh edition of the AJCC Cancer Staging Manual published in 2010 (Table 1).

SURGERY

Extent of Gastric Resection

For tumors in the middle or distal stomach, several studies have compared distal or subtotal gastrectomy with total gastrectomy. In the French cooperative trial of 169 patients with antrum tumors, 93 patients underwent total gastrectomy, and 76 underwent subtotal gastrectomy. No significant difference was found in perioperative mortality rate, and no difference was seen in 5-year survival rate (48%). In the Italian Gastrointestinal Study group multicenter, randomized trial of 618 patients with tumors of the distal half of stomach, there was also no difference in 5-year survival rate between subtotal and total gastrectomy (65% vs 62%). Thus, for patients with middle or distal tumors, distal or subtotal gastrectomy is adequate and total gastrectomy does not improve survival.

For proximal gastric cancers, few high-quality studies have examined the extent of gastric resection, and thus, the extent of gastric resection is largely governed by the preference of the surgeon. In one nonrandomized Norwegian study of 763 patients, complication and mortality rates were *higher* for patients who underwent proximal gastrectomy (52% and 16%) compared with total gastrectomy (38% and 8%). In another large study from Korea, An and colleagues examined a total of 89 patients who had a proximal gastrectomy and 334 patients who had a total gastrectomy for proximal gastric cancer. Complications were markedly higher in the proximal gastrectomy group, with major differences found in the rate of anastomotic stenosis and reflux esophagitis. Some groups, however, continue to advocate proximal gastrectomies for proximal gastric cancers.

In terms of the surgical incision required to remove a tumor confined to the proximal stomach, a laparotomy incision is usually sufficient. The National Cancer Center (NCC) group in Tokyo randomized 167 patients with proximal gastric tumors to total gastrectomy and D2 lymphadenectomy via a laparotomy or via a left thoracoabdominal incision. Higher morbidity and mortality rates were seen in the left thoracoabdominal incision group, but no difference was found in survival rate. However, for proximal third tumors extending into the gastroesophageal junction (GEJ) or distal esophagus, a left thoracoabdominal or Ivor-Lewis approach may be necessary.

TABLE 1: Seventh American Joint Committee on Cancer staging system for gastric adenocarcinoma

Primary Tumor	Tx	Primary tumor cannot be assessed.		
	T0	No evidence of primary tumor.		
	Tis	Carcinoma in situ: intraepithelial tumor without invasion of the lamina propria.		
	T1	Tumor invades lamina propria, muscularis mucosae, or submucosa.		
	T1a	Tumor invades lamina propria or muscularis mucosae.		
	T1b	Tumor invades submucosa.		
	T2	Tumor invades muscularis propria.		
	T3	Tumor penetrates subserosal connective tissue without invasion of visceral peritoneum or adjacent structures. T3 tumors also include those extending into the gastrocolic or gastrohepatic ligaments or into the greater or lesser omentum, without perforation of the visceral peritoneum covering these structures.		
	T4	Tumor invades serosa (visceral peritoneum) or adjacent structures.		
	T4a	Tumor invades serosa (visceral peritoneum).		
	T4b	Tumor invades adjacent structures, such as spleen, transverse colon, liver, diaphragm, pancreas, abdominal wall, adrenal gland, kidney, small intestine, and retroperitoneum.		
Regional Nodes	Nx	Regional lymph node(s) cannot be assessed.		
	N0	No regional lymph node metastasis.		
	N1	Metastasis in 1 to 2 regional lymph nodes.		
	N2	Metastasis in 3 to 6 regional lymph nodes.		
	N3	Metastasis in 7 or more regional lymph nodes.		
	N3a	Metastasis in 7 to 15 regional lymph nodes.		
	N3b	Metastasis in 16 or more regional lymph nodes.		
Metastases	Mx	Distant metastases cannot be assessed.		
	M0	No distant metastases.		
	M1	Distant metastases.

Gastric Reconstruction

Few good studies are found on the optimal reconstruction after distal or subtotal gastrectomy. In Japan and Korea, the preferred type of reconstruction is generally a Billroth I reconstruction; most United States surgeons prefer a Billroth II reconstruction. Roux-en-Y reconstruction results in less bile reflux into the stomach but can result in a Roux stasis syndrome. One Japanese study randomized 50 patients after distal gastrectomy for cancer to Billroth I or Roux-en-Y reconstruction. Five of 24 patients (21%) in the Roux group had gastrojejunal stasis develop in the early postoperative period, and this group had a longer mean hospital stay, but the Billroth I group had a higher incidence rate of bile reflux gastritis at 6 months after surgery (62% vs 30%).

Reconstruction after total gastrectomy is generally performed with a Roux-en-Y esophagojejunostomy with or without a jejunal pouch. Lehnert and colleagues reviewed 14 small randomized trials of jejunal pouch versus no pouch, each with 20 to 70 patients. The pouch added minimal operative time and did not increase morbidity. Food intake was somewhat improved in the early months, but this advantage decreased with time. Only 2 of 12 trials found a difference is postoperative weight, and only 2 of 9 trials found an improvement in quality of life. More recently, Fein and colleagues randomized 138 patients and found no differences in operative morbidity or mortality rates; short-term and long-term weight loss were similar in both groups. However, quality of life was found to be improved in years 3 to 5 after surgery in the pouch group.

Nodal Station and Lymphadenectomy Definitions

The extent of lymphadenectomy has been a persistent area of controversy in the treatment of gastric adenocarcinoma. Before discussion of lymph node dissections for gastric adenocarcinoma, one must define the terms to be used. The lymph node stations that surround

the stomach have been precisely defined by the Japanese Gastric Cancer Association (JGCA) (Figure 1 and Table 2). Table 3 shows the lymph node stations that should be removed for a D1 and D2 lymphadenectomy based on the extent of gastrectomy. The JGCA recommends D2 lymphadenectomy for any tumor T2 or deeper or with clinically positive nodes.

Location of Metastatic Lymph Nodes

For decades, centers in Japan and Korea have performed gastrectomies with extensive lymphadenectomies and then *ex vivo* dissected out and labeled the nodal stations. Pathologists then examine each nodal station separately and document which nodal stations contain metastatic disease. Thus, many excellent studies are found on the location of metastatic lymph nodes from gastric cancer based on tumor location and other tumor and patient factors. With use of a large database of patients treated with D2 or greater lymphadenectomy, Maruyama and colleagues at the NCC calculated the risk of the lymph node metastases in each lymph node station by location of primary tumor (Table 4). In 1989, the NCC database of 3843 cases was used to create the Maruyama computer program. This program estimates the risk of lymph node metastasis for each lymph node station based on the input of eight variables: gender, age, endoscopic or Bormann classification, depth of invasion, maximal diameter, location (upper, middle, or lower third), position (lesser or greater curvature, anterior or posterior wall, or circumferential), and World Health Organization (WHO) histologic classification. The Maruyama computer program was later expanded to include 4302 cases (WinEstimate 2.5, Springer, Berlin, Germany). By matching input variables to this large database of patients, the program gives a percent likelihood of disease in each of 16 lymph node stations. The applicability and accuracy of the Maruyama computer program have been confirmed in Western patients treated in Germany and in Italy.

Potential Benefits of More Extensive Lymphadenectomy

Lymphadenectomy for cancer can serve three *potential* purposes: staging of disease, prevention of locoregional recurrence, and improvement in overall survival. There is little doubt that more extensive lymphadenectomies for gastric adenocarcinoma lead to better staging of disease. The 2010 7th edition of AJCC Staging

Manual for gastric adenocarcinoma recommends that at least 16 lymph nodes be examined for correct assessment of the N category. Despite this, one analysis of the United States Surveillance, Epidemiology and End Results (SEER) database found that only 29% of 10,807 resected gastric cancer patients had 15 or more lymph nodes examined. It is difficult to be confident that a gastric cancer is truly node negative when few lymph nodes are examined, and N1 tumors can be upstaged to N2 or even N3 tumors as more lymph nodes are harvested. Furthermore, it is impossible to be categorized as N3b if less than 16 lymph nodes are harvested. In our analysis of more than 18,000 patients with gastric cancer in the SEER database, we found that more than 50% of patients were misclassified because of inadequate lymph node sampling.

Some evidence shows that more extensive lymphadenectomies result in lower rates of locoregional recurrence. Locoregional recurrence after potentially curative surgery for gastric adenocarcinoma can be quite high. In a 1982 series from the University of Minnesota, 107 patients with gastric adenocarcinoma underwent second look laparotomy, and 80% had a recurrence. Of these recurrences, 88% were locoregional, 54% were peritoneal, and 29% were distant. More recently, in United States Intergroup 0116 trial, 177 of 275 patients (64%) in the surgery-only group had recurrent disease develop. In terms of the site of first relapse, 29% had local recurrence, 72% had regional recurrence, and only 18% had distant recurrence. Rates of locoregional recurrence are generally lower in reports from both Western and Asian institutions that perform more extensive lymphadenectomies.

The effect of more extensive lymphadenectomies on overall survival for gastric cancer is still quite controversial. Most gastric surgeons in Japan and Korea believe that D2 or greater lymphadenectomies improve overall survival and refuse to perform a prospective, randomized trial of D1 versus D2 lymphadenectomy. Maruyama and colleagues determined the 5-year survival rate of patients with positive lymph nodes in each of the nodal stations, and many D2 node stations, when positive for metastases, have a significant percentage of patients surviving 5 years. For example, a lower third tumor has a 25% incidence rate of metastases in the common hepatic artery nodes. When these nodes were positive and resected as part of a D2 lymphadenectomy, the 5-year survival rate was 31%.

Several *retrospective* studies show that more extensive lymphadenectomies are correlated with improved survival. However, these retrospective studies suffer from the confounding issue of stage migration. Dissecting out additional lymph nodes results in patients often being upstaged, which makes subsequent comparisons regarding therapeutic benefit invalid.

Two large prospective randomized trials in the United Kingdom and the Netherlands failed to identify a survival advantage for D2 over D1 lymphadenectomy. However, these two trials had fairly high morbidity (43% to 46%) and mortality (10% to 13%) rates for the D2 lymphadenectomy group. In these trials, the distal pancreas and spleen were often resected during dissection of station 10 and 11 nodes, which significantly increased morbidity. Of note, in the Dutch trial, if patients with hospital mortality are excluded, patients with N2 disease had significant survival advantage when treated with a D2 lymphadenectomy. Several more recent studies now show that D2 lymphadenectomies can be performed without the need for distal pancreatectomy or splenectomy. Furthermore, a recent randomized trial in Taiwan showed an overall survival advantage of more extensive lymphadenectomy over D1 lymphadenectomy, with an overall 5-year survival rate of 59.5% compared with 53.6%, respectively ($P = 0.041$). Fifteen-year follow-up results from the previously described Dutch trial now show decreased locoregional recurrence and gastric cancer–related death in the D2 group. Degiuli and colleagues in Italy have shown that Western surgeons, following extensive training, can perform D2 lymphadenectomies on Western patients with low morbidity and almost no mortality, and survival results from a prospective randomized trial of D1 versus D2 lymphadenectomy from this group are pending.

TABLE 4: Frequency of lymph node metastasis based on location of primary tumor

Lymph node basin	Upper third (% with metastasis)	Middle third (% with metastasis)	Lower third (% with metastasis)
Paracardial (stations 1 and 2)	22	9	4
Lesser or greater curve (stations 3 and 4)	25	36	37
Right gastric artery/suprapyloric (station 5)	2	3	12
Infrapyloric (station 6)	3	15	49
Left gastric artery (station 7)	19	22	23
Common hepatic artery (station 8)	7	11	25
Celiac axis (station 9)	13	8	13
Splenic artery/hilum (stations 10 and 11)	11	3	2

D2 LYMPHADENECTOMY TECHNIQUE FOR SUBTOTAL/DISTAL GASTRECTOMY

Greater Curvature (Station 4sb and 4d) Node Dissection

An upper midline incision is made from the xiphoid to just below the umbilicus. An Omni retractor can be used to provide optimal exposure. The abdomen should be explored to rule out intraabdominal or liver metastases. The primary tumor should be assessed for proximal and distal extent and possible invasion of adjacent structures. A marking suture can be placed on the anterior gastric wall to identify the proximal extent of the tumor. One or two lap pads should be placed behind the spleen to push the spleen forward and prevent capsular tears.

The greater omentum is taken off the transverse colon, beginning from center and moving to the left, widely opening up the lesser sac (Figure 2, *A*). The dissection is continued such that the greater omentum is taken off the splenic flexure and the inferior aspect of the spleen. This dissection should expose the body and tail of the pancreas, and the left gastroepiploic vessels are divided near their origin from the splenic vessels just anterior to the pancreas (Figure 2, *B*). The greater curvature of the stomach between the end of the left gastroepiploic arcade and the start of the short gastric vessels should then be identified. This marks the left-most end of the greater omentum dissection. The omentum is divided from peripherally toward the gastric wall. On reaching the gastric wall, ultrasonic coagulating shears can be then used to dissect between the gastric wall and greater omentum from proximal to distal (Figure 2, *C*).

Infrapyloric (Station 6) Node Dissection

One should now return to where the mid portion of the greater omentum was taken off the transverse colon and continue this dissection toward the hepatic flexure. The infrapyloric lymph nodes are now dissected off the head of the pancreas. Dissection in this area should proceed cautiously to avoid tearing small vessels that lead to troublesome bleeding; use of ultrasonic coagulating shears is often helpful. Dissection should proceed such that all the soft tissue anterior to the pancreas is swept superiorly onto the specimen. The right gastroepiploic vein should be identified at its origin from the inferior pancreaticoduodenal arcade, ligated, and divided (Figure 2, *D*). The right gastroepiploic artery should also be divided at its origin from the gastroduodenal artery. A tunnel is then created between the first portion of the duodenum and the head of the pancreas.

Hepatoduodenal Ligament Hepatic Artery (Station 12a) and Suprapyloric (Station 5) Node Dissection

The peritoneal covering and soft tissue of the porta hepatis is opened from the mid lesser omentum near the undersurface of the liver toward the superior porta hepatis. One should then dissect on the lateral border of the proper hepatic artery from superior to inferior. The soft tissue between the suprapyloric nodes and proper hepatic artery nodes is then divided. This nodal tissue is then dissected from right to left, completely exposing the common hepatic artery/proper hepatic artery/gastroduodenal artery trifurcation. To the left of the proper hepatic artery, dissection continues posteriorly, exposing the left side of the portal vein. Once this portion of the dissection is completed, the right gastric artery (which usually originates from the proper hepatic artery or the gastroduodenal artery) is divided (Figure 3, *A*). The right gastric vein that originates from portal vein should also be divided.

The plane between the superior first portion of the duodenum and underlying pancreas is developed until the prior dissection from inferiorly is reached. Small vessels to the first portion of the duodenum are ligated and divided with the harmonic sealing device, thus mobilizing the entire first portion of the duodenum. The duodenum can now be transected distal to the pylorus (Figure 3,*B*).

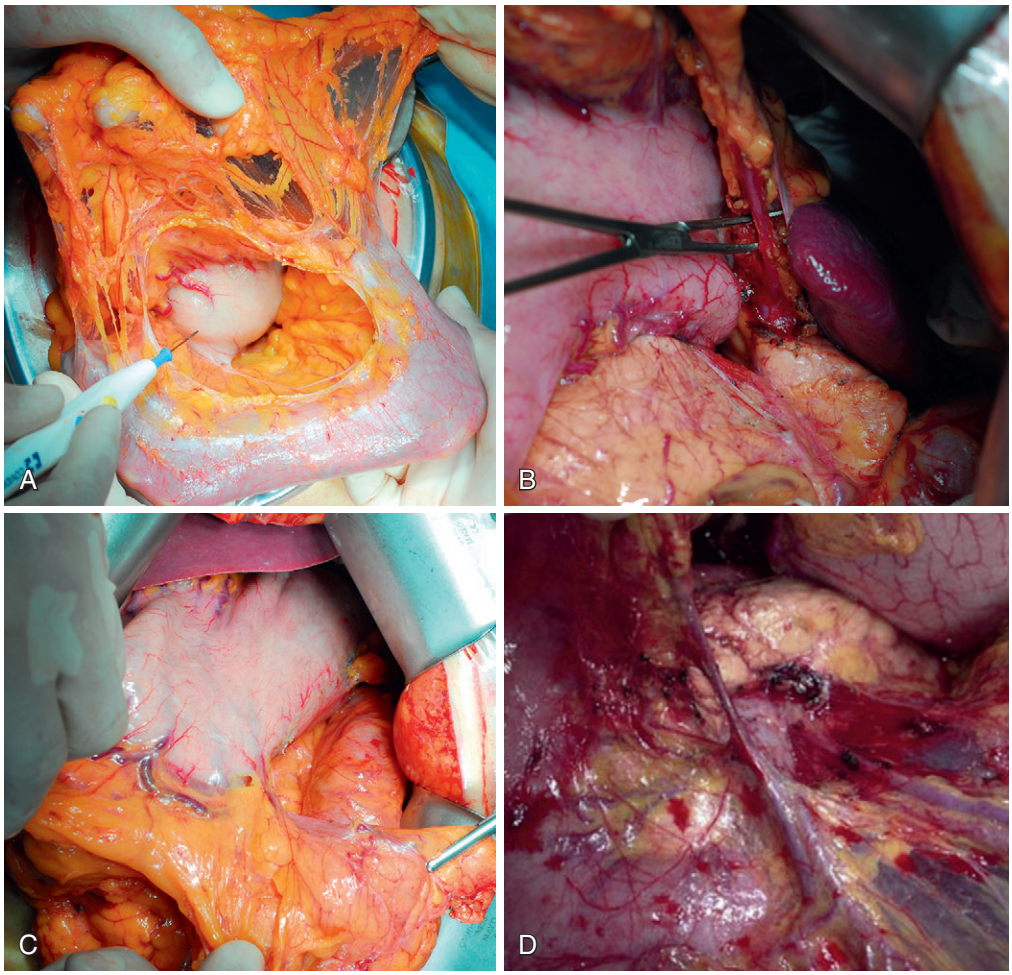

FIGURE 2 Operative photographs show: **A,** dissection of greater omentum off transverse colon; **B,** dissection of left gastroepiploic vessels near their origin from splenic vessels; **C,** dissection of greater curvature nodes; and **D,** dissection of right gastroepiploic vein from inferior pancreaticoduodenal arcade.

Common Hepatic Artery Dissection (Station 8a), Celiac Axis (Station 9), Proximal Splenic Artery (Station 11p), and Left Gastric Artery (Station 7) Lymph Node Dissection

This dissection begins with opening up the peritoneum overlying the superior border of the pancreas from the proximal splenic artery toward the common hepatic artery. Dissection proceeds from left to right and inferiorly to superiorly. All the nodal tissue anterior and superior to the proximal splenic artery should be cleared until retroperitoneal fat is reached. All the nodal tissue medial to the portal vein and anterosuperior to the common hepatic artery should be swept off the retroperitoneum and right crus. Again, this tissue tends to be vascular, and use of the ultrasonic coagulating shears is helpful. The left gastric vein (also known as coronary vein) originates from the portal vein and travels just to the right of the origin of the left gastric artery. This vessel should now be identified and divided. Dissection proceeds from inferior to superior, exposing the left gastric artery, which is taken at its origin. At the end of this dissection, the celiac axis and its branches are skeletonized (Figure 3,*C*).

Lesser Curvature (Station 3) and Right Paracardial (Station 1) Node Dissection

The lesser omentum is divided inferiorly to superiorly near its insertion onto the liver. A replaced/accessory left hepatic artery may be encountered and is generally divided unless the patient has underlying hepatic dysfunction. The lesser omentum dissection is continued to the GEJ, ensuring that the right paracardial nodes are incorporated. To ensure that the lesser curvature lymph nodes are included, all the soft tissue on the lesser curvature is taken off the lesser curvature of the stomach, from the GEJ to beyond where the stomach will be transected (Figure 3,*D*). The soft tissue in this region exists in two leaflets. A finger can be inserted between the leaflets, and soft tissue anterior and posterior to the finger can be divided off the stomach wall with the harmonic sealing device. The stomach can now be transected, and the proximal and distal margins should be sent for frozen section analysis.

Specimen Processing for Pathology

Back table ex vivo dissection of the operative specimen after removal of the specimen can aid the pathologist in identifying lymph nodes. Separate containers with each nodal station optimize the chances of having an adequate number of lymph nodes recovered by the pathologist. On the back table, the proximal and distal gastric staple lines are removed. The stomach is opened longitudinally along the lesser or greater curvature, whichever is away from the tumor. The gross proximal and distal margins are examined. The lymph node stations are then dissected out and sent as separate specimen. During initial cases, it may be best to mark these node stations with tags during the dissection to ensure proper ex vivo nodal dissection.

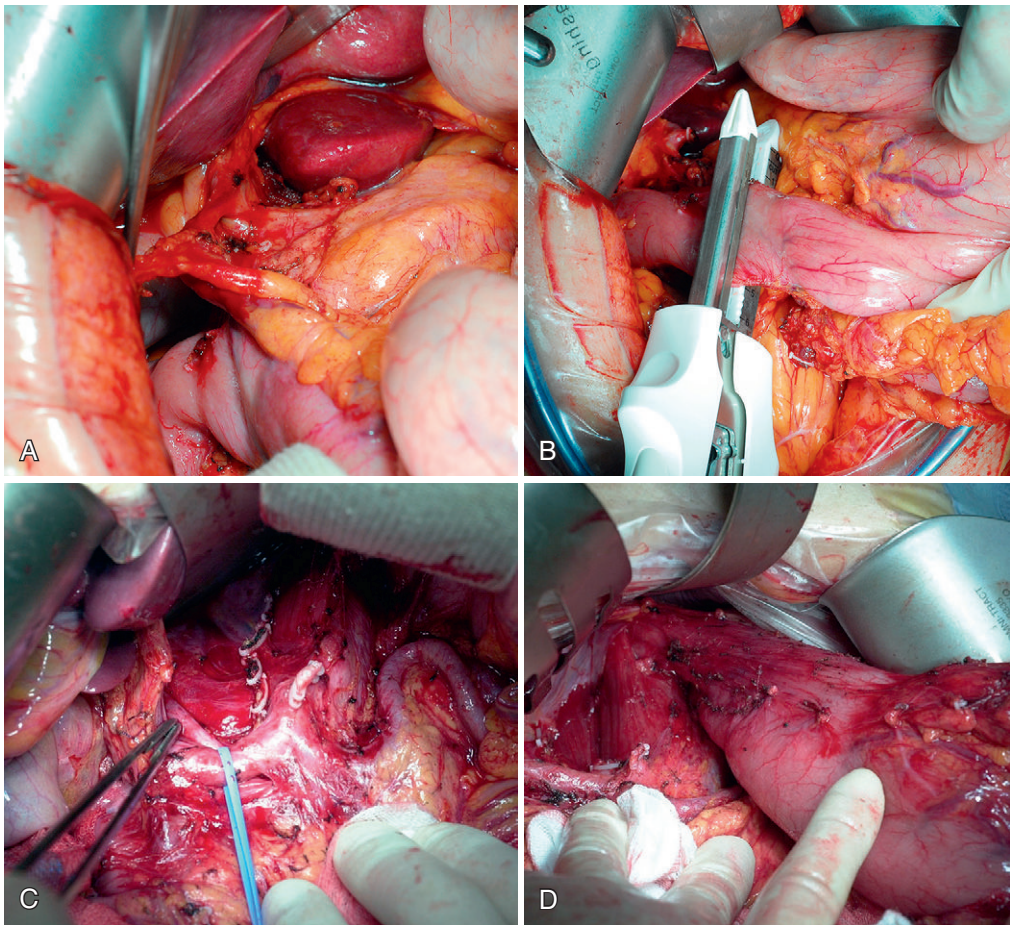

FIGURE 3 Operative photographs show: **A,** dissection of right gastric artery near origin from proper hepatic artery; **B,** transection of duodenum; **C,** completed dissection of proximal splenic artery, celiac axis, common hepatic artery, and divided left gastric artery; and **D,** dissection of right paracardial nodes off the gastroesophageal junction and lesser curvature.

D2 LYMPHADENECTOMY TECHNIQUE FOR TOTAL GASTRECTOMY

Compared with a distal gastrectomy, the only additional nodal stations that require dissection for a total gastrectomy are the greater curvature nodes along the short gastric vessels (station 4sa), left paracardial nodes (station 2), distal splenic artery nodes (station 11d), and splenic hilum nodes (station 10).

The station 4sa nodes can be taken early on after dividing the left gastroepiploic vessels near their origin. One can then continue the greater curvature dissection superiorly toward the GEJ, dividing the short gastric vessels near the medial border of the spleen. On reaching the GEJ, the left paracardial nodes can be dissected by dividing the phrenoesophageal ligament and sweeping all nodal tissue toward the GEJ.

Dissection of the distal splenic artery nodes should be performed after dissection off the proximal splenic artery nodes. Nodal tissue anterior and superior to the splenic artery is dissected of the retroperitoneal fat (Figure 4, *A*). To facilitate dissection of the splenic hilum nodes, the spleen and tail of pancreas can be mobilized anterior and to the left. The splenic artery forms several segmental branches, and all the nodal tissue anterior to these branches is dissected (Figure 4, *B*).

Reconstruction is generally performed with a Roux-en-Y method. The use of an end-to-end anastomosis (EEA) circular stapler may result in anastomotic stricture, which requires dilation. The authors now generally perform the side-to-side stapled technique, which is a modification of a technique described by Orringer. The esophagus is transected with endoscopic linear staples (3.5-mm staple size; Figure 4,*C*). The jejunal limb is brought posterior to the transected esophagus. A small enterotomy is made in the jejunal limb, 6 to 7 cm proximal to the transected end, and the mid portion of the esophageal staple line is removed. An endoscopic linear stapler (3.5-mm staple size, 45 mm in length) is used to create a side-to-side anastomosis (Figure 4,*D*), and the holes are closed with interrupted 3-0 silk sutures.

NEOADJUVANT AND ADJUVANT THERAPY

The risks of locoregional and distant recurrence are high for all T2 or more or node-positive gastric cancers even with surgical resection, thus providing rationale for the delivery of neoadjuvant and adjuvant therapies. The United States Intergroup 0116 trial was the first prospective randomized trial to show a survival benefit of 5-fluorouracil (5-FU) chemoradiation after surgery over surgery alone. Three-year overall survival rate was increased from 41% to 50% with chemoradiation ($P = 0.005$). In this trial, 54% of patients received less than a D1 lymphadenectomy and only 10% of patients received a D2 lymphadenectomy, and the chemoradiation appeared to primarily reduce logoregional recurrence. Thus, some have argued that the chemoradiation likely improved survival by making up for inadequate surgery. Of note, an observational study from Samsung Medical Center (Seoul, Korea) of 990 patients who underwent surgical resection along with D2 lymphadenectomy found that median survival rate was significantly increased in the 544 patients who underwent chemoradiation compared with the 446 patients who underwent no adjuvant therapy. More recently, the Adjuvant Chemoradiation Therapy in Stomach Cancer (ARTIST) trial randomized Korean

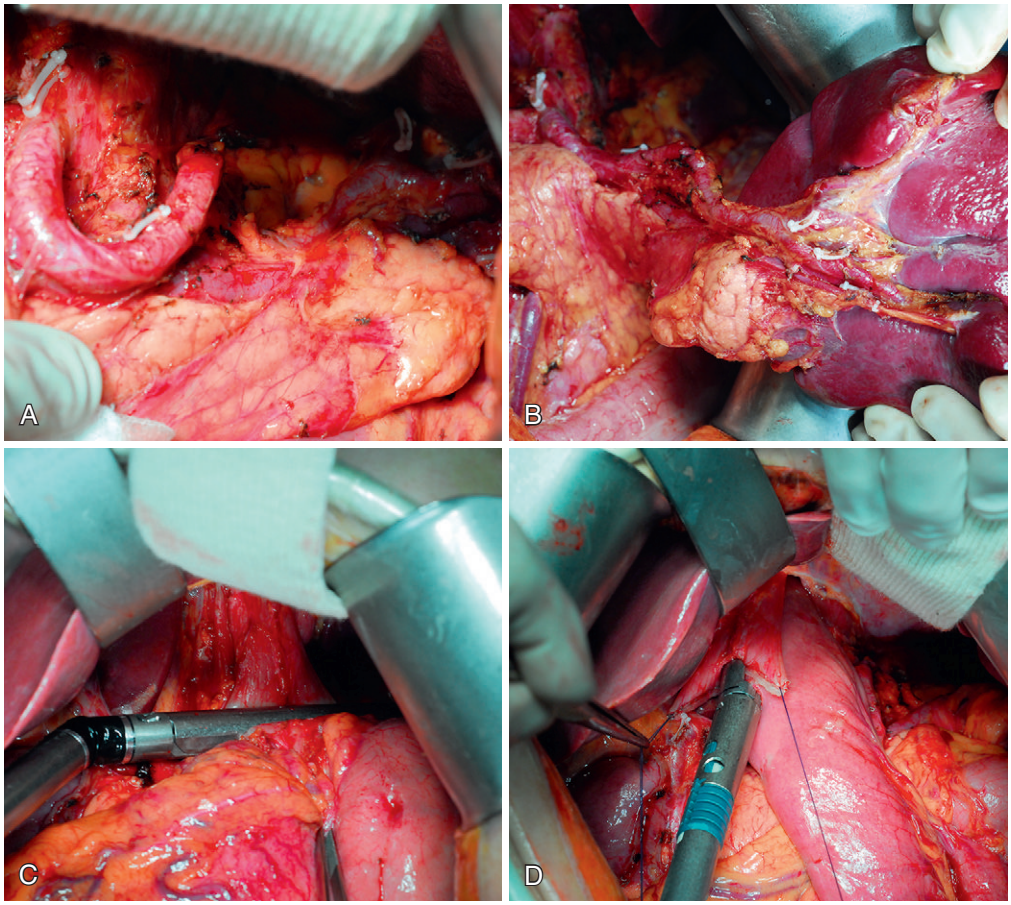

FIGURE 4 Operative photographs show: **A,** dissection of distal splenic artery; **B,** dissection of splenic hilum; **C,** transection of esophagus; and **D,** side-to-side esophagojejunostomy with linear stapler.

patients after gastrectomy to capecitabine and cisplatin (XP) chemotherapy or XP plus radiation and capecitabine. The overall trial results were negative, but disease-free survival rate was improved with chemoradiation in the subgroup of patients with node-positive disease.

Three prospective randomized trials, one from Europe and two from Asia, have shown survival benefits for neoadjuvant or adjuvant chemotherapy without radiation therapy. The European Organisation for Research and Treatment of Cancer (EORTC) Medical research Council Adjuvant Gastric Infusional Chemotherapy (MAGIC) trial randomized patients to three cycles of epirubicin, cisplatin, and 5-FU (ECF) chemotherapy before and after surgery or surgery alone and found a 5-year overall survival rate of 36% in the chemotherapy plus surgery group and 23% in the surgery-alone group ($P = 0.009$). Sakuramoto and colleagues randomized Japanese patients to surgery plus S-1, a 5-FU prodrug combined with an agent that lowers bowel toxicity and an agent that prevents 5-FU degradation, or surgery alone and found that the 3-year overall survival rate was 80% in the S-1 plus surgery group and 70% in the surgery-alone group ($P = 0.002$). Most patients in the EORTC MAGIC trial received at least a D1 lymphadenectomy, and most patients in the Japanese trial received a D2 lymphadenectomy, supporting the notion that chemotherapy alone can improve survival in patients with gastric cancer. The Adjuvant Capecitabine and Oxaliplatin for Gastric Cancer after D2 Gastrectomy (CLASSIC) trial randomized Asian patients after D2 gastrectomy to capecitabine and oxaliplatin chemotherapy or no chemotherapy; the 3-year disease-free survival rate was 74% in the chemotherapy group compared with 59% in the no-chemotherapy group ($P = 0.0001$). The Chemoradiation after Induction Chemotherapy in Cancer of the Stomach (CRITICS) multicenter trial is currently comparing MAGIC-style perioperative chemotherapy with preoperative chemotherapy followed by postoperative chemoradiation.

FOLLOW-UP

The utility of intensive follow-up of patients with gastric cancer after surgical resection is controversial, and significant differences are found in the recommendations of various groups. The European Society for Medical Oncology (ESMO) clinical recommendations for the follow-up of gastric cancer state, "there is no evidence that regular intensive follow-up improves patient outcomes, [and] symptom-driven visits are recommended for most cases." However, many patients are uncomfortable with minimal or no follow-up. The National Comprehensive Cancer Network practice guidelines for gastric cancer recommend a history and physical examination every 3 to 6 months for 1 to 3 years, every 6 months for 3 to 5 years, and then annually. Complete blood cell count (CBC), chemistry profile, tumor markers (carcinoembryonic antigen [CEA] and carbohydrate antigen 19-9 [CA19-9]), radiologic imaging, and endoscopy are recommended as clinically indicated. Ultimately, the decision regarding the intensiveness of follow-up is left to the treating physician after discussion with the patient.

SUMMARY

The surgical management of patients with gastric adenocarcinoma varies significantly around the world, and much of this is related to the wide range in incidence rates and thus wide range in exposure of surgeons to this disease. Useful diagnostic studies include upper

endoscopy, EUS, abdomen and pelvis CT scan, and diagnostic laparoscopy with peritoneal washings. The extent of gastric resection is governed by the location of the tumor. For mid and distal tumors, distal or subtotal gastrectomy can be performed, but for proximal tumors, total gastrectomy is generally performed. The extent of lymphadenectomy is also governed by the location of the tumor, but controversy exists as to whether a D1 or D2 lymphadenectomy is optimal. Unfortunately, more than half of patients in the United States receive less even a D1 lymphadenectomy. Two large randomized studies from Western countries that compared D1 and D2 lymphadenectomy showed no survival benefit for a D2 lymphadenectomy when performed with high morbidity and mortality. Performance of a D2 lymphadenectomy requires surgical training. Experienced surgeons in countries with high incidence rates such as Japan and Korea perform D2 lymphadenectomies for gastric with low morbidity and almost no mortality. Long-term results from the Dutch randomized trial and a Taiwanese trial suggest there may be a survival benefit for D2 lymphadenectomy. Overall survival results are pending from an Italian prospective randomized trial of D1 versus D2 lymphadenectomy in which the D2 group had low morbidity and mortality.

Gastrointestinal Stromal Tumors

Chandrajit P. Raut, MS, MSc, and Timothy M. Pawlik, MD, MPH, PhD

INTRODUCTION

Gastrointestinal stromal tumors (GISTs) are rare neoplasms that represent only 0.1% to 3% of all gastrointestinal malignancies. However, they are the most common sarcoma and account for 80% of gastrointestinal mesenchymal neoplasms. In the last 12 years, the understanding and treatment of GIST have witnessed remarkable advances as the result of two key developments: (1) the identification of constitutively active signals (oncogenic mutation of the c-KIT and platelet-derived growth factor alpha [PDGFRA] genes encoding receptor tyrosine kinases); and (2) the development of therapeutic agents that suppress tumor growth by specifically targeting and inhibiting this signal (imatinib mesylate, sunitinib malate). These developments in the management of GIST represent a proof of principle of translational therapeutics in oncology, confirming that specific inhibition of tumor-associated receptor tyrosine kinase activity may be an effective cancer treatment. The advent of effective therapy has dramatically improved outcomes for GIST, and instead of diminishing the role of surgery, it has redefined it. This chapter reviews the biology, treatment, and emerging clinical challenges of these mesenchymal neoplasms.

PATHOLOGIC FEATURES

Historical Background

The term *GIST* was initially proposed in 1983 by Mazur and Clark to describe intra-abdominal nonepithelial neoplasms that lacked the ultrastructural features of smooth muscle cells and the immunohistochemical characteristics of Schwann cells. A diagnosis of GIST is often suspected histologically because most cases have uniform appearances that fall into one of three categories: spindle cell type, epithelioid type, or mixed type. Interestingly, most gastric GISTs feature an epithelioid phenotype, and small intestinal, anorectal, colonic, and esophageal tumors more often feature spindle cell morphology.

On the basis of their histologic and immunohistochemical features, GISTs are believed to arise from the interstitial cells of Cajal, components of the intestinal autonomic nervous system that serve as potential intestinal pacemakers. Nonetheless, until the late 1990s, no objective criteria existed to classify GISTs. They were frequently misclassified as leiomyomas, leiomyoblastomas, leiomyosarcomas, schwannomas, gastrointestinal autonomic nerve tumors, or other similar soft tissue histologies. Consequently, interpretation of clinical results for reports on GISTs published before 2000 can be challenging.

Receptor Tyrosine Kinase Mutations

In a landmark publication in 1998, Hirota and colleagues reported two critical findings: (1) near-universal expression of the transmembrane receptor tyrosine kinase KIT in GIST; and (2) presence of gain-of-function mutations in the corresponding c-*KIT* proto-oncogene. The KIT receptor is normally activated by binding its cytokine ligand known as steel factor or stem cell factor and plays a critical role in the development and maintenance of components of hematopoiesis, gametogenesis, and intestinal pacemaker cells. Oncogenic *KIT* mutations have been identified in neoplasms corresponding to these functions, including mast cell tumors, myelofibrosis, chronic myelogenous leukemia, germ cell tumors, and GIST. Mutated KIT remains constitutively active even in the absence of ligand binding and results in both unregulated cell growth and malignant transformation.

GISTs are now identified with immunohistochemical staining for the CD117 antigen, part of the KIT receptor, in the appropriate histopathologic context. CD117 expression (KIT positivity) is characteristic of most GISTs but not of other gastrointestinal smooth muscle tumors such as leiomyosarcoma. Application of CD117

staining as a diagnostic criterion for GIST has altered the understanding of the prevalence of this disease.

More than 85% of GISTs have activating *KIT* mutations. These mutations commonly occur in exon 11 (in 57% to 71% of cases), exon 9 (10% to 18%), exon 13 (1% to 4%), and exon 17 (1% to 4%). The presence of CD117 immunoreactivity does not necessarily correlate with a *KIT* gene mutation, and conversely, a *KIT* mutation can exist in the absence of CD117 immunoreactivity. GISTs with *KIT* exon 9 mutations predominantly arise in the small intestine. Approximately 35% of neoplasms that lack *KIT* mutations have activating mutations in a gene encoding a related receptor tyrosine kinase, the platelet-derived growth factor receptor alpha (PDGFRA). *PDGFRA* mutations have been identified in exon 12 (1% to 2% of GISTs), exon 18 (2% to 6%), and exon 14 (<1%). Finally, a few GISTs, the so-called wild-type (WT) GISTs, exhibit no detectable *KIT* or *PDGFRA* mutations and have alternate pathways for pathogenesis. Recently, additional putative mutations in several succinate dehydrogenase (SDH) subunits and *BRAF* and overexpression of insulin-like growth factor–1 receptor have been identified in a small percentage of WT tumors.

DOG1, a monoclonal antibody against a chloride channel protein expressed by GIST, is immunoreactive in 95% of GISTs irrespective of their mutation status. However, DOG1 is not specific to GIST, and uterine retroperitoneal leiomyomas, peritoneal leiomyomatosis, and synovial sarcomas may also be positive for DOG1.

EPIDEMIOLOGY

Age

The median age at diagnosis of GIST is 60 years (range, 40 to 80 years). GISTs are equally common in men and women, and no racial or ethnic predilection is found. GIST does occur rarely in children, often as a familial syndrome or as part of Carney's triad. The clinical presentation is typically different in children, who tend to present with multifocal gastric GISTs, with WT for *KIT* and *PDGFRA*, and have a higher incidence of lymph node metastases.

Hereditary Gastrointestinal Stromal Tumors

The overwhelming majority of GISTs are sporadic. Nevertheless, kindred germline *KIT* or *PDFGRA* mutations have been reported. Individuals with GISTs secondary to germline *KIT* mutations are usually younger than those with sporadic GISTs, manifest multifocal disease at presentation, and only rarely have metastatic disease develop. The phenotype includes skin hyperpigmentation and diffuse hyperplasia of the intestinal myenteric plexus, and cases of melanoma and esophageal and breast cancers have also been reported in individuals with hereditary GIST.

Approximately 7% of individuals with the autosomal dominant disorder Recklinghausen's neurofibromatosis (NF1) have GIST, most commonly multifocal in the small intestine and with a higher incidence in women (1.4:1). In addition to their *NF1* mutations, these individuals express *KIT* and *PDGFRA* point mutations in 8% and 6% of GISTs, respectively. Conversely, *NF1* mutations have not been identified in individuals without NF1 with sporadic GISTs.

Gastric GISTs can be a component of both Carney's triad and Carney-Stratakis syndrome. Described by Carney in 1977, Carney's triad consists of GIST, paraganglioma, and pulmonary chondromas. More recently, esophageal leiomyomas and adrenal cortical adenomas have been added as components of the syndrome. Approximately 85% occur in women, and 80% are diagnosed before the age of 30 years. Patients with Carney's triad do not have somatic *KIT* or *PDGFRA* mutations. The similarly eponymous Carney-Stratakis syndrome describes familial cases expressing the dyad of gastric GIST and paraganglioma. Mutations in several SDH subunits have been reported in Carney-Stratakis syndrome kindreds. GISTs associated with both syndromes have a chronic yet indolent course.

Incidence

Investigators have attempted to determine the true incidence of GIST with the Surveillance, Epidemiology, and End Results (SEER) database from the National Cancer Institute. However, these data are difficult to interpret because many GISTs were previously misclassified as other gastrointestinal (GI) mesenchymal neoplasms. Although a near doubling of the incidence rate of all GI mesenchymal tumors (more than 80% were GIST) has been reported (0.17/100,000 in 1992 to 0.31/100,000 in 2002), this may be the result of increased recognition or increased screening or a true increased incidence rate. The annual incidence rate in the United States is estimated to be approximately 5000 to 6000 new cases per year (15 to 20 cases per million). European population-based studies identified annual incidence rates ranging from 11 to 15 cases per million population, with an estimated prevalence of approximately 129 per million.

CLINICAL PRESENTATION

GISTs commonly arise in the stomach (50% to 70%), small intestine (25% to 35%), colon and rectum (5% to 10%), mesentery or omentum (7%), and esophagus (<5%). Occasionally, GIST may arise in the duodenal ampulla, appendix, gallbladder, and urinary bladder.

GISTs are generally found as a result of symptoms. In one study, 69% of tumors were symptomatic, 21% were discovered incidentally at surgery, and 10% were discovered at autopsy. GISTs are often highly vascular, soft, and friable, and bleeding is a common presenting symptom. They may cause life-threatening hemorrhage by erosion into the bowel lumen. Alternatively, tumor rupture may cause potentially catastrophic intraperitoneal bleeding or dissemination by peritoneal seeding. Intestinal obstruction may lead to perforation. Smaller tumors may remain asymptomatic and only be incidentally detected on radiographic studies, endoscopy, or laparotomy. Between 15% and approximately 50% of patients with GIST have metastatic disease at diagnosis. Common sites of metastasis include liver, peritoneum, and omentum; metastases to lymph nodes and extra-abdominal structures (lung, bone, subcutaneous tissues, and brain) are rare (<5% of patients).

DIAGNOSIS

Radiographic Studies

The initial imaging study of choice for a suspected or confirmed GIST is a contrast-enhanced computed tomographic (CT) scan of the abdomen and pelvis. Primary GISTs are typically well-circumscribed masses within the walls of hollow viscera. Magnetic resonance imaging (MRI) may help characterize primary rectal disease (Figure 1) or metastatic liver. Although [^{18}F]fluoro-2-deoxy-D-glucose positron emission tomography (FDG-PET) may help characterize masses ambiguous on CT scan, monitor response to therapy, and detect emergence of drug-resistant clones, it is not specific for GIST and thus is not recommended for most patients with suspected primary disease. Much has been written about its utility in patients with metastatic GIST, but in general, PET scans are not necessary in the management of patients with metastatic disease and thus may be used sparingly.

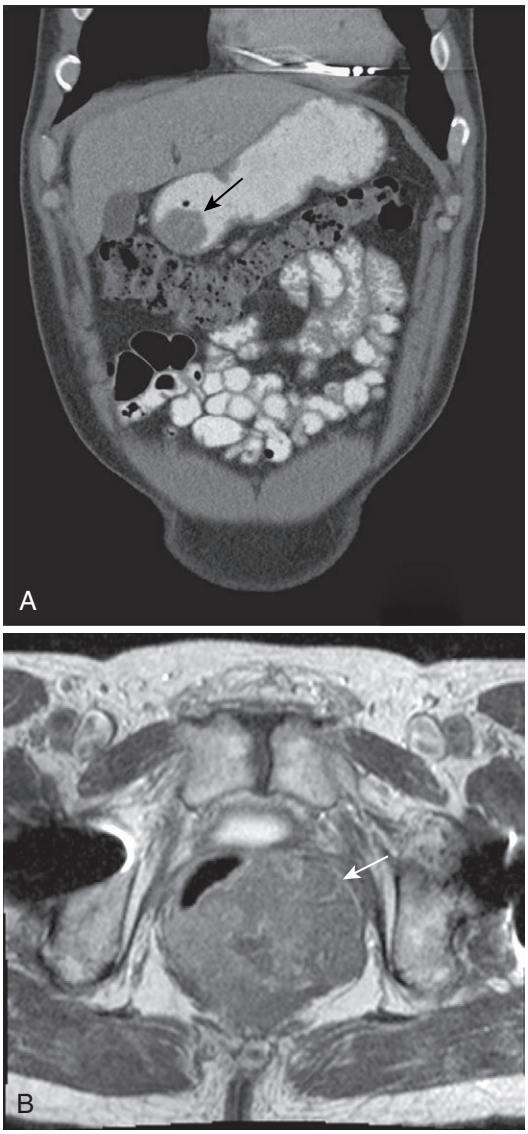

FIGURE 1 Cross-sectional imaging depicts: **A,** a computed tomographic scan image of a distal gastric gastrointestinal stromal tumor *(arrow);* and **B,** a magnetic resonance image of a nearly obstructing rectal gastrointestinal stromal tumor *(arrow).*

Endoscopy, Fine-Needle Aspiration, and Biopsy

Endoscopically, a primary GIST may appear as a submucosal lesion, with or without ulceration, present in the upper or lower GI tract. GISTs are often indistinguishable from other GI tumors of smooth muscle origin, such as leiomyomas. Upper endoscopy with endoscopic biopsy has a low diagnostic yield (17% to 42%). Endoscopic ultrasound scan (EUS) is not necessary to evaluate a confirmed GIST. However, EUS-guided fine-needle aspiration (FNA) may be attempted to establish diagnosis, with a diagnostic yield and sensitivity of approximately 80%. Nevertheless, EUS FNA is not consistently diagnostic. Additional cytologic morphology, immunohistochemistry, and reverse-transcriptase polymerase chain reaction analysis for *KIT* mutations may be necessary to confirm a diagnosis.

A preoperative biopsy is not routinely necessary for a primary, resectable neoplasm suspicious for GIST. In fact, preoperative biopsy may rupture a suspected GIST and increase the risk of dissemination. However, if the differential diagnosis includes entities such as lymphoma that would be treated differently, if neoadjuvant therapy is under consideration, or if there is metastatic disease, biopsy is appropriate.

PROGNOSTIC FACTORS

Although tumors of less than 1 cm likely have a low risk of recurrence, no tumors can be definitively called benign and most large tumors have malignant potential. The three established prognostic factors are tumor size (single largest dimension), mitotic index, and tumor site of origin, with mitotic count being the most important as the strongest predictor of recurrence (Table 1). Individuals with small bowel GISTs have a higher risk of progression than those with gastric GISTs of comparable size and mitotic count.

More recently, a validated nomogram has been reported (Figure 2). The nomogram assigns points for each of the three known prognostic factors based on a particular patient's presentation and uses the point totals to predict the probability of remaining recurrence-free at 2 and 5 years. Tumors that arise in the small intestine carry more "points" because of their worse prognosis compared with those that arise in the stomach or colon or rectum. Of note, the nomogram bases the probability of recurrence on a cohort of patients diagnosed initially in the therapy era before tyrosine kinase inhibitors (TKIs).

Additional adverse prognostic factors observed in some but not all studies include high cellular proliferation index, aneuploidy, telomerase expression, *KIT* exon 9 mutations, and *KIT* exon 11 deletions that involve amino acid W557 or K558. Point mutations and insertions of *KIT* exon 11 appear to have a favorable prognosis.

THERAPY FOR PRIMARY DISEASE

Surgery

Technique

Surgery remains the standard of care and only potentially curative therapy for patients with primary, resectable, localized GIST. At laparotomy, the abdomen is thoroughly explored to identify and remove any previously undetected peritoneal metastatic deposits. Although primary GISTs may demonstrate inflammatory adhesions to surrounding organs, they do not generally invade other organs beyond the site of origin despite CT scan appearance. The goal of the operation should be a margin negative resection. The ideal margin of resection is unknown. A macroscopically complete resection with negative or positive microscopic margins (R0 or R1 resection, respectively) is associated with a better prognosis than a macroscopically incomplete resection (R2 resection). Post hoc analysis of a randomized trial evaluating the utility of 1 year of adjuvant imatinib mesylate therapy after resection of primary GISTs at least 3 cm in size showed no significant difference in recurrence-free survival (RFS) for patients undergoing an R0 versus R1 resection with or without the use of adjuvant imatinib. However, data on overall survival (OS) rates are unknown. What is clearly known is that tumor rupture or violation of the tumor capsule during surgery is associated with an increased risk of recurrence and therefore should be avoided.

In general, the extent of surgery is usually a wedge or segmental resection of the involved stomach or bowel without the wide margins necessary for adenocarcinoma. In a series of 140 patients with gastric GISTs, wedge resections were performed in 68%, partial gastrectomies in 28%, and total gastrectomies in only 4%. Occasionally, a more extensive resection (total gastrectomy for a large proximal gastric GIST, pancreaticoduodenectomy for a periampullary GIST, or abdominoperineal resection for a low rectal GIST) may be necessary. Several recent multiinstitutional retrospective series have questioned the need for extensive resections such as pancreaticoduodenectomy or abdominoperineal resection in the setting of well-tolerated, orally

TABLE 1: Risk assessment for primary gastrointestinal stromal tumors

		Percentage of patients with progressive disease/risk classification, based on site of origin			
Mitotic rate	**Tumor size**	*Stomach*	*Duodenum*	*Jejunum/Ileum*	*Rectum*
≤5 per 50 HPF	≤2 cm	0	0	0	0
	>2, ≤5 cm	1.9/very low	8.3/low	4.3/low	8.5/low
	>5, ≤10 cm	3.6/low	34/high	24/moderate	57/high
	>10 cm	12/moderate	34/high	52/high	57/high
>5 per 50 HPF	≤2 cm	–	–	–	54/high
	>2, ≤5 cm	16/moderate	50/high	73/high	52/high
	>5, ≤10 cm	55/high	86/high	85/high	71/high
	>10 cm	86/high	86/high	90/high	71/high

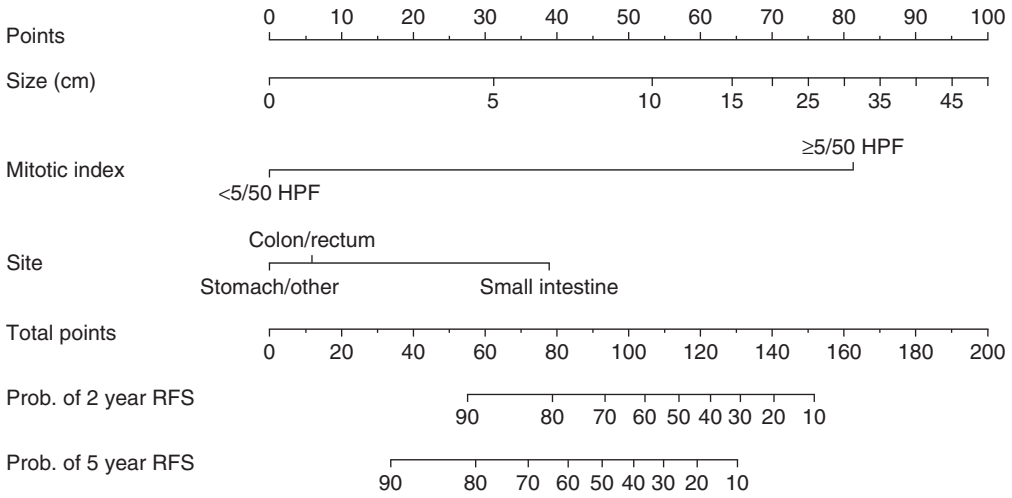

FIGURE 2 Nomogram to predict the probabilities of 2-year and 5-year recurrence-free survival (RFS). Points are assigned for size, mitotic index, and site of origin by drawing a line upward from the corresponding values to the *Points* line. The sum of these three points, plotted on the *Total points line,* corresponds to predictions of 2-year and 5-year RFS. *HPF,* High-power field. *(Used with permission from Gold JS, Gonen M, Guiterrez A, et al: Development and validation of a prognostic nomogram for recurrence-free survival after complete surgical resection of localised primary gastrointestinal stromal tumour: a retrospective analysis,* Lancet Oncol *10[11]:1045–1052, 2009.)*

available targeted therapies. No data indicate that patients who have an R1 resection need reexcision, and in fact, the lack of any difference in RFS between patients undergoing R0 versus R1 resection suggests that reexcision or more radical resections may be avoided. Furthermore, margins may retract after resection, or the pathologist may trim away the staple line (converting a technically negative microscopic margin into a positive one). Therefore, all cases of positive microscopic margins should be carefully reviewed by a multidisciplinary team of surgical oncologists, pathologists, and medical oncologists to assess the need for reexcision. Lymphadenectomy is not required because lymph nodes are rarely involved (in adult patients).

All GISTs 2 cm in size or greater should be resected when possible because none of these can be considered benign. However, the natural history of GISTs less than 2 cm in size is unknown; thus, their management is more debatable. Although the low risk of progression of GISTs less than 2 cm may support a more conservative approach, an accurate mitotic index cannot be determined with biopsy or FNA. Therefore, observation for GIST 1 to 2 cm is difficult to recommend. As such, resection of GIST measuring 1 to 2 cm should be considered, and the risks and benefits of surgery versus observation should be reviewed with the patient. Given the higher risk of aggressive behavior of small bowel and colon GISTs, any tumor in such locations should be resected irrespective of size. In contrast, most gastric GISTs under 1 cm in size may be followed. Two studies have established that subcentimeter gastric GISTs are relatively common, with detection in 22.5% of autopsies in adults over the age of 50 years in Germany and in 35% of patients undergoing gastrectomy for gastric cancer in Japan. Despite their relative frequency, few of these neoplasms appear to become clinically relevant. Until further data are available, the most appropriate management of such small tumors remains uncertain. Although endoscopic resection of small gastric GISTs has been reported, this cannot be recommended. Unlike early gastric cancers (mucosal malignancies) amenable to endoscopic mucosal resection, GISTs involve the muscularis propria, so attempts

at endoscopic resection risk leaving a positive margin and, because of the depth of the lesion, could result in perforation. Regardless of their size, any small GISTs that are symptomatic (e.g., hemorrhage from erosion through the mucosa) or increase in size on serial follow-up examination should be resected.

Laparoscopic or laparoscopy-assisted resection of primary GISTs may be performed following standard oncologic principles. Two early studies confirmed both the safety and the feasibility of a laparoscopic approach. In a series of 35 gastric GISTs (2 to 5 cm) resected laparoscopically, no local or distant recurrences were observed for tumors under 4 cm in size with a median follow-up period of 53 months. In a study of 50 patients with gastric GISTs (1.0 to 8.5 cm) resected laparoscopically or with laparoscopy assistance, 92% of patients were disease-free with a mean follow-up period of 3 years.

Despite a macroscopically complete resection, as many as 50% of individuals may have recurrent disease develop at a median of 24 months after surgery. An R0 or R1 resection is associated with 5-year OS rates of 34% to 63%, whereas R2 resection is associated with 5-year OS rates as low as 8% in the preimatinib era.

Perioperative Therapy for Primary Disease

The identification of two effective, relatively well-tolerated orally available targeted TKIs, imatinib mesylate (STI571, Gleevec, Novartis Pharmaceuticals, Basel, Switzerland) and sunitinib malate (SU11248, Sutent, Pfizer, Inc., New York, NY), revolutionized the treatment of GIST. Imatinib selectively inhibits several tyrosine kinases, including KIT, PDGFRA, and BCR-ABL. Several clinical trials have confirmed that up to 80% of patients with metastatic GIST achieve a complete response or partial response or show stable disease radiographically on imatinib. Although these agents were initially developed for the management of patients with metastatic disease, increasing interest has been seen in using imatinib in the perioperative period given the high incidence rate of recurrence after resection of GIST.

The role of neoadjuvant therapy with imatinib combined with resection has been prospectively studied (Table 2). Specifically, the Radiation Therapy Oncology Group (RTOG) 0312 phase II trial was a multicenter study that evaluated the use of imatinib as a neoadjuvant agent. Patients with resectable primary or recurrent GIST were treated with 600 mg per day of imatinib for 8 to 12 weeks before surgery. Patients without progression underwent surgery and were then maintained on adjuvant imatinib for 2 years. An objective response was shown in 90% of patients with primary GIST, and 92% underwent R0/R1 resections. The 2-year RFS rate was 83%. Although this trial confirmed the safety of imatinib as a neoadjuvant therapy, the optimal length of preoperative therapy is still unclear. Data from trials of advanced GIST have shown that maximal radiographic response to imatinib generally required 6 to 9 months of treatment. Thus, the optimal preoperative imatinib regimen may be 6 months or more as long as continued radiographic response is observed.

In practice, when to use neoadjuvant imatinib is still unclear. In situations where tumor shrinkage may either simplify an operation or potentially allow the scope of an operation to be downstaged (for instance, converting a pancreaticoduodenectomy into a localized resection for a duodenal GIST or converting an abdominoperineal resection into a transanal excision for a rectal GIST), neoadjuvant imatinib may be used. Alternatively, even if the extent of resection is unlikely to change, converting from an open procedure to a laparoscopic one may be another indication for neoadjuvant imatinib.

The role of adjuvant therapy with imatinib combined with resection of primary disease has been explored in numerous prospective trials (see Table 2). These trials examined different durations of adjuvant imatinib of 12 months (American College of Surgeons Oncology Group [ACOSOG] Z9000, ACOSOG Z9001, China Cooperative Group), 24 months (European Organization for the Research and Treatment of Cancer [EORTC] 62024, Korean trial), 12 versus 36 months (Scandinavian Sarcoma Group [SSG] XVIII), or 5 years (recently completed phase II multiinstitutional trial, PERSIST5). In the phase III ACOSOG Z9011 trial, patients with completely resected primary GIST at least 3 cm in size were randomized to receive either placebo or imatinib postoperatively for 12 months. The trial was halted early after a planned interim analysis of 644 evaluable patients confirmed that the 1-year RFS rate was significantly better in the imatinib arm (97% vs 83%; $P = 0.0000014$). Interestingly, the slopes of the Kaplan-Meier curves representing the two treatment arms, once recurrences were observed, were similar. This suggests that 1 year of adjuvant imatinib may delay recurrence but may not necessarily cure anyone over the short follow-up interval. Furthermore, no difference was seen in OS between the two treatment arms.

In the phase III SSG XVIII trial, patients with high-risk GISTs who underwent a complete resection were randomized to receive either imatinib postoperatively for 12 months versus 36 months. The key entry criteria were: (1) tumor at least 10 cm in size; (2) tumor rupture; (3) mitotic count of more than 10 per 50 high-power field (HPF); (4) tumor greater than 5 cm in size and mitotic count more than 5 per 50 HPF; or (5) primary GIST of any size or mitotic count with synchronous liver or peritoneal metastases (which were also resected). The trial, which included 397 evaluable patients, confirmed that patients treated with 36 months of adjuvant imatinib had longer 5-year RFS rates than those treated with 12 months of adjuvant imatinib (66% vs 48%; $P < 0.01$). More importantly, it showed that those treated with longer duration of imatinib had improved 5-year OS rates (92% vs 82%; $P = 0.02$).

The EORTC 62024 trial has completed accrual, but data are not yet available. Data from that trial plus the recently completed PERSIST5 trial will help determine the comparative benefit of 2 and 5 years of imatinib on RFS and time to imatinib failure. Perhaps the most important question is whether administration of imatinib after resection of primary disease or after disease recurrence delays time to second-line therapy (imatinib dose escalation or changing to sunitinib). However, with the recent approval of imatinib for adjuvant use by both the Food and Drug Administration in the United States and the European Medicines Agency in Europe, it seems unlikely that any trial will ever be designed to answer this question. Therefore, at this time, the standard of care is that patients with high-risk GIST should be treated with a minimum of 36 months of adjuvant imatinib.

THERAPY FOR ADVANCED DISEASE

Targeted Therapy

Despite successful resection of the primary tumor, most patients experience tumor recurrence. Recurrences are most commonly in the liver (two thirds) or along the peritoneal surface (half). Before the advent of TKI therapy, median survival time after recurrence was approximately 18 months. Historically, patients with recurrent GIST had limited therapeutic options. More recently, imatinib mesylate and sunitinib malate are now available for the treatment of metastatic GIST. Imatinib is the first-line therapy for advanced (unresectable primary or metastatic) GIST, based on data from international phase I, II, and III trials. Partial responses (PRs) or stable disease (SD) were noted in nearly 85% of patients with advanced GIST treated with imatinib. In the U.S. phase III trial, the median RSF and OS times with imatinib therapy were 18 to 20 months and 51 to 55 months, respectively. The starting dose for imatinib is generally 400 mg once daily. In patients with development of progressive disease on 400 mg, dose escalation up to 400 mg twice daily is effective. However, greater toxicity and more dose reductions are generally required at doses above 400 mg per day. The toxicities of imatinib include edema, nausea, muscle cramps, diarrhea, headache, dermatitis, fatigue, anemia, and neutropenia. Fortunately, most side effects (>70%) are mild to moderate in severity and often resolve with continuing

TABLE 2: Multiinstitutional trials of the use of neoadjuvant or adjuvant imatinib in the perioperative management of resected primary gastrointestinal stromal tumors

Trial	Imatinib therapy	Design	Eligibility	Dose	Primary endpoint	Status
RTOG S0132	Neoadjuvant	Phase II	Any of the following: primary tumor ≥ 5 cm recurrent tumor ≥ 2 cm Potentially resectable	600 mg daily × 8-10 wk before surgery + 600 mg daily × 24 mo after surgery	RFS	Published
ACOSOG Z9000	Adjuvant	Phase II	Any of the following: tumor ≥ 10 cm rupture/hemorrhage multiple tumors (<5) Complete resection	400 mg daily × 12 mo	RFS	Reported
ACOSOG Z9001	Adjuvant	Phase III	Tumor ≥ 3 cm Complete resection	400 mg daily vs placebo × 12 mo	RFS	Published
China Gastrointestinal Cooperative Group	Adjuvant	Phase II	Any of the following: tumor > 5 cm mitotic rate > 5/50 HPF	400 mg daily × 12 mo	RFS	Reported
SSG XVIII	Adjuvant	Phase III	Any of the following: tumor ≥ 10 cm rupture mitotic rate > 10 tumor > 5 cm + mitotic rate > 5 primary tumor + liver/peritoneal metastases Complete resection	400 mg daily × 12 mo or 36 mo	RFS	Published
EORTC 62024	Adjuvant	Phase III	Any of the following: tumor > 5 cm mitotic rate > 10 tumor < 5 cm + mitotic count 6-10/50 HPF Complete resection	400 mg daily vs no treatment × 24 mo	Time to second-line therapy	Completed
Korea	Adjuvant	Phase II	Any of the following: tumor > 5 cm + mitotic count > 5/50 HPF tumor > 10 cm mitotic count > 10/50 HPF Complete resection	400 mg daily × 24 mo	RFS	Reported
CSIT571BUS282	Adjuvant	Phase II	Any of the following: tumor ≥ 2 cm + mitotic count ≥ 5/50 HPF any nongastric tumor ≥ 5 cm Complete resection	400 mg daily × 5 y	RFS	Completed

therapy. The location of the *KIT* mutation correlates with response to imatinib therapy. In a 121 patient subset from the U.S.-Finland study, patients whose disease harbored an exon 11 mutation had a response rate of 72%, and only 32% of patients with exon 9 *KIT* mutants and 12% of wild type *KIT* patients responded to imatinib. In a study of 117 patients treated with imatinib for metastatic GIST, the median event-free survival for patients whose tumors had mutations of exon 11 was 22.5 months, compared with 6.6 months for patients with mutations in exon 9. In a meta-analysis of the two large phase III studies, a slight advantage in progression-free survival (PFS) was noted in patients initially treated with higher dose imatinib, but that advantage was essentially limited to patients with *KIT* exon 9 mutations.

A French randomized imatinib discontinuation study showed that patients with GIST on imatinib who stop imatinib therapy after 1, 3, and 5 years had a much higher rate of disease progression than

those who continued on therapy. Interestingly, from the original U.S. phase II trial, approximately 18% of the original cohort remained on imatinib after 9.4 years. As such, imatinib should be continued indefinitely in the setting of advanced disease. If patients continue to progress on higher doses of imatinib or do not tolerate such doses, then second-line sunitinib is started. Sunitinib is a multitargeted TKI whose targets include KIT, PDGFR, vascular endothelial growth factor receptor (VEGFR1, VEGFR2, VEGFR3), the ret proto-oncogene receptor (RET), and Fms-like tyrosine kinase-3 receptor (Flt3). A placebo-controlled phase III trial showed significant improvement in time to progression in patients treated with sunitinib compared with those treated with placebo (27.3 weeks vs 6.4 weeks, respectively), as well as PFS and OS. Initially dosed as 50 mg daily in a 4-week-on/2-week-off cycle, many oncologists now favor a continuous dose regimen of 37.5 mg daily.

When sunitinib resistance develops, protocol-based therapies should be considered. Additional TKIs under investigation include regorafenib (which recently showed benefit as a third-line agent), sorafenib, nilotinib, dasatinib, masitinib, and vatalanib among others. Crenolanib is a novel PDGFR kinase inhibitor undergoing evaluation in patients with GIST whose tumors carry a *PDGFRA* D842V mutation to most other kinases available. Other potential molecules for targeted therapy include heat shock protein–90, mammalian target of rapamycin (mTOR), histone deacetylyase, and insulin-like growth factor type I receptor.

Surgery

Cytoreductive surgery for resectable advanced or metastatic disease is a relatively common practice for disseminated solid tumors that originate in the colon, appendix, ovary, and testicle. With the advent of imatinib and sunitinib therapy, a number of investigators have pursued a similar strategy of aggressive cytoreductive surgery in patients with advanced, metastatic GIST on TKI therapy. Three observations support such an approach. First, most patients experience durable periods of PR or SD on imatinib, lasting months to years. Second, pathologic complete responses are rare, noted in fewer than 5% of patients. Third, response to imatinib is not maintained indefinitely; the median time to progression from the development of secondary resistance to imatinib is 18 to 24 months. Once drug resistance develops, disease progression may be either limited (progression at one site of tumor, with other tumor deposits showing ongoing response to TKI) or generalized (progression at more than one site).

Several single-institution retrospective studies have documented the PFS and OS rates after extensive cytoreductive surgery in patients with advanced GIST treated with TKI therapy. The goal of such operations is to perform a macroscopically complete (R0 or R1) resection when safely possible. However, the disease may frequently be too extensive to be removed completely, in which case progressing lesions are preferentially removed. In the experience at Brigham and Women's Hospital/Dana-Farber Cancer Institute, the best results were generally seen in patients whose disease was still responsive to TKI therapy at the time of surgery. The ability to remove all macroscopic disease was greatest in patients with ongoing response to TKI therapy. After surgery, no evidence was found of any residual disease in 78%, 25%, and 7% of patients with responsive disease, limited progression, and generalized progression, respectively ($P < 0.0001$). In contrast, bulky residual disease remained postoperatively in 4%, 16%, and 43% of patients with responsive disease, limited progression, and generalized progression, respectively.

On the basis of the available data, from limited single-institution series, the patients who seemed to derive the most benefit from cytoreductive surgery are the ones still responding to TKI therapy at the time of surgery (PR or SD). Such patients should be considered for surgery on an individual basis. Patients with generalized progression do not appear to derive any benefit from cytoreductive surgery and are best treated without surgery. Such patients may nevertheless need urgent surgery for palliative or emergency purposes such as obstruction or hemorrhage. Although cytoreductive surgery is feasible in patients with responsive disease, there is still no evidence that outcomes are superior or even equal to those for patients who continue on TKI therapy without surgery. Efforts to answer this question in a randomized controlled trial in the United States, Europe, and China have been unsuccessful because of accrual issues.

SURVEILLANCE

The National Comprehensive Cancer Network (NCCN) consensus panel recommended that patients who have had resection of a primary GIST should undergo a history, physical examination, and abdomen/pelvis CT scans with intravenous contrast every 3 to 6 months during the first 3 to 5 years and then annually thereafter. Given the rarity of pulmonary or other extraabdominal metastases, CT scans of the chest, head, etc, are unnecessary. Routine PET scans for screening are also unnecessary. Because more recurrences occur within the first 5 years after surgery, imaging intervals of 3 to 6 months are standard for patients in the first 5 years of posttreatment follow-up, with annual evaluation thereafter. At present, no specific serum-based markers are used for the detection of recurrent GIST.

CONCLUSION

The principal and only potentially curative treatment for GIST is surgery. However, recurrences are common. In the era before the institution of TKI therapy, survival in the setting of recurrent or metastatic disease was poor. Because of its relatively low toxicity and significant efficacy in the treatment of GIST, TKI therapy has dramatically altered the natural history of this disease. The type and dose of TKI administered may soon be guided by mutational analysis. The role of imatinib has been expanded to patients with primary GIST, where it may be used safely as a neoadjuvant agent and improves RFS as an adjuvant agent after complete macroscopic resection. Ongoing studies will address the issues of optimal length and dose of adjuvant and neoadjuvant imatinib therapy, define the subset of candidates most likely to benefit from such therapy, and determine the long-term impact on OS. Cytoreductive surgery may be considered in a subset of patients with advanced disease, but phase III trial data are necessary to determine whether surgery adds any PFS or OS benefit over continuing imatinib therapy alone. Future studies will focus on the integration of surgery with targeted therapy and the development of new agents for drug-resistant GIST.

Morbid Obesity

Katherine Graw Lamond, MD, MS, and Anne O. Lidor, MD, MPH

OVERVIEW

Morbid obesity is becoming increasingly prevalent throughout the United States and other industrialized nations. Body mass index (BMI) is a calculated measurement that takes into account height and weight (BMI = weight [kg]/height [m]).

More than 60% of adults in the United States are considered overweight (BMI ≥25), and more than 33% of Americans are obese (BMI ≥30). Almost one in three children and adolescents in the United States are also overweight (Table 1).

The medical comorbidities of obesity are hazardous and include type 2 diabetes, obstructive sleep apnea, heart disease, and increased risk of stroke, gastroesophageal reflux disease (GERD), osteoarthritis, and liver disease. Medical therapies for weight reduction are largely unsuccessful at maintaining significant weight loss in the severely obese population.

Bariatric surgery continues to be the only durable method to achieve sustained weight loss for many patients. Almost 150,000 bariatric procedures are performed in the United States annually. The two fundamental mechanisms of surgical weight loss are: 1, restrictive; and 2, malabsorptive. Some of the procedures described have components of both. There are multiple theories surrounding the metabolic changes which occur following bariatric surgery. These changes can result in a near instant resolution of diabetes mellitus, as well as a change in set-point of body weight. These alterations may occur by hormonal influences and neuronal feedback loops which are made possible by surgery.

The three most common operations include the laparoscopic Roux-en-Y gastric bypass, laparoscopic adjustable gastric band (LAGB), and vertical sleeve gastrectomy. All of these procedures assist with weight loss by restriction of calorie intake. The Roux-en-Y gastric bypass also causes malabsorption of food, which leads to weight loss.

Duodenal switch with biliopancreatic diversion is a less commonly performed malabsorptive and restrictive procedure.

PATIENT SELECTION

In 1991, the National Institute of Health issued a consensus statement regarding the effectiveness of bariatric surgery based on certain patient criteria. Insurance companies, including Medicare and Medicaid, typically base their reimbursements on these indications. The indications include a BMI of 40 or more, or 35 or more with a significant obesity-related comorbidity. Patients must have documented attempts at weight loss that were unsuccessful, typically for a 6-month period. Finally, patients must also be cleared by a dietician and a mental health profession and have no other medical contraindications for surgery.

The American Society for Metabolic and Bariatric Surgery and the American College of Surgeons have produced guidelines of accreditation for both bariatric programs and hospitals. The policies insist that programs can provide excellent surgical technique and thorough postoperative care, follow-up, and specialty consultants.

A multidisciplinary team approach has been shown to provide the best benefit for the evaluation of potential bariatric surgery cases. This team should include a dietician and a mental health professional familiar with bariatric surgery. Their purpose is to obtain a complete dietary and behavioral eating history, educate the patient on postoperative dietary expectations, examine the social support structure, and ensure that any psychiatric or behavioral disorders are optimally controlled.

At the Johns Hopkins Center for Bariatric Surgery, all patients are required to attend a multidisciplinary preoperative education seminar. Preoperative and postoperative participation in obesity and bariatric support groups is also encouraged.

Age limits for surgery have expanded considerably over the last decade. Select centers, including Johns Hopkins, may offer surgery to adolescent patients and to patients over the age of 70 years.

OPERATIVE PROCEDURES

Most bariatric surgical procedures are now performed laparoscopically, with a hospital stay of 48 hours or less. Open surgery may be necessary and planned for patients who undergo revision surgery,

TABLE 1: Body mass index

Classification	Body mass index (kg/m^2)
Underweight	≤18.49
Normal range	18.5-24.9
Overweight	≥25.0
Obese	≥30.0
Obese class I	30.0-34.9
Obese class II (moderately obese)	35.0-39.9
Obese class III (severely obese)	40.0-49.9
Obese class IV (super obese)	≥50.0

those with prior extensive abdominal operations, or patients with a high BMI (>70).

Before surgery, all patients should receive appropriate antibiotics and subcutaneous unfractionated or low–molecular weight heparin within an hour of incision. Obese patients undergoing laparoscopic surgery have a significant risk of development of potentially life-threatening deep venous thrombosis.

Patient positioning on the operative table is essential for safe placement of the patient in the steep reverse Trendelenburg's position. This placement should include a footboard, secured arms and legs, and a split leg table if possible. Laparoscopic entry in a morbidly obese patient can be difficult. The authors have found that the safest way to enter is in the left upper quadrant with direct vision, with a device that allows visualization of the abdominal wall layers during entry with a 0-degree laparoscope (12-mm Visiport; Covidien, Norwalk, Conn).

Laparoscopic Roux-en-Y Gastric Bypass

Gastric bypass (Figure 1) is the most common bariatric procedure performed in the United States (60% to 70%). Numerous reports have shown achievement of durable long-term weight loss and remission of metabolic disease with a reasonably low complication rate.

The authors perform the procedure with five laparoscopic trocars (three 12-mm and two 5-mm) and a subxiphoid puncture for placement of a Nathanson liver retractor (Cook Medical, Bloomington, Ind).

The jejunojejunal anastomosis is created first. The jejunum is divided approximately 40 cm distal to the ligament of Treitz with a 60-mm white stapler cartridge (Endo-GIA Universal XL; Covidien, Norwalk, Conn). The mesentery is divided with a gray stapler cartridge and ultrasonic shears (AutoSonix XL; Covidien, Norwalk, Conn). The proximal biliopancreatic limb of jejunum is then anastomosed to the distal segment of jejunum 75 to 100 cm distal to the point of division. The authors perform this anastomosis in a side-to-side fashion with a white Endo-GIA stapler cartridge and complete it with a blue or tan tristaple Endo-GIA load and running suture. The mesenteric defect is then closed with a running permanent suture to help minimize the risk of internal hernia.

Next, the patient is placed in steep reverse Trendelenburg's position, and the gastric pouch is created. Dissection is performed at the angle of His, to expose the left crus, and at the gastrohepatic ligament, to gain access to the lesser sac. Division of the neurovascular bundle on the lesser curve side of the stomach, just distal to the left gastric artery and vein, is accomplished with a gray vascular cartridge. Multiple 60-mm blue staple or tan tristaple cartridges are then used to transect the stomach up to the angle of His, creating a vertically oriented, 20-mL proximal gastric pouch. Any bleeding at the staple lines is controlled with clips or suture ligation. Care is taken not to place clips in a region that interferes with the gastrojejunal anastomosis.

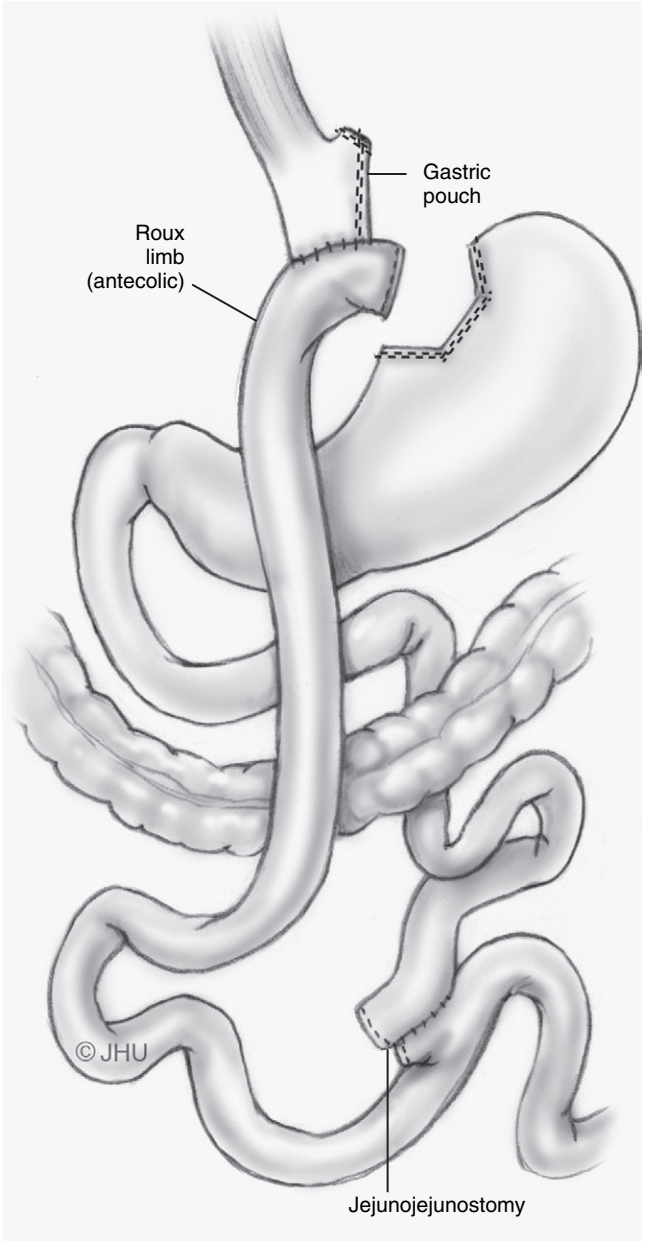

FIGURE 1 Antecolic-antegastric Roux-en-Y gastric bypass. *(Courtesy Corinne Sandone, Johns Hopkins University.)*

The authors routinely bring the Roux limb of the jejunum up to the gastric pouch in an antecolic-antegastric orientation. This has been shown to reduce the incidence of internal hernia and is simpler to perform than the retrocolic-retrogastric approach.

The gastrojejunostomy is performed by first suturing the side of the Roux limb to the gastric pouch staple line. A small enterotomy is performed proximal to the end of the Roux limb, and a similarly sized gastrotomy is made in the gastric pouch for insertion of the Endo-GIA blue 45-mm stapler. The stapler is fired with 30-mm of the cartridge to create an appropriately sized anastomosis. A stay suture is then placed on the lesser curve of the opening and is used to retract the anastomosis to expose the posterior staple line. This staple line is reinforced with a running 2-0 suture.

Carefully, a blunt 32F bougie is then passed by the anesthesia or surgical team via the patient's mouth through the gastrojejunal

anastomosis and into the Roux limb. The bougie can be seen through the opening formed after the stapler is removed. Another stay suture is placed at the halfway point of this opening. The stay sutures are then elevated, and a 60-mm blue staple or purple tristapler is used to close half of the opening. The remaining small defect is closed with a 2-0 vicryl running suture.

For completion of the gastrojejunostomy, a running 2-0 suture is used to create a second layer across the entire anterior portion of the anastomosis. The resultant ostomy is approximately 12 mm in diameter. A leak test can be performed by clamping the Roux limb distal to the anastomosis and insufflating air via endoscope or orogastric tube, while the anastomosis is submerged in saline solution. Alternatively, a retrograde air leak test can be performed by puncturing the Roux limb with a large bore 14-gauge needle and placing the CO_2 insufflator on low (3 L/min) to provide flow. This can be accomplished via a tool similar to one used for laparoscopic gallbladder drainage. Once the retrograde leak test is performed, a stitch must be placed over the bowel entry point to avoid leakage.

The mesenteric defects between the Roux limb mesentery and the transverse mesocolon (Petersen's defect) is then closed to the level of the transverse colon. If desired, a drain can be placed adjacent to the gastric pouch. If clinically indicated, a Gastrografin swallow study is performed on postoperative day 1 or 2 to check for leakage or obstruction.

Laparoscopic Adjustable Gastric Band

The LAGB received United States Food and Drug Administration approval in 2002. Before this time, the LAGB was widely used in Europe. The band is adjustable via fluid injection into a subcutaneous port to allow for tightening or loosening of the band. Advantages of the band include reversibility, lack of stapling, and ease of placement. The band requires an average of five to six adjustments in the first year after surgery, and its success requires patient compliance with return appointments and a diet and exercise regimen. Relative contraindications for band placement include the super obese (see Table 1), large paraesophageal hernia, prior gastric resection or Nissen fundoplication, and chronic inflammatory changes in the gastroesophageal junction.

The LAGB procedure (Figure 2) is routinely performed via the pars flaccida technique, with two 12-mm trocars, one 5-mm trocar, and a 15-mm trocar for band insertion. The liver is retracted with a Nathanson retractor. Dissection is performed bluntly at the angle of His, freeing up attachments for later insertion of the band. The gastrohepatic ligament adjacent to the lesser curve of the stomach is then divided with electrocautery. The right crus is identified, and the anterior peritoneal tissue is divided. If a hiatal hernia is identified, reinforcement of the hiatus is important, either anteriorly or posteriorly, to discourage further herniation once the band has been placed. Two graspers are used to carefully dissect the plane of tissue posterior to the gastroesophageal junction to provide a tunnel for the LAGB.

An articulating dissector such as the Realize Endoscopic Dissector (RED; Ethicon Endosurgery, Cincinnati, Ohio) is then placed from the right crus toward the angle of His. The RED is then flexed to create a right angle and locked into place. The adjustable band is placed into the abdomen through the 15-mm trocar in the left upper quadrant. The band is secured to the articulating dissector and brought around the stomach while the instrument is withdrawn. The band is then locked into place with approximately a 45-degree angle towards the patient's left shoulder. A minimum of two sutures are then placed from the fundus to the proximal gastric tissue around the band to secure the band into place. This reduces the possibility of band migration or herniation. The authors use two 2-0 vicryl sutures to accomplish this. It is important to ensure that the balloon portion of the band has not been compromised while either placing the band or suturing it into position.

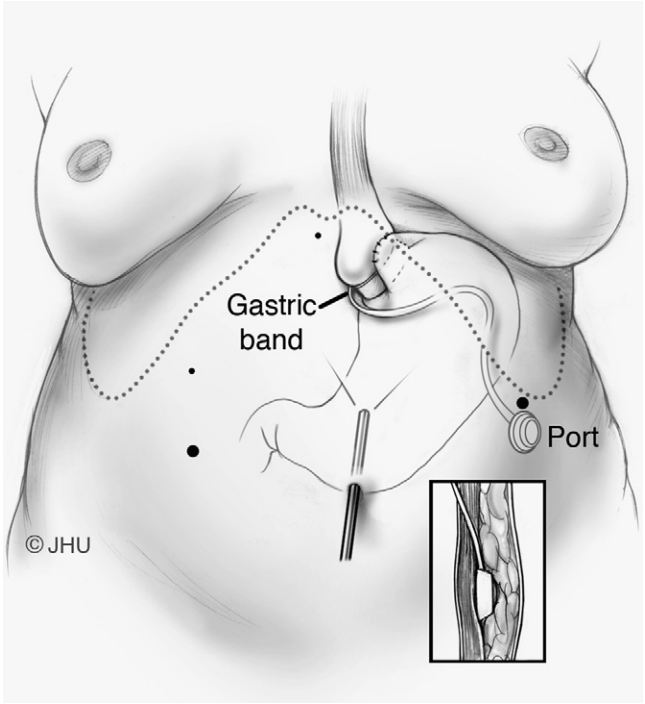

FIGURE 2 Laparoscopic adjustable gastric band. *(Courtesy Corinne Sandone, Johns Hopkins University.)*

The band tubing is brought out through the left upper quadrant port and secured externally to the subcutaneous injection port. Manufacturer's instructions must be followed, so as not to institute fluid or air into the band at this time. When securing the port to the fascia, a sufficient space must be cleared along the rectus sheath. After hemostasis has been achieved in the pocket, the port can be sutured or deployed into position while care is taken to leave the majority of the tubing intraabdominally. Finally, the port can be tested via Huber needle to ensure that the tube and band are functional and not kinked or malpositioned.

The authors do not perform a band fill before 6 weeks after surgery so that the site heals appropriately. If manual palpation of the subcutaneous port is difficult, fluoroscopy can be of assistance to fill the band. In patients with very thick subcutaneous tissue, placement of the band at the costal margin may be advantageous, for better palpation of the port during fills. Bands are typically filled approximately six times during the first year after placement. Each fill volume is 0.5 to 1 mL, depending on the amount of restriction. The patients must be able to swallow liquid without difficulty before leaving the clinic.

Laparoscopic Vertical Sleeve Gastrectomy

Laparoscopic vertical sleeve gastrectomy (LVSG) is the most recently introduced of the bariatric surgery procedures (Figure 3).

As mentioned previously, this procedure is primarily restrictive, as it removes the lateral aspect of the stomach to create a sleeve-like reservoir. The resection may also assist with weight loss by causing hormonally assisted satiety. The fundus produces the proappetite hormone ghrelin, and because the fundus is removed, these hormone levels are reduced after LVSG. Although this bariatric procedure is not reversible, it can be converted into a Roux-en-Y gastric bypass or duodenal switch if greater weight loss is desired.

The LVSG is typically performed with one 5-mm, two 12-mm, and one 15-mm trocar. With the liver retracted with the Nathanson,

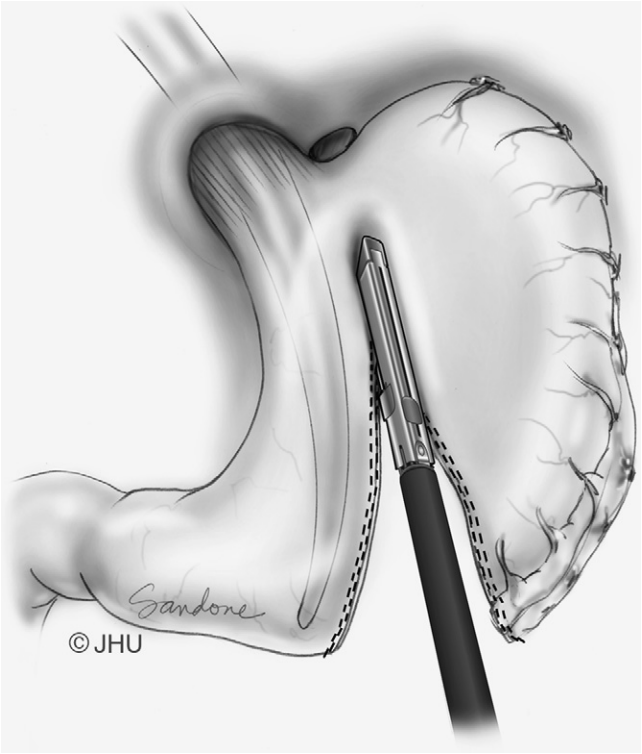

FIGURE 3 Creation of the gastric sleeve. *(Courtesy Corinne Sandone, Johns Hopkins University.)*

the short gastric vessels are divided along the greater curve of the stomach. A LigaSure device (Covidien, Norwalk, Conn) is typically used to accomplish this. A 40F blunt tip bougie is placed in the stomach and directed along the lesser curve. The stomach is divided at the greater curvature, beginning 6 cm proximal to the pylorus. Green and blue staple loads are used adjacent to the 40F bougie and extending to the angle of His. The staple line is oversewn or an absorbable buttress material can be used with the staples to assist with hemostasis. To test the anastomosis, an endoscopic air test or liquid dye infused through an orogastric tube can be used.

The partial gastrectomy specimen is removed through the 15-mm trocar site. Care should be taken to repair the fascial opening of this enlarged trocar site to prevent postoperative herniation. The authors typically place a drain in the left upper quadrant that is removed before discharge. As with Roux-en-Y gastric bypass, an UGI study is only performed if clinically indicated.

Laparoscopic Duodenal Switch With Biliopancreatic Diversion

The laparoscopic duodenal switch with biliopancreatic diversion (DS-BPD) is primarily a malabsorptive operation that involves preservation of the pylorus and creation of a short, 100-cm ileal "common channel" (Figure 4). The DS-BPD is the least common bariatric procedure performed because of its surgical complexity and potential for extreme malabsorptive nutritional deficiencies.

This procedure can be performed in a single operation, or in two stages if the patient has a high BMI (>70). The first stage is similar to LVSG. After approximately a 1-year period of weight loss, the patients can be converted to DS-BPD. This is performed by dividing the small bowel 250 cm from the ileocecal valve. The proximal end of bowel is then anastomosed to the distal ileum 100 cm from the cecum.

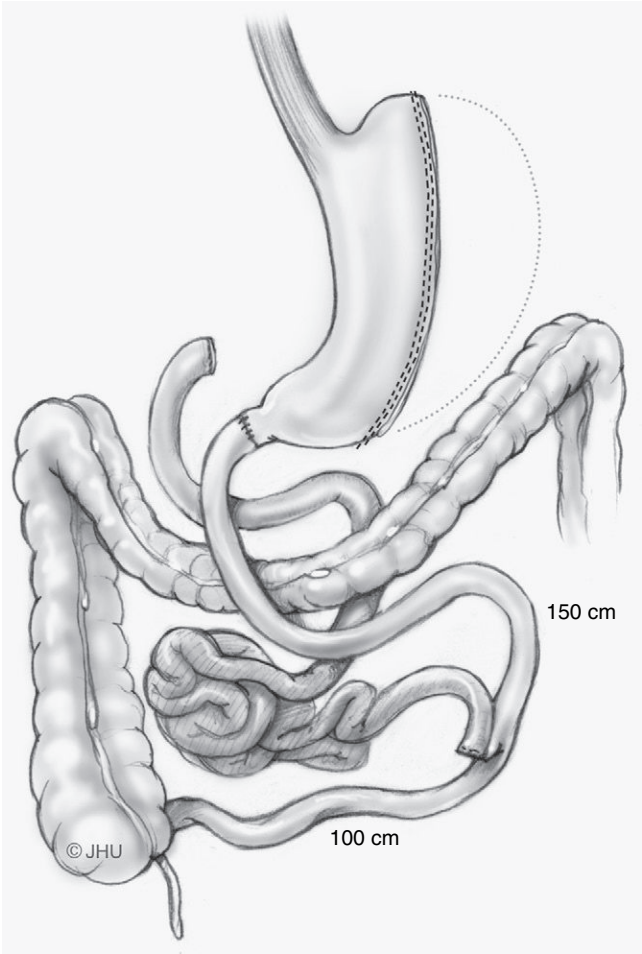

FIGURE 4 Antecolic duodenal switch with biliopancreatic diversion. *(Courtesy Corinne Sandone, Johns Hopkins University.)*

The patient is then placed in steep reverse Trendelenburg's position and the liver is retracted. If the sleeve gastrectomy portion has not been previously performed, then partial gastrectomy proceeds as described previously. The duodenum is then divided approximately 3 to 4 cm distal to the pylorus with a blue Endo-GIA 60-mm stapler.

The Roux limb is directed in an antecolic fashion, and a side-to-side anastomosis is performed with the duodenum. An air leak or dye test can be performed to check for leaks at the stomach staple line and new duodenal-jejunal anastomosis. Finally, the mesenteric defect is then closed between the Roux limb mesentery and the transverse mesocolon.

OUTCOMES AND COMPLICATIONS

After all bariatric procedures, patients are seen in follow-up at 2 weeks to ensure that they are well hydrated, exercising, and without wound complications. They are then seen at 3, 6, 12, 18, and 24 months and annually thereafter to follow weight loss and nutritional issues. Patients are encouraged to meet with dieticians and remain with their support groups indefinitely.

For 1 month after surgery, patients are all maintained on a high-protein puree consistency diet; they are gradually advanced to solid food. They also receive multivitamins, calcium, and vitamin B_{12} supplements. This is especially important for patients with gastric bypass and DS-BPD who are at higher risk for malabsorption and possible malnutrition. Supplemental iron is always considered for menstruating women.

Weight loss after gastric bypass and DS-BPD occurs primarily in the first 12 to 18 months after surgery and averages approximately 70% and 80% excess weight loss (EWL), respectively. Gastric banding and sleeve gastrectomy typically have less EWL, typically 40% to 50% over a 2-year to 3-year period.

One of the most important outcome measures after bariatric surgery is remission of obesity-related metabolic diseases, such as type 2 diabetes. More than 70% to 80% of patients with diabetes experience complete resolution after undergoing gastric bypass or DS-BPD. The restrictive operations have a 50% remission rate of diabetes. Hypertension, sleep apnea, hyperlipidemia, and fatty liver disease have similar remission rates.

Overall complication rates after bariatric surgery are less than 15% in most reports. Like most surgeries, there are early and late complications for bariatric surgery. Early or perioperative complications include bleeding, anastomotic leaking, and deep venous thrombosis. The mortality rate is less than 1% and is usually attributable to a pulmonary emboli or sepsis from anastomotic leak. Typical symptoms such as anorexia and abdominal pain can be difficult to elicit from morbidly obese patients, so it is important to be prompted by unexplained persistent tachycardia. This should raise suspicion for possible staple line leak or pulmonary embolus and trigger a thorough workup.

Vitamin B_{12}, calcium, iron, vitamin D, and protein deficiencies are long-term complications that can occur within the first year after surgery. Rigorous monitoring of nutrition status is necessary. Vitamin B_1 deficiency can also occur in patients with protracted vomiting after surgery and may present with extremity paresthesias and confusion. Lower extremity weakness and paresthesias can also be seen with vitamin B_{12} deficiency. Anastomotic stenosis and obstruction at the gastrojejunostomy in the first few months after surgery occur in less than 5% of patients after gastric bypass and can usually be managed with endoscopic dilation.

Internal hernias are also a possible complication and can occur at any time after surgery. The symptoms of internal hernia can be similar to an acute bowel obstruction or be chronic in nature and described as postprandial cramping pain. If there is even a slight suspicion of internal hernia, operative intervention is important to avoid bowel ischemia.

In general, the results of weight-loss surgery are excellent, with most patients losing more than 50% of their excess weight and resolving comorbidities. Approximately 10% to 15% of patients either do not achieve significant weight loss or partially regain their weight after 2 to 3 years. Ideally, these patients respond to dietary counseling, although some may need operative revision or conversion to a more malabsorptive procedure, such as the DS-BPD.

Unfortunately, no perfect method exists for choosing the best operation for each individual patient. Certainly, a multidisciplinary team approach is helpful in providing patient support throughout the preoperative and postoperative course. Reducing obesity-related diseases should be the major goal, not merely cosmetic improvement. Patients must understand that bariatric surgery is a tool to assist with weight loss, and it must be combined with drastic changes in dietary, exercise, and lifestyle habits.

Small Bowel Obstruction

Lisa M. Kodadek, MD, and
Martin A. Makary, MD, MPH

OVERVIEW

Although the incidence of mechanical small bowel obstruction (SBO) is decreasing with the advent of laparoscopic surgery, it remains a common surgical problem. Postoperative adhesions are the most common cause and account for nearly 75% of all cases. More than 300,000 patients are hospitalized each year in the United States for an adhesiolysis operation, and SBO represents nearly 20% of surgical admissions for acute abdominal conditions. After some open surgeries, 4% to 30% of patients may develop adhesion-related SBO. Approximately 10% to 30% of patients who undergo adhesiolysis for SBO will develop recurrent SBO and will require an additional operation.

Hernia and neoplasm are other common causes of SBO. Metastatic disease, such as melanoma or ovarian cancer, is more common than primary neoplasm of the small bowel. Less common causes of SBO include Crohn's disease, abscess, intussusception, Meckel's diverticulum, bezoar, gallstone ileus, volvulus, radiation enteritis, traumatic intramural hematoma, congenital abnormalities, and superior mesenteric artery syndrome.

Approximately 25% of all patients with SBO need an operation during the index admission, and those who undergo operative management have fewer recurrent episodes of SBO when compared with those managed without surgery (Foster, 2006). Patients who have not had prior abdominal surgery are far more likely to need surgery than those with a history of abdominal surgery.

Diagnosis of SBO is most often made after a focused history and physical examination. Imaging studies are important adjuncts, and laboratory studies are important to ascertain the degree of metabolic derangement and fluid status. The white blood cell count can help indicate the timing and level of urgency to operate. The etiology of obstruction, the type and location of obstruction, and patient factors including surgical history and comorbidities are important considerations in determining the need for operative intervention. Some patients with regular patterns of recurrent bowel obstruction know themselves best. They often describe a predictable frequency and duration of episodes. In fact, in the absence of leukocytosis or other concerning signs, patients can play an important role in the decision to have surgery versus continue a pattern of nonoperative management, especially in patients at high surgical risk.

Much of the management of SBO surrounds recognition of signs and symptoms concerning for bowel strangulation. For most patients with SBO, bowel strangulation is not present. In these cases, early diagnosis, gastrointestinal decompression, bowel rest, and fluid resuscitation remain the most important strategies. When strangulation is a concern, timely operative intervention is critical to prevent further complications of bowel strangulation, such as perforation, septic shock, and death.

EVALUATION AND DIAGNOSIS

Classic symptoms of SBO include colicky abdominal pain, nausea, emesis, distension, and obstipation. Diarrhea may also be present. Mechanical SBO must be distinguished from nonobstructive motility disorders such as paralytic ileus. Ileus may be associated with abdominal trauma, mesenteric ischemia, or electrolyte disturbances, such as hypokalemia, or most commonly, with open abdominal operations involving bowel manipulation,. The distinction can be subtle and often requires a careful history taking.

The clinical presentation of SBO may vary based on three factors: (1) severity of the obstruction; (2) anatomic site of obstruction; and (3) elapsed time between onset and presentation. Early recognition of SBO severity is critical for proper management. A SBO may be *complete,* meaning the bowel lumen is completely obstructed with no distal passage of stool or air, or only *partial,* meaning the bowel lumen is narrowed and there is some distal passage of bowel contents. An *open-loop* obstruction occurs when proximal decompression is possible via emesis or nasogastric tube (NGT). *Closed-loop* obstruction occurs when both proximal and distal bowel are obstructed; common causes include bowel incarceration in a hernia sac or intestinal torsion. *Simple* obstruction does not compromise blood flow to the bowel; *strangulation* involves compromise of blood flow with inevitable bowel necrosis. Anatomic site of obstruction may be classified as proximal (pylorus to proximal jejunum), intermediate (midjejunum to midileum), or distal (distal ileum to ileocecal valve). The anatomic site of obstruction may also be classified in relation to the intestinal wall as intraluminal (intussusception or bezoar), intramural (neoplasm or Crohn's disease), or extrinsic (adhesions or hernia).

A shorter period of elapsed time is typical between onset of symptoms and presentation for closed-loop obstruction as compared with open-loop obstruction because of the rapid evolution of symptoms in the former. Similarly, a complete obstruction often presents earlier and with more acute findings than partial obstruction. The character of vomitus should be ascertained; feculent vomitus is typically associated with a later presentation and a more established obstruction.

Physical examination findings and signs that portend risk of strangulation include findings consistent with an infection (fever, tachycardia, leukocytosis) and localized abdominal tenderness. Laboratory tests are often advocated for detection of strangulation, but

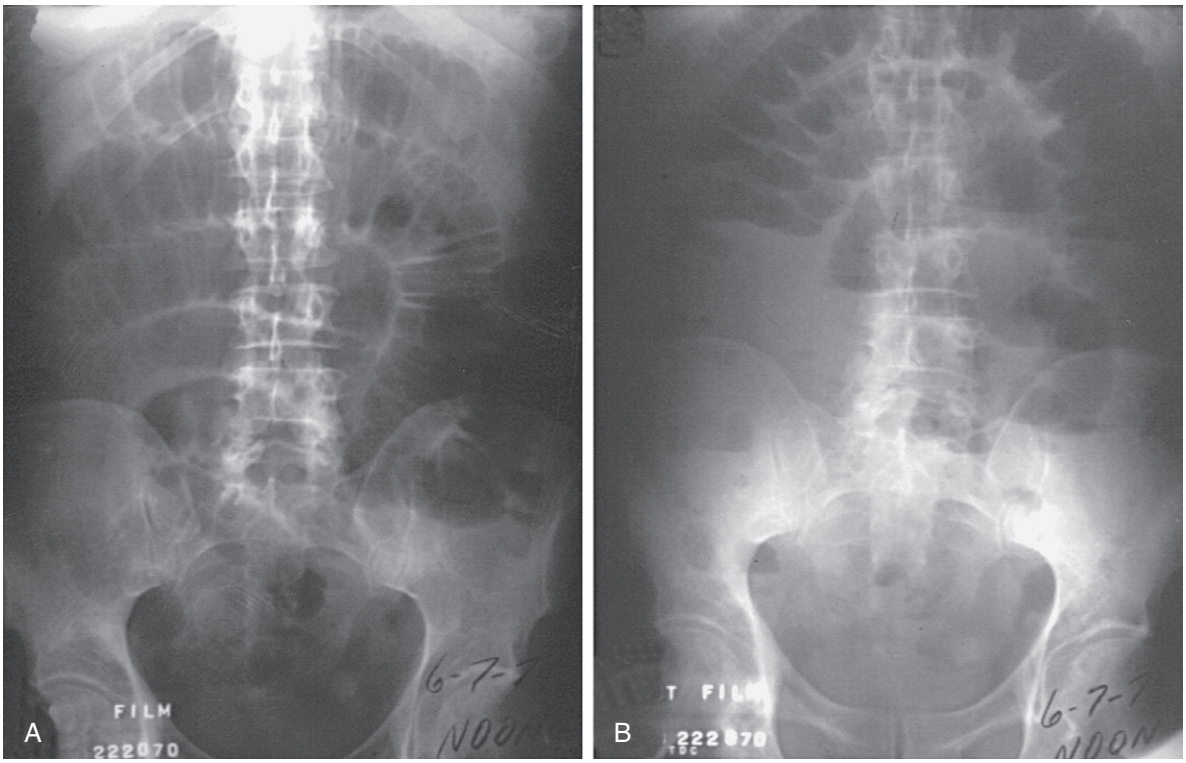

FIGURE 1 Plain abdominal radiographs of a patient with complete small bowel obstruction. **A,** Supine film shows dilated loops of small bowel without evidence of colonic gas. **B,** Upright film shows multiple, short air-fluid levels arranged in a stepwise pattern. *(Courtesy of Melvyn H. Schreiber, MD, The University of Texas Medical Branch, Galveston, Tx.)*

keep in mind that there is no definitive laboratory test to diagnose imminent bowel necrosis and, similarly, there are no laboratory criteria to reliably exclude strangulation. However, increases in serum amylase, serum D-lactate, and intestinal fatty acid binding protein are associated with intestinal ischemia.

Radiographic evaluation often includes an abdominal x-ray series, which includes supine and upright plain radiographs of the abdomen and an upright chest radiograph. The most specific findings for SBO on plain film are dilated loops of small bowel (greater than 3 cm), air-fluid levels, and a paucity of gas in the colon (Figure 1). The chest film is critical to rule out pneumoperitoneum (free air) because this finding in the setting of bowel obstruction may warrant immediate operative exploration (Figure 2). Although an abdominal series may be a reasonable first study, the sensitivity of this test for SBO is poor.

The computed tomographic (CT) scan with intravenous (IV) contrast has become the favored radiographic study for evaluation of SBO. Given the rapid study time, the CT scan has the advantage of more information than an x-ray and evaluation of the passage of contrast when an ileus is also suspected. CT scan also has the advantage of diagnosis of the cause of obstruction such as hernia, mass, inflammatory lesion, or intussusception (Figure 3). CT scan can also be used for assessment of the presence of strangulation with signs such as bowel wall thickening, poor contrast enhancement of the bowel wall, pneumatosis intestinalis, mesenteric vascular engorgement, and mesenteric haziness (Figure 4). CT scan is accurate in distinguishing malignant from benign obstruction in patients with a history of abdominal surgery for malignant disease (Figure 5). Studies have shown that CT scan has an 80% to 90% sensitivity and a 70% to 100% specificity for diagnosis of SBO. One study has shown that helical CT scan has an 84% sensitivity and 90% specificity for diagnosis of the cause of SBO and 100% sensitivity and specificity for diagnosing strangulation (Obuz et al., 2003).

For evaluation of a SBO in the postoperative setting, a study with gastrointestinal contrast can evaluate obstruction. Contrast studies

of the small intestine include CT enterography, enteroclysis, and small bowel series.

CT enterography involves administration of large volumes of oral contrast such as water-methylcellulose solution to achieve intraluminal distension. This study is most often used for patients with Crohn's disease–related strictures and allows excellent imaging of the bowel

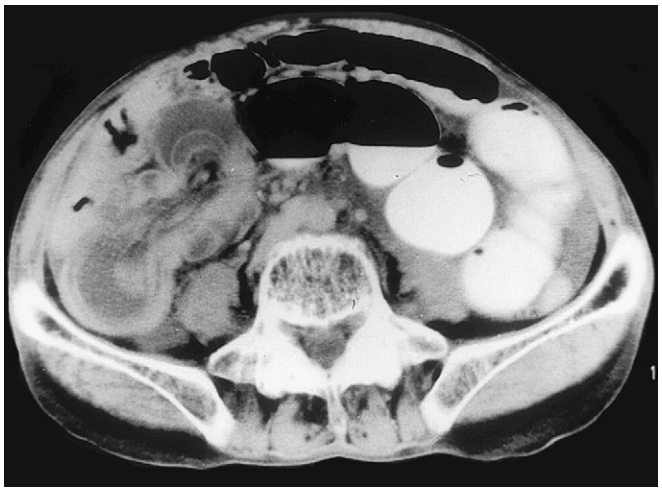

FIGURE 3 Strangulated small bowel obstruction from ileocecal tumor causing intussusception with characteristic "bowel in bowel appearance." *(From Obuz F, Terzi C, Sokmen S, et al: The efficacy of helical CT in the diagnosis of small bowel obstruction,* Eur J Radiol *48(3):299–304, 2003, Fig 5,A.)*

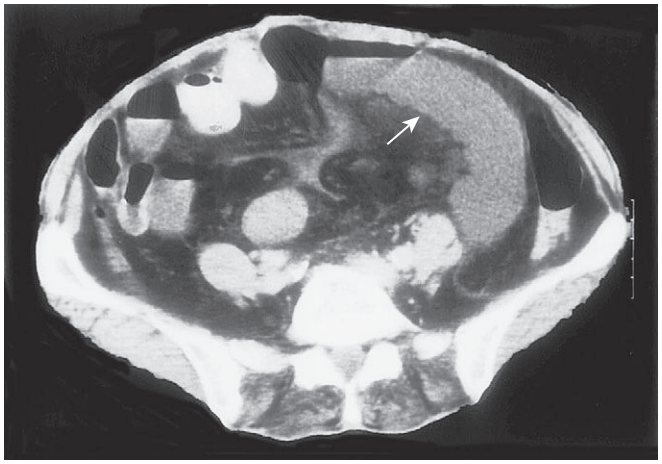

FIGURE 4 Strangulated small bowel obstruction with computed tomographic scan shows poor contrast enhancement of the small bowel wall *(arrow). wall. However, this study is impractical in patients with gastrointestinal distress who are unable to tolerate contrast by mouth. The amount of oral contrast administered and the timing of the oral contrast should be determined based on the purpose of the CT scan.

Enteroclysis, a fluoroscopic study in which the proximal small bowel is instilled with air and contrast, can detect minimal adhesions and mucosal changes. However, this modality has many disadvantages, including the need for nasoenteric intubation and sedation; furthermore, enteroclysis is contraindicated in patients with complete obstruction.

If small bowel series is used, it is important to recognize that barium use may delay CT examination and surgery. Barium should not be used in cases of suspected perforation, strangulation, or a complete or closed loop obstruction. Barium impaction, although rare, is a known complication of this modality and may ultimately worsen a SBO.

An endoscopy procedure is contraindicated for a SBO. The exception to this rule is a gastric outlet obstruction in a patient who is not optimized for surgery (e.g., a malnourished patient). When a narrowing of the distal stomach or duodenum is the cause of a gastric

FIGURE 5 Small bowel obstruction from peritoneal carcinomatosis. The patient had a history of total gastrectomy for gastric carcinoma. There is irregularly concentric wall thickness as a result of serosal implants and proximal bowel dilation. *(From Obuz F, Terzi C, Sokmen S, et al: The efficacy of helical CT in the diagnosis of small bowel obstruction,* Eur J Radiol *48(3):299–304, 2003, Fig 2.)*

outlet obstruction (e.g., a periampullary tumor, distal gastric mass, etc.) and endoscopic intervention can dilate or stent the obstruction, endoscopy may be warranted and can be ideal to bridge a patient to surgery at a time when the patient is less sick and better nourished. This interval strategy can lower the complication risk of definitive surgery.

NONOPERATIVE MANAGEMENT

An initial trial of conservative therapy is appropriate for most cases of partial SBO, obstruction in the early postoperative period, obstruction from Crohn's disease, and those patients with history of SBO. Nonoperative management is appropriate provided there is no clinical deterioration and the patient shows some evidence of improvement over the first 12 to 24 hours. Heightened clinical awareness and repeat assessments are critical to ensure that no change in patient status necessitates operative intervention.

Nonoperative management begins with aggressive fluid resuscitation and correction of any electrolyte disorders. Adequate IV access and urinary output monitoring are important. Patients who present after protracted emesis classically have a hypochloremic, hypokalemic metabolic alkalosis with concomitant paradoxical aciduria.

Intraluminal distension can lead to mucosal ischemia. Thus, gastrointestinal decompression and bowel rest is paramount in management of a SBO. A standard NGT provides symptomatic relief, minimizes intraluminal distension with air and fluid, and allows for serial assessment of NGT output as a marker of antegrade small bowel movement. Care should be taken to ensure that nasoenteric tubes are properly functioning because they render the lower and upper esophageal sphincters incompetent and pose a risk for aspiration. A NGT may not be necessary in a patient who does not have gastric dilation.

The use of narcotic pain medication during nonoperative treatment of SBO has been debated because pain medication can mask worsening symptoms that may be diagnostic. Because CT scans are such a tremendous diagnostic tool in management of patients with a SBO, the authors advocate for adequate pain control with a patient-controlled analgesic device or equivalent regimen. Patients with escalating need for pain medication indicate the need for repeat CT scanning.

Many cases of SBO resolve with fluid resuscitation, bowel rest, and gastrointestinal decompression. Over the subsequent days, patients often begin to show improving symptoms, decreased

distension, and improving imaging studies. Occasionally, small bowel series or enteroclysis may be helpful for those patients who do not achieve complete resolution, especially in the postoperative period when a prolonged ileus may be high on the differential diagnosis. For those with Crohn's disease, medical therapy (steroids and other immunosuppressive therapy) may help resolve partial SBO from inflammatory lesions. For those with SBO after blunt abdominal trauma, obstruction is typically the result of an intramural hematoma and usually resolves with nonoperative therapy after 2 to 4 weeks. Total parenteral nutrition may be considered for selected patients with SBO to prevent the sequelae of negative nitrogen balance. Patients with Crohn's disease and trauma are two common exceptions to the principle that SBO patients without prior surgery are more likely to need surgery intervention.

A recent systematic review and meta-analysis of 14 prospective studies has shown diagnostic and therapeutic use of water-soluble contrast in patients with adhesive SBO (Branco et al., 2010). The appearance of contrast in the colon within 4 to 24 hours after administration had a sensitivity of 96% and specificity of 98% in predicting resolution of SBO. In cases in which contrast reached the colon, obstruction resolved in 99% without surgery. In cases in which contrast failed to reach the colon, obstruction failed to resolve without surgery in 90% of patients.

OPERATIVE MANAGEMENT

Approximately 25% of inpatients admitted for a SBO need an operation. Patients with a complete or high-grade partial SBO are most likely to need surgery. Patients with evidence of peritonitis, bowel perforation, or strangulation need immediate surgery. Patients with development of fever, tachycardia, or worsening leukocytosis should be considered for operative intervention.

Patients with no history of abdominal surgery are unlikely to have adhesions and are likely to need operative management. Hernia, tumor, or Crohn's disease should be considered in the differential for this group of patients.

Patients with a history of intraabdominal malignancy may be difficult to manage. When a patient has known recurrent disease, nonoperative therapy or surgical palliation may be most appropriate depending on the stage of the malignancy and the patient's goals. However, studies have shown that two thirds of these patients have a lesion amenable to surgical correction such as an adhesive band. Surgical palliation for patients with advanced disease such as carcinomatosis may involve a percutaneous gastrostomy tube placement, a diverting ileostomy, or a limited small bowel resection. Carcinomatosis can be difficult to ascertain with preoperative imaging.

Intussusception is much more common in the pediatric population, but it may present in adults as a SBO. In adults, intussusception is the result of a pathologic nidus such as a polyp or tumor. Whereas most pediatric cases are benign, 50% of adults with intussusception are diagnosed with a malignancy. Radiographic decompression is often successful for pediatric patients, but adults generally need surgery to rule out a malignant lead point.

For patients with a history of recurrent SBO, an initial trial of nonoperative treatment is preferred. However, if the patient does not respond to a course of bowel rest, gastrointestinal decompression, and use of total parenteral nutrition, operative intervention is warranted. These cases can present a significant technical challenge because most patients have undergone multiple prior abdominal operations.

For patients with suspected duodenal intramural hematoma after traumatic injury, surgical intervention is infrequently needed. However, if symptoms of obstruction persist beyond 6 to 8 weeks, consideration of possible progression to fibrosis is important. Surgery should be reserved for those with development of fibrosis; gastrojejunostomy or duodenojejunostomy may be necessary to bypass the area of fibrotic narrowing.

Rare sources of intraluminal obstruction include bezoar, gallstone ileus, and barium impaction. These conditions generally cause complete obstruction and warrant surgery. Patients with gallstone ileus usually have radiographically apparent stones within the intestinal lumen, often in the distal ileum or at the ileocecal valve. Pneumobilia may also be apparent from a biliary-enteric fistula. Operative management involves enterotomy in a region of proximally dilated small bowel with stone extraction. Partial small bowel resection may be required for severely impacted stones. The entire small bowel should be inspected for evidence of remaining stones. Cholecystectomy and biliary-enteric fistula repair should be performed to prevent recurrence of gallstone ileus and cholangitis from reflux of intestinal contents. If the fistula occurs between the distal common bile duct and the duodenum, the definitive repair necessitates closure of the fistula and biliary reconstruction with choledochojejunostomy. The timing of cholecystectomy and fistula repair depends on a patient's overall condition and hemodynamic stability.

Technical Considerations

When small bowel distention does not allow for adequate visualization with laparoscopic insufflation, a laparotomy is performed. In cases in which the bowel is decompressed or the distention is mild, a laparoscopic approach can be attempted, but the initial port site should not involve a previous scar where adhesive disease could risk a bowel perforation on entry. Data from retrospective trials suggest that laparoscopy may have lower mortality and morbidity, faster recovery, and shorter hospital stay than the traditional open approach for SBO. Some series have reported an 80% success rate for resolution of SBO with laparoscopic approach. Surgeon experience likely plays a major factor in successful laparoscopic adhesiolysis.

Once the obstruction has been addressed with appropriate surgical treatment, a diligent and complete determination of bowel viability is critical. The bowel often appears pink and clearly viable; assessment can be rendered with subjective criteria in this situation.

If a large segment of bowel appears threatened, or if bowel viability cannot be clearly established, the surgeon can leave the abdomen open with plans to return to the operating room in 24 to 48 hours for a repeat assessment. If a small segment of bowel appears threatened, resection and closure at the initial operation is usually best.

Luminal decompression may be a helpful maneuver to promote blood flow to bowel that is distended and edematous from obstruction. This maneuver may also help allow closure of the abdomen. Enteric contents may be milked in the retrograde direction to reach the NGT. This should be performed in close communication with the anesthesia team to ensure a properly functioning NGT given the risk for aspiration. Great care should be taken to avoid extensive manipulation and injury. If bowel resection is deemed necessary, decompression can be achieved by inserting a drainage catheter into the proximal segment before completing the anastomosis.

Adhesion Prevention

The overall increased use of laparoscopy in surgery is decreasing the incidence of SBO from adhesions. Laparoscopy when possible results in a lower rate of long-term SBO than laparotomy.

Bioresorbable membrane technology holds promise in adhesion prevention but has not been shown to decrease the rate of SBO. Currently available products include Seprafilm (chemically modified sodium hyaluronate/carboxymethylcellulose; Genzyme, Cambridge, Mass) and Interceed (oxidized regenerated cellulose; Ethicon, Somerville, NJ). These products are supplied as a thin transparent film and may be difficult to handle. SurgiWrap (polyactide; MAST Biosurgery, San Diego, Calif) is also a bioresorbable sheet but may be easier to handle and can be used laparoscopically. Although bioresorbable membrane technology has been shown to decrease adhesion

formation and severity, no evidence is found to suggest that these products reduce the rate of SBO or decrease the need for reoperation.

The Management of Crohn's Disease of the Small Bowel

Isaac Howley, MD, and
Susan L. Gearhart, MD, FACS, FASCAS

OVERVIEW

Crohn's disease (CD), or *regional enteritis,* is a complex, multifactorial disorder that affects the entirety of the gastrointestinal (GI) tract. The hallmark of the disease is a chronic, relapsing, and remitting inflammatory process that may ultimately cause infectious, obstructive, hemorrhagic, or neoplastic complications. The cause of CD is unknown, but there is strong evidence of a genetic predilection; more than 100 genes and loci for inflammatory bowel disease (IBD) have been defined. First-degree relatives of patients with IBD have a fivefold to twentyfold increased risk for developing the disease. The genetic variants of the *NOD2* gene appear to have the greatest association with CD; however, the presence of this gene and others varies among different populations of various descents. Environmental factors, such as intestinal microbes, are also known to influence the development of the disease.

There is currently no known cure for CD. Medical interventions are aimed at control of symptoms and prevention of long-term sequelae, such as disease recurrence and loss of functional intestinal length, which leads to malabsorption. Therefore endpoints of medical therapy are somewhat ambiguous, with no universally accepted mark of efficacy for treatments. Commonly used endpoints include various quality-of-life grading systems, evidence of mucosal healing by endoscopic assessment, and failure of medical therapy, documented by the requirement for surgical intervention. Surgical interventions are aimed at restoring normal gastrointestinal function when medical therapy has not been successful. Approximately 70% of patients with CD eventually require surgery for the disease, and 50% of these require a second operation for disease recurrence.

Patients with CD frequently present with nonspecific symptoms such as abdominal pain, bloating, diarrhea, and anorexia. Unlike acute abdominal processes such as appendicitis, CD may be characterized by progressive, chronic, intermittent GI distress that is localized or diffuse. Many affected patients are malnourished and anemic. Approximately 40% of affected patients have involvement of the terminal ileum, 20% have involvement of the colon, 10% have isolated disease in the jejunum and ileum, and 10% have isolated involvement of the anus. The remaining 20% have disease in multiple locations throughout the GI tract.

The clinical diagnosis of CD is based on an accurate history and physical examination, including anal examination, and a combination of several of the following studies: (1) upper endoscopy to evaluate gastroesophageal and duodenal disease; (2) colonoscopy to characterize colonic or ileal disease; (3) traditional small bowel contrast studies, advanced computed tomographic (CT) enterography, or magnetic resonance enterography to reveal intraluminal manifestations that include strictures and fistulas, and (4) traditional CT scan with oral contrast media to evaluate extraluminal complications such as intraabdominal abscesses or inflammatory masses. The disease is confirmed pathologically when gross features of the disease—including fat wrapping, aphthous ulcers, and transmural inflammation—are seen. Microscopic inspection of gastrointestinal biopsy samples may reveal increased inflammatory features, architectural abnormalities, and epithelial abnormalities.

MEDICAL MANAGEMENT

In the Vienna Classification of CD, age, location, and disease type are the key variables used to predict disease behavior. The most widely quoted variable is disease type, which is based on the following phenotypes; *inflammatory, fibrostenotic,* and *penetrating.* This classification can be problematic at times because there is crossover that occurs between each phenotype, and perianal fistulizing disease does not seem to characterize a specific phenotype. However, CD classification systems may be helpful in guiding therapy and predicting recurrent disease. Recurrent disease commonly occurs with the same phenotypic presentation and in the same anatomic location: for example, ileocolic fibrostenotic disease recurrence at the site of a prior ileocecectomy anastomosis. Furthermore, the inflammatory phenotype in CD is the most common and frequently the most responsive to medical therapy. Fibrostenotic phenotypes tend to be the least responsive to medical therapy.

In the absence of a clear surgical indication, CD is managed with medical therapy. Several classes of medications are used to treat it, including aminosalicylate (5-ASA) derivatives, steroids, antibiotics, immunomodulators, and biologic agents. 5-ASA derivatives, steroids, and immunomodulators have been the mainstay therapy for CD since the 1970s and have well-described side effects. The mechanisms by which these agents exert their effects are uncertain and probably

nonspecific. Newer entities, the biologic agents, are intended to target known immune and inflammatory pathways. Although highly specific, biologic agents can cause severe side effects, such as allergic reactions and increased incidence of new or reactivation of old viral infections (meningitis, John Cunningham [JC] virus, progressive multifocal leukoencephalopathy). Furthermore, biologic therapy is expensive. As biologic therapy becomes more widely used, more information regarding its safety and efficacy will become available.

Smoking cessation is among the most effective treatments for Crohn's disease, as well as being inexpensive and free of toxic side effects. Among patients with Crohn's, smoking is associated with a higher incidence of fibrostenotic and penetrating phenotypes. In patients with CD who smoke, perianal disease is worse, rates of surgical therapy are higher, and rates of postsurgical recurrence are higher. Despite its clear benefits, smoking cessation remains a difficult goal for such patients, as it does with other patients. Even in cessation programs targeted at patients with CD, only 12% to 23% of patients have been reported to be successful with abstinence on long-term follow-up.

Traditionally, medications have been prescribed along a "step-up" approach (Figure 1). Therapy begins with the least toxic, least expensive, but least effective drugs, such as 5-ASA derivatives, and proceeds "upwards" with enterally active steroids, antimetabolites, systemic corticosteroids, and biologic drugs. There has been considerable discussion about a "top-down" approach, which starts with powerful biologic therapies for treating medication-naïve disease. This approach to use the most effective therapies initially has not achieved widespread use. Although certain CD types may respond to more aggressive therapy first, a top-down approach involves treating many patients who would be well served by the less expensive and less toxic regimens.

In the following paragraphs, the most commonly used medications in the treatment of CD are discussed (Table 1). Aminosalicylates such as sulfasalazine and mesalamine are antiinflammatory derivatives used orally or rectally to treat and maintain remission in mild to moderate CD with a known 70% response rate. These 5-ASA derivatives are formulated to allow distribution of medication to a specific intestinal location. Mesalamine (Pentasa) 4 g/day, which is released throughout the gastrointestinal tract, has been shown to be effective in the treatment of small bowel and large bowel disease. Derivatives of 5-ASA have not been shown to prevent relapse of CD, are not associated with increased perioperative complications, and can be taken until surgery and restarted immediately afterwards.

Steroids may be used orally, intravenously, or rectally for the treatment of acute moderate to severe disease. In the short term, steroids decrease inflammation in 60% to 92% of affected patients and allow for improved intestinal function, but long-term steroid dependence is associated with significant side effects that include growth retardation, osteopenia, cushingoid features, hypertension, glomerular nephritis, cataracts, necrosis of the femoral head, and adrenal suppression. It has been reported that up to 35% of patients treated with corticosteroids develop either steroid dependence or steroid

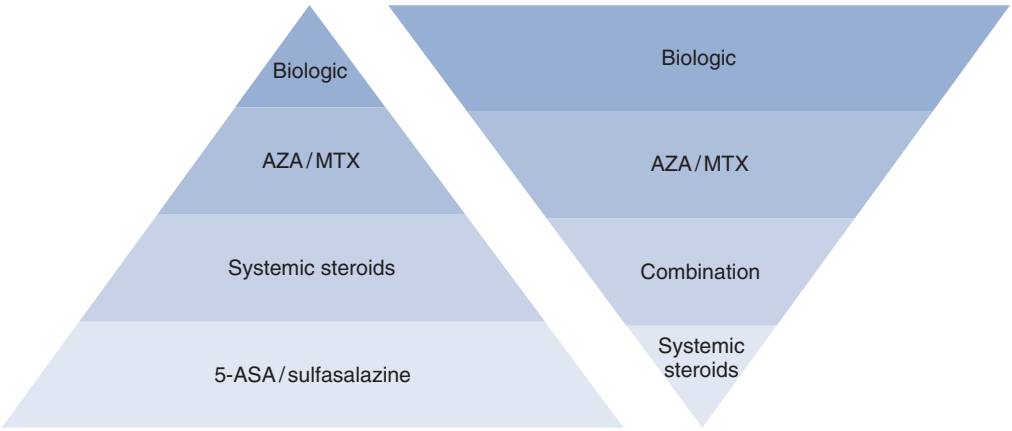

FIGURE 1 Step-up approach versus top-down approach in the medical management of Crohn's disease. *5-ASA,* aminosalicylate; *AZA,* azathioprine; *MTX,* methotrexate. *(Modified from Buchner AM, Blonski W, Lichtenstein GR: Update on the management of Crohn's disease,* Curr Gastroenterol Rep *13(5):465-474, 2011.)*

TABLE 1: Indications and risk of perioperative use of commonly used medication for the treatment of Crohn's disease

Medical therapy	Indication	Effect on perioperative risks
Aminosalicylate (5-ASA) derivatives	Mild acute small and large bowel disease	None
Corticosteroids	Mild to moderate ileocecal disease No role in maintenance	Increased infection risk, poor wound healing greatest at ≥40 mg/day For adrenal insufficiency, stress dose needed if steroids have been used in the past 6 mo (no need for stress dose steroids with oral budesonide therapy)
Antibiotics	Perianal disease, in combination for acute intestinal disease	Increased prevalence of *Clostridium difficile* colitis
Immunomodulators	Maintenance therapy for moderate to severe disease	None
Biologic agents	Acute moderate to severe disease	Recommendation to stop therapy 30 days before surgery

resistance. Unless stress-dose steroids are administered, patients receiving long-term steroid therapy are at risk for perioperative adrenal crisis that can result in hemodynamic instability. In addition, long-term use of steroids can result in poor wound healing, increased risk of infectious complications, and other perioperative problems. Long-term use of steroids may complicate diagnosis of abdominal complications such as perforation and abscess by masking signs and symptoms of disease. The side effects of systemic corticosteroids can be avoided by the use of budesonide (Entocort), which has extensive first-pass liver metabolism. Budesonide has been shown to be more effective than placebo for inducing remission in patients with mild to moderate CD of the terminal ileum and proximal colon. However, no data suggest that budesonide alone can reduce the incidence or relapse, and therefore it has no utility in maintenance therapy. Because of the limited systemic effects, the use of budesonide has not been shown to be problematic during the perioperative period.

The rationale for the use of antibiotics in the treatment of CD is the hypothesis that the cause of CD may be related to unidentified bacterial pathogens. A meta-analysis showed that treatment with broad-spectrum antibiotics was more than twice as effective as placebo at inducing clinical improvement. Antibiotics are often used in conjunction with other medications for the treatment of acute inflammation, including perianal fistulas. Fluoroquinolones (e.g., ciprofloxacin), metronidazole, and rifaximin are commonly used. Antibiotics have not been shown to be detrimental when used in the perioperative setting, but they are associated with an increase in the prevalence of *Clostridium difficile* diarrhea in patients with inflammatory bowel disease. This complication may occur even in patients receiving metronidazole, despite this drug's frequent use in the treatment of *C. difficile.*

Immunologic antimetabolites such as azathioprine (AZA) and 6-mercaptopurine (6-MP) work by inhibiting RNA synthesis, having a disproportionate effect on the rapidly proliferating lymphocyte cell lines that mediate CD. These drugs have a slow onset of action (up to 6 months) and are not used in the treatment of acute flares, but they are a mainstay of maintenance therapy for patients in remission. Their use is particularly beneficial in reducing corticosteroid use and the incidence of postoperative recurrence of disease. Studies have shown that in patients who take an immunomodulator postoperatively, the need for recurrent surgery is reduced by 8% and the risk of endoscopic recurrence is reduced by 15% at 1 year. The disadvantage of immunomodulator therapy is the increased rate of adverse events that necessitate withdrawal of the drug in up to 17% of patients in some studies. Side effects include pancreatitis, flu-like symptoms, myelosuppression, and lymphoma. To limit side effects, it is important to evaluate thiopurine methyltransferase (TPMT) activity in each patient before therapy with 6-MP or AZA begins. This enzyme is responsible for the metabolism of these drugs, and up to 11% of patients have abnormal TPMT activity. There is no evidence of higher rates of postoperative complications with these drugs. Methotrexate (MTX), a folic acid antagonist that inhibits purine synthesis, has also been used for remission in the attempt to avoid steroids. A Cochrane meta-analysis showed that low-dose MTX is threefold more effective than placebo in maintaining remission. The side effects of higher dose MTX include myelosuppression and hepatotoxicity.

Biologic agents are the newest, most effective, and most expensive class of medications in the CD armamentarium; response rates are as high as 70%, even in previously difficult-to-treat, penetrating disease. The three biologic agents in use in the United States are infliximab (IFX, Remicade), adalimumab (Humira), and certolizumab pegol (Cimzia). All are directed at tumor necrosis factor (TNF) and reduce T-cell proliferation, thereby decreasing inflammation. These medications are delivered by intravenous infusion or subcutaneous injection and may be used for both acute flares and, on a continuing basis, to maintain remission. Side effects include infusion reactions, increased risk of infections such as tuberculosis and histoplasmosis, and lymphoma. A newer selective adhesion molecule inhibitor, natalizumab (Tysabri), has been evaluated for use in patients with active moderate to severe CD who do not respond to or tolerate conventional biologic agents. Some research findings suggest an increased risk of postoperative complications in patients receiving biologic therapy, especially intraabdominal sepsis and wound healing. To date, these studies have focused only on infliximab and are limited by small study populations and heterogeneous methods. It is best to avoid operating on patients with therapeutic levels of biologic agents. Unfortunately this is frequently not possible, as patients needing operations are those whom have received maximal medical management without response.

Combination therapy for the treatment of patients with moderate to severe disease has gained favor since the publication of the recent Study of Immunomodulator-Naive Patients in Crohn's Disease (SONIC). In this study, the 508 participants were randomly assigned to receive AZA alone, IFX alone, or AZA plus IFX. The results showed that patients treated with combination therapy (AZA plus IFX) had a nearly twofold increase in steroid-free clinical remission and mucosal healing rates at 26 weeks. Furthermore, immunoreaction to IFX therapy was reduced when the drug was given in combination. No data suggested that combination therapy may be beneficial in the prevention of postoperative recurrence of disease.

Patients with CD may require nutritional supplementation. Absorption may be decreased as a result of inflammation or stricture. Furthermore, bacterial overgrowth in prestenotic dilated intestinal loops may contribute to malabsorption. Absorption of fat-soluble vitamins such as vitamins A, D, E, and K may be reduced as a result of ileal disease or prior resections. Bowel rest with parenteral supplementation may also be used as a treatment for CD, but this has not been supported by results of randomized studies. Furthermore, research continues with regard to the disease-modifying properties of enteral formulas.

A newer modality that is gaining enthusiasm is endoscopic balloon dilatation. Small bowel CD strictures may be endoscopically dilated; however, endoscopic therapy is frequently limited by inaccessibility and fixed strictures. A systematic review of this treatment showed that strictures dilated endoscopically that are 4 cm or smaller were more likely (odds ratio = 4.01) not to necessitate surgery. Furthermore, the reported mean complication rate was 2%.

INDICATIONS FOR SURGICAL MANAGEMENT

Timing of when a patient should go to surgery is important in the management of this disease. Treatment planning is best performed by a multidisciplinary team that includes gastroenterologists, surgeons, radiologists, pathologists, nutritionists, and, when needed, enterostomal therapists and psychologists. As all surgeons know, it is very difficult to promote healing and improve quality of life in a malnourished, immunocompromised patient. In part for this reason, a multicenter trial is currently under way to investigate whether patients should continue with more aggressive therapy (biologic) or undergo laparoscopic surgery for distal ileitis. Further evaluations of the timing of surgery in this population are needed.

The most common indication for surgical intervention is medically refractory CD. Disease symptoms continue or worsen with therapy, or patients are unable to tolerate pharmacologic treatment. Patients may continue to lose weight, have substantial diarrhea, or have recurrent abdominal pain despite optimal therapy, and they may elect to undergo surgery. Growth retardation secondary to chronic disease and use of medications, including steroids, are an indication for surgery in up to 50% of children with CD. Other indications include progression of disease to complete obstruction, abscess, fistulization, presence of neoplasia, toxic megacolon, and GI hemorrhage.

The development of a bowel obstruction in CD frequently results from acute inflammation on top of preexisting fibrostenotic disease.

As with patients without CD, conservative management with nasogastric tube decompression, bowel rest, and IV hydration is frequently appropriate, and medical management may continue if symptoms resolve. Progressive disease is a common feature, and surgery may be required for recurrent obstructions.

Inflammatory masses (phlegmon) and abscesses typically cause abdominal pain and obstruction; in severe cases, they progress to fistulas or become the source of systemic sepsis. They may be palpated on examination or noted on computed tomography (Figure 2). When patients are stable, initial treatment consists of percutaneous drainage of the liquid component under ultrasound or CT guidance. Antibiotics with gram-negative and anaerobic coverage are prescribed until the surrounding inflammation has resolved. A period of initial bowel rest aids in decreasing inflammation and should be maintained while symptoms persist. Surgery may be necessary if the inflammation does not completely resolve with drainage, bowel rest, and antibiotics. If necessary, parenteral nutrition can be used for nutritional supplementation while the abscess resolves and inflammation subsides.

Not all internal fistulas in CD are symptomatic, and some may not require surgical therapy. A large fistula from proximal ileum to the distal sigmoid colon may cause a functional bypass of absorptive intestinal surface and consequent diarrhea or malabsorption, whereas a short fistula from the terminal ileum to the cecum may be tolerated without difficulty. In addition, enterocutaneous or colocutaneous fistulas, fistulas to the vagina after hysterectomy, or fistulas to the bladder are often symptomatic and require surgical resection.

Patients with CD are at increased risk for neoplasia. Colorectal cancer is more prevalent among such patients than in the general population, and small bowel adenocarcinoma is as much as 100 times more likely to occur. In patients without IBD, the incidence of small bowel cancer tends to decrease from proximal to distal small bowel. In CD, the incidence increases along the length of the small bowel and mimics disease distribution. Sporadic small bowel cancers form a mass or growth that is noted on imaging or at the time of resection. In CD, cancers are often not associated with a mass lesion, which complicates diagnosis and screening. Therefore, it is recommended that in patients with long-standing CD, any strictures treated with strictureplasty and not resection should be subjected to biopsy.

Hemorrhage and toxic megacolon are common indications for surgery in ulcerative colitis, but these are much less common in CD. GI hemorrhage can originate from anywhere in the GI tract. Localization techniques—including endoscopy, angiography, and nuclear imaging—can be helpful in preoperative planning or in directing treatment. Intraoperative enteroscopy can be helpful in localizing small bowel hemorrhage. Toxic megacolon occurs in the setting of Crohn's colitis, and significant dilatation of the colon with signs of sepsis such as leukocytosis, fever, or hemodynamic instability is an indication for immediate surgical intervention.

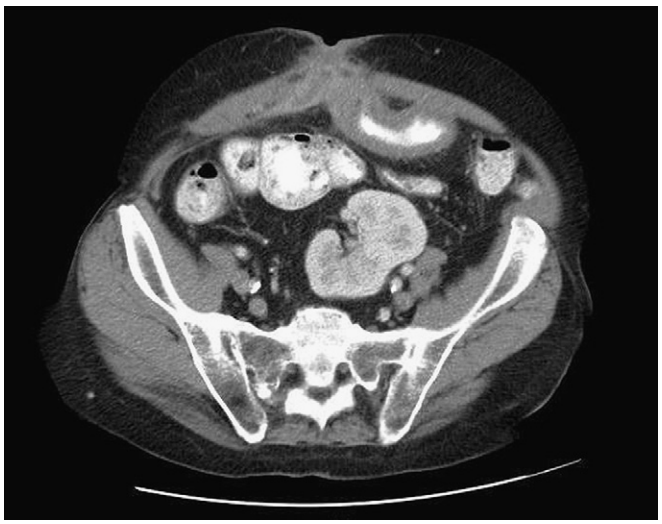

FIGURE 2 Computerized tomographic image of small intestinal stricture with an associated enterocutaneous fistula in Crohn's disease.

Technical Considerations of Surgical Intervention

Thorough preoperative evaluation is paramount in the success of operative outcomes in patients with CD. Such patients may be dehydrated from chronic diarrhea and may have electrolyte imbalances that should be addressed before surgery. Malnutrition, anemia, and vitamin deficiencies are common and may require preoperative repletion or, on occasion, parenteral supplementation. Knowledge of preoperative medications is necessary. Concern remains about increased infectious complications among patients receiving anti–TNF therapy, and attempts should be made to delay surgery for several weeks after administration when possible. Chronic steroid use causes adrenal insufficiency. Patients maintained on chronic steroids, or recently weaned from steroids, may require perioperative stress dosing, generally with intravenous hydrocortisone or methylprednisolone. Steroid doses should be rapidly tapered over several postoperative days to avoid adrenal insufficiency. Patients who have been appropriately surgically treated for CD should not require continued long-term steroid administration.

Preoperative planning for all but the most urgent indications should involve a careful review of surgical history and thoughtful use of imaging studies. This is particularly true for planning a laparoscopic approach, in which there will be loss of tactile sensation. Reports of previous operations should be obtained and reviewed as part of the preoperative planning process. This information allows estimation of residual small bowel length, an important factor for deciding between resection and strictureplasty. Colonoscopy helps to evaluate the extent of colonic disease. CT or MRI, capsule or push enteroscopy, and upper GI series with small bowel follow-through studies help evaluate small bowel disease, especially abscesses, strictures, and fistulas (see Figure 2). Upper endoscopy is useful in evaluating for gastroesophageal and duodenal disease.

The appropriate preoperative evaluation guides discussions of informed consent, although these discussions should account for the fact that some pathologic processes may not be detectable until operative exploration. It is important to note that up to 50% of fistulas are not detected on preoperative evaluation, and strictures distal to a proximal obstruction may be undetectable before exploration. Consent forms should also address possible additional surgical treatments, including creation of a diverting ostomy. In addition, malabsorption after small bowel resection may occur when insufficient small bowel remains, especially in the absence of an ileocecal valve. Loss of the terminal ileum may lead to deficiencies of fat, fat-soluble vitamins, and bile salts, which cause increased diarrhea. Severe malnutrition and diarrhea may occur, especially when less than 200 cm of small bowel remains.

Any operation on a patient with CD should begin with a thorough intraabdominal examination, with evaluation of both known and possible previously undetected pathologic processes that may be amenable to surgical repair. The small bowel and intraperitoneal colon should be inspected in entirety and their total length measured to assess the potential for the development of the short gut syndrome. Because CD is a lifelong recurring disease, affected patients are at risk for intestinal failure with sequential resections.

All attempts should be made to preserve intestinal length when possible. Only symptomatic and heavily diseased segments should be resected. Findings of mild disease, such as creeping fat, are not an indication for resection. A Foley catheter may be used to grossly evaluate segments for resection or strictureplasty. After gentle insertion of the catheter into the intestinal loop via an enterotomy in the anticipated site of resection or strictureplasty, the balloon is inflated

to 1 cm and gently pulled through the potentially narrowed bowel. Any site through which the balloon does not easily pass should be carefully evaluated for additional surgical therapy.

Longer segments of small intestine and any segment of large intestine affected with CD are resected with a primary anastomosis. A 2-cm margin of grossly normal-appearing bowel is all that is necessary. Microscopic evaluation of margins is not necessary during resections for benign disease. The authors typically use a GIA stapler to divide the bowel at the proximal and distal resection margins, and create a classic side-to-side, functional end-to-end two-layered hand-sewn anastomosis. Often the bowel may be thicker and less amenable to stapling; however, a stapled anastomosis is an acceptable alternative.

To preserve bowel length, strictureplasty should be considered when technically feasible, especially in patients who have undergone prior resection. Contraindications to stricturoplasty, relative and absolute, are listed in Table 2. For short, isolated segments, a 2-layered Heineke-Mikulicz strictureplasty can be used. A Finney strictureplasty is useful for longer segments but has the unwanted side effect of a capacious intestinal side diverticulum. The Michelassi strictureplasty is an option for more extensive disease of the small bowel. In the appropriately selected patient, strictureplasty provides a favorable risk/benefit ratio: Despite longer operative time and slightly increased incidence of postoperative bleeding, recurrence rate is decreased, bowel length is preserved, and function may be restored.

Fistulas are treated with resection of the primary diseased segment and closure of the opening on the target organ, if it is uninvolved with CD. In most cases, fistulas arise from a diseased segment of intestine and drain into an "innocent bystander" loop of bowel. This commonly occurs between two loops of small bowel or between diseased terminal ileum and adjacent sigmoid colon. Recurrent disease of the neoterminal ileum may fistulize to the duodenum, or primary disease from the transverse colon may fistulize to the stomach or fourth portion of the duodenum. When the bystander segment is closed, care should be taken to avoid narrowing the lumen by closing in a transverse direction. If the fistulous opening on the target loop is large, very edematous, or situated on the mesenteric side, a segmental resection with primary anastomosis may be necessary. Fistulas to the bladder may be oversewn with absorbable suture to minimize the risk of stone formation at the site of permanent suture. Vaginal and uterine fistulas often heal spontaneously after resection of the primary diseased intestine. Overlaying the repair with a vascularized tissue pedicle such as omentum can prevent leak or recurrence. Enterocutaneous or colocutaneous fistulas necessitate débridement of the fistulous tract through the aponeurotic and cutaneous planes of the abdominal wall, with complete drainage of intervening abscesses.

Surgery for CD is frequently performed laparoscopically. This holds the potential advantage of reducing not only postoperative pain but also postoperative adhesion formation in a patient population with a high chance of needing further abdominal surgery. Challenges facing the laparoscopic approach include matted loops of bowel, adhesions, fistulas, thickened mesentery, and prior surgical interventions. There are no contraindications to laparoscopy in CD patients, although patients with prior abdominal operations may have longer operative times and potentially higher rates of conversion to open operation. It appears that after age and comorbid conditions are controlled, laparoscopic surgery is associated with significantly fewer complications—including abdominal sepsis, wound complications, and postoperative pneumonia—than is open surgery. In addition, by hastening return of bowel function, laparoscopic surgery reduces length of hospital stay. Laparoscopy should be strongly considered for initial ileocecectomy, but is frequently appropriate for reoperative surgery.

The practice at the author's institution is to obtain abdominal access through the open Hassan technique. As with open surgery, the abdomen should be inspected thoroughly after any necessary adhesiolysis. The small intestine should be inspected for any disease that may not have been visualized on preoperative imaging. When technically possible, we perform exploration and resection laparoscopically and then mobilize the bowel so that it can be extracted through a small laparotomy incision at one of the port sites, and a standard two-layer hand-sewn anastomosis is created.

TABLE 2: Relative and absolute contraindications to strictureplasty in Crohn's disease*

Absolute	Relative
Perforation neoplasia	Abscess
Fistula	Long, severely narrowed segments†
Severe malnutrition	

*As techniques improve, contraindications to strictureplasty become fewer.
†In the presence of long, severely narrowed segment of small bowel preceded and followed by a loop with sequential strictures, the middle segment can be resected; the proximal and distal diseased loop may be preserved as part of a side-to-side isoperistaltic strictureplasty.

Recurrence of Disease

Recurrence is a significant concern in patients with Crohn's disease. Up to 50% of patients eventually require a second surgery, often at the site of prior interventions (e.g., ileocolectomy for recurrence at the site of prior ileocecectomy). Smoking cessation reduces the long-term chance of disease recurrence by as much as 50%, but remains a difficult goal for most smokers. Other less well elucidated factors play a role in disease recurrence; phenotype, granulomas, and prior recurrence are risk factors for future surgical interventions. Early postoperative medical therapy has been advocated for CD patients at high risk of recurrence. Patients may be prescribed antibiotics, aminosalicylates, antimetabolites, or biologic agents within 10 days of surgical intervention. Metronidazole has been shown to decrease the rate of endoscopic recurrence when used for 3 months postoperatively, and aminosalicylates have been shows to reduce recurrence rates in postoperative patients by up to 30%. Antimetabolites such as AZA and 6-MP show a decrease in recurrence rates of up to 50%. In patients with severe inflammation who present with abscess that is probably secondary to occult perforations, prolonged bowel rest with parenteral support may be considered. Infliximab has also been shown to prevent recurrence, although to date this has been demonstrated only in very small series. Multidisciplinary management in conjunction with medical gastroenterology consultation should be considered before discharge for all CD patients.

Strictureplasty in Crohn's Disease

Leon Maggiori, MD, and Fabrizio Michelassi, MD

INTRODUCTION

Crohn's disease (CD) is a chronic inflammatory bowel disease, characterized by transmural bowel inflammation that may occur anywhere in the gastrointestinal tract, from the mouth to the anus. Chronic intestinal inflammation can lead to the development of strictures, septic complications such as abscesses and fistulas, hemorrhage, and malignant transformation. Despite improvements in medical therapy, more than half of all patients with CD need surgical treatment for such complications within 10 years of diagnosis.

Unfortunately, CD is a recurrent disease, and 20% to 60% of patients have postoperative clinical symptoms of recurrence and 15% to 50% need further surgical intervention at some time after the index procedure. With the need for repeated intestinal resections, patients may eventually have intestinal insufficiency and short bowel syndrome develop, leading to the need for total parenteral nutrition support. Surgical treatment of CD should therefore aim to address complications without jeopardizing bowel function.

Bowel-sparing surgical techniques, such as strictureplasty, have been proposed as an alternative to lengthy intestinal resections in the treatment of CD small bowel strictures. This chapter reviews indications, contraindications, technical aspects, and results of strictureplasty techniques.

OVERVIEW

Indications and Contraindications

Strictureplasty is the treatment of choice for patients with symptomatic nonphlegmonous jejuno-ileal CD fibrotic strictures, as highlighted in both American and European guidelines for CD management. Symptoms may vary from postprandial cramped abdominal pain to complete bowel obstruction.

Several studies have also reported excellent results when strictureplasty techniques have been performed for strictures in other gastrointestinal locations, such as in the duodenum or at the site of a strictured ileocolonic anastomosis. Strictureplasty has been reported also in the treatment of isolated colonic strictures: yet, the length and thickness of colonic strictures is usually not conducive to strictureplasty techniques.

Strictureplasty is contraindicated in the presence of local sepsis, such as phlegmon, abscess, or generalized peritonitis. In these situations, strictureplasty is associated with a higher risk of postoperative dehiscence. The presence of enteric fistulae has been hitherto viewed as a contraindication for strictureplasty, but recent reports have suggested that strictureplasty might be performed in the presence of fistulae surrounded by chronic, rather than active, inflammation without increasing postoperative morbidity.

Profoundly impaired nutritional status is also considered as a contraindication to this technique. Suspicion of small bowel adenocarcinoma or dysplasia should lead to intraoperative biopsy and, if confirmed, resection of the bowel loop rather than a bowel-sparing procedure (Box 1). Finally, in the economy of a surgical procedure, if a stricture is located in close proximity of a diseased intestinal segment in need of resection, the resection is usually extended to include the stricture to minimize the length of the overall surgical procedure and the number of suture length.

Preoperative Preparation

As for all elective surgical procedures for CD, a complete assessment of disease extension should be performed with magnetic resonance imaging (MRI) or computed tomographic (CT) scan enterography. MRI is the most sensitive and specific imaging procedure for CD extension assessment: it aids in distinguishing between active inflammatory strictures, which might be medically managed, and fibrotic strictures, which should be surgically treated. The authors also advocate a preoperative total colonoscopy, even in patients with CD apparently strictly limited to small bowel.

Several studies have focused on predictive risk factors of postoperative morbidity in CD surgery. Yamamoto and colleagues identified three independent risk factors: preoperative corticosteroids medication, poor nutritional status, and intraabdominal phlegmon or fistula. Corticosteroid weaning is rarely feasible without a recrudescence of the disease, and abdominal phlegmons are frequently the reason for surgical intervention; by contrast, poor nutritional status should be addressed before surgery with enteric or intravenous nutrition. On the other hand, azathioprine has no impact on postoperative morbidity and can therefore be maintained. Finally, the influence of infliximab on postoperative CD complication is still controversial, although several recent studies have suggested that it has no negative impact on healing of intraabdominal anastomosis.

Intraoperative "Design of a Roadmap"

The authors start all of their small bowel CD cases with examination of the entire small bowel from the ligament of Treitz to the ileocecal valve, with special care paid to recording all CD-related complications (strictures, phlegmonous masses, abscesses, fistulae). This phase of the procedure is called "the design of a roadmap." A strategic approach to the patient's disease is then developed by studying the "roadmap" and includes the use of strictureplasty, intestinal resection, drainage of abscesses, repair of fistulous openings on target intestinal loops or hollow viscera, or a combination of these techniques (Figure 1).

STRICTUREPLASTY TECHNIQUES

Strictureplasty techniques may be divided into three subgroups: short strictureplasty, including the highly common Heineke-Mikulicz technique; intermediate length procedure, including the Finney and Jaboulay procedures; and long enteroenterostomy, like the side-to-side isoperistaltic strictureplasty. The choice among these different techniques should be made according to the number of strictures and length of each one (Table 1).

Short Strictureplasty

The most common strictureplasty technique is the Heineke-Mikulicz technique. This strictureplasty was introduced by Emmanuel Lee for the treatment of CD in 1976 after he became aware of a similar technique on tubercular strictures of the terminal ileum described by Katarya. The technique is similar to a Heineke-Mikulicz pyloroplasty from which it derives its name. The technique is optimal to address short strictures (≤7 cm). This technique is performed by making a longitudinal incision on the antimesenteric side of the bowel,

BOX 1: Absolute contraindications for strictureplasty in Crohn's disease surgical management

Impaired nutritional status
Dysplasia or cancer at the stricture site
Locoregional sepsis:

- Abscess
- Peritonitis

TABLE 1: Choice of strictureplasty technique according to disease characteristics

Stricture length	Technique
Short (≤7 cm)	Heineke-Mickulicz
Intermediate (>7 cm and ≤15 cm)	Finney
Multiple short strictures clustered over a lengthy segment	Side-to-side isoperistaltic

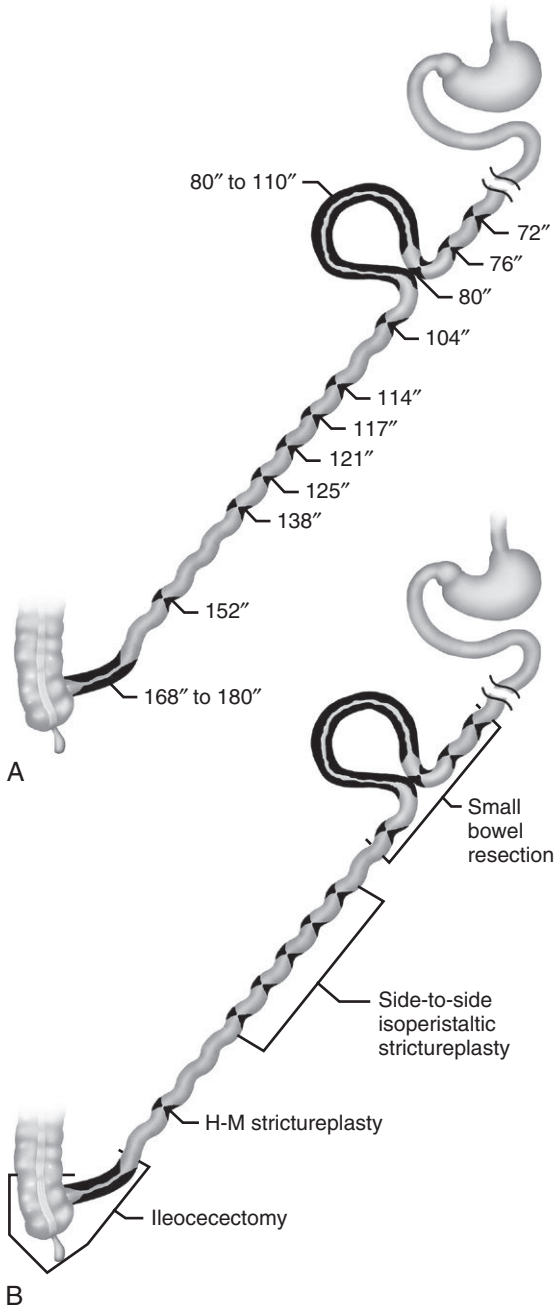

FIGURE 1 Design of a roadmap **(A)** and subsequent surgical plan **(B)** for extensive Crohn's disease. *H-M,* Heineke-Mikulicz.

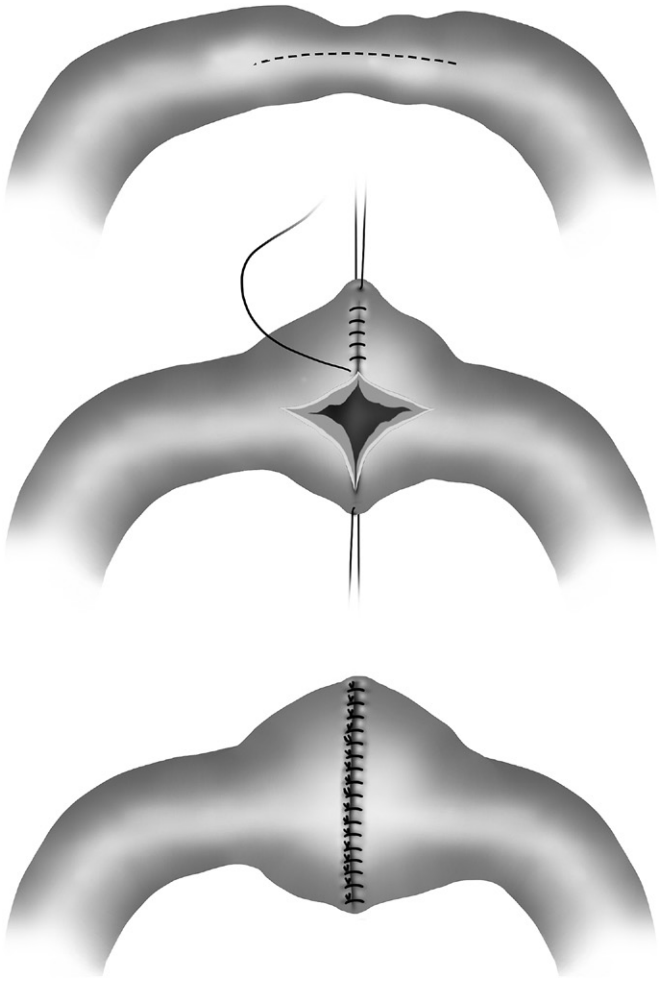

FIGURE 2 Heineke-Mikulicz strictureplasty on an isolated, short, small bowel stricture.

extending from 2 cm proximal to 2 cm distal to the stricture. The enterotomy is then closed in a transverse fashion in one or two layers. The senior author prefers to close this enterotomy in two layers with interrupted Lembert nonabsorbable 3-0 sutures for the outer layer and a running absorbable 3-0 suture for the inner layer (Figure 2).

The Judd strictureplasty is a variation of the Heineke-Mikulicz technique described for the surgical management of short strictures associated with a fistula opening. During this procedure, the longitudinal incision encompasses the fistula opening. The enterotomy is then closed as described in Heineke-Mikulicz technique.

Small bowel stricture can be responsible for a dilation on the proximal loop, leading to a size discrepancy between the proximal and distal loops. In this situation, the Moskel-Walske-Neumayer

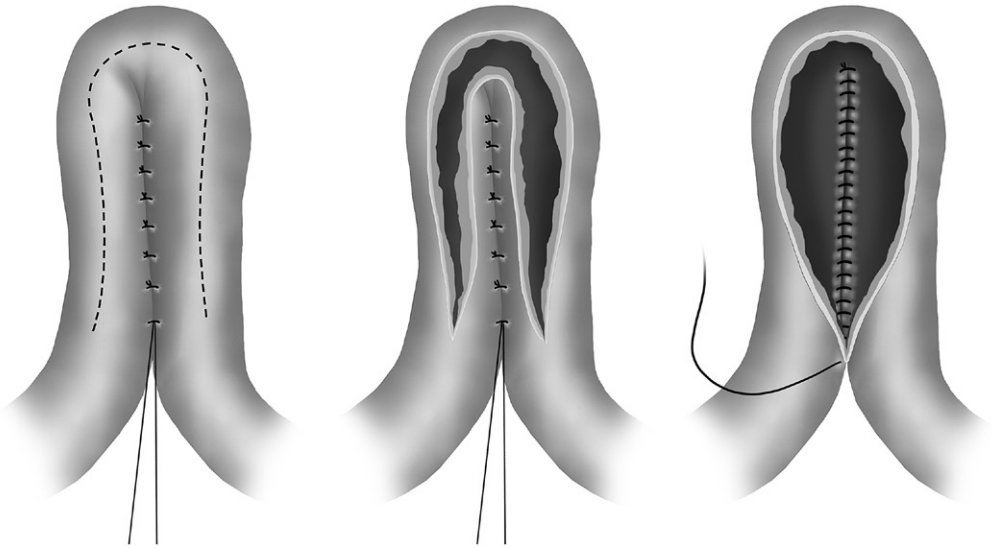

FIGURE 3 Finney strictureplasty on an intermediate small bowel stricture.

strictureplasty compares favorably with the original Heineke-Mikulicz technique. A Y-shaped enterotomy is performed on the stricture, with the Y fork pointing to the dilated loop. The enterotomy is then closed in a transverse fashion in a V shape.

Intermediate Length Procedures

Intermediate length procedures have been described to address longer strictures (>7 cm and ≤15 cm) than those manageable with the Heineke-Mikulicz technique or its variations. In this situation, the most commonly performed procedure is the Finney strictureplasty, named after the Finney pyloroplasty, first described in 1937. The strictured loop is folded over itself at its midpoint section, forming a U shape. A longitudinal enterotomy is then performed halfway between the mesenteric and the antimesenteric side on the folded loop. The opposed edges of the bowel are sutured together to create a short side-to-side anisoperistaltic enteroenterostomy (Figure 3). The senior author prefers a two-layer closure similar to the one described for the Heineke-Mikulicz strictureplasty. Concerns about long-term complications, such as bacterial overgrowth in the bypassed segment, limit the length of the stricture to be addressed by this strictureplasty to less than 15 cm.

Long Enteroenterostomy

The side-to-side strictureplasty, first described in 1996 by the senior author, is the technique of choice to address multiple short strictures closely clustered over a lengthy small bowel segment (>15 cm).

In this technique, the mesentery of the small bowel loop to undergo the strictureplasty is first divided at its midpoint. The proximal intestinal loop is then moved over the distal one in a side-to-side fashion. Care is taken to ensure that stenotic areas of one loop are placed adjacent to the dilated areas of the other loop. The two loops are then approximated by a layer of interrupted seromuscular Lembert stitches, with nonabsorbable 3-0 sutures (Figure 4, *A*). A longitudinal enterotomy is performed on both loops, with the intestinal ends tapered to avoid blind stumps (Figure 4, *B*). Frozen-section biopsies of suspicious areas of disease are obtained to exclude occult malignant disease. Hemostasis is obtained with suture ligatures or electrocautery. The outer suture line is reinforced with an internal row of running full-thickness 3-0 absorbable sutures, continued anteriorly as a running Connell suture (Figure 4, *C*); this layer is reinforced by an outer layer of interrupted seromuscular Lembert stitches with nonabsorbable 3-0 sutures (Figure 4, *D*).

Many variations of this side-to-side isoperistaltic strictureplasty technique have been described. These variations fall into four distinct categories: integration of other strictureplasty techniques (e.g., Heineke-Mikulicz or Finney techniques) with the side-to-side isoperistaltic strictureplasty technique, length of bowel selected for strictureplasty, bowel location selected for procedure (jejunum, ileum, or terminal ileum where the side-to-side isoperistaltic strictureplasty is performed between the ileum and the ascending colon), and the condition for which this technique is applied (CD, multiple nonsteroidal antiinflammatory drug [NSAID]–small bowel strictures, and small bowel stricture arising from chronic ischemic enteritis).

RESULTS

Postoperative Short-Term Outcomes

A large number of publications highlighted the safety of strictureplasty for CD. A meta-analysis that included more than 3000 strictureplasties was published in 2007. Short strictureplasties were the most commonly performed (81%), followed by intermediate procedures (10%) and long enteroenterostomies. Overall, mortality was nil, and 13% of patients had postoperative complications, including 4% septic complications (anastomotic leak, fistula, and abscess) and 3% postoperative hemorrhages. This meta-analysis also showed that the strictureplasty technique had no impact on postoperative outcomes.

The short-term results associated with the side-to-side isoperistaltic strictureplasty technique have been reported by one single-center study. This study showed the feasibility and safety of the procedure and the optimal gastrointestinal motility at the level of the side-to-side isoperistaltic strictureplasty.

A recent comparative study has evaluated strictureplasty versus resection in small bowel CD and has established that the postoperative outcomes of strictureplasty compare favorably with those obtained after small bowel resection. In specific regard to functional outcomes, efficacy of strictureplasty has been largely shown, with satisfactory relief of obstructive symptoms, improved food tolerance, and subsequent weight gain.

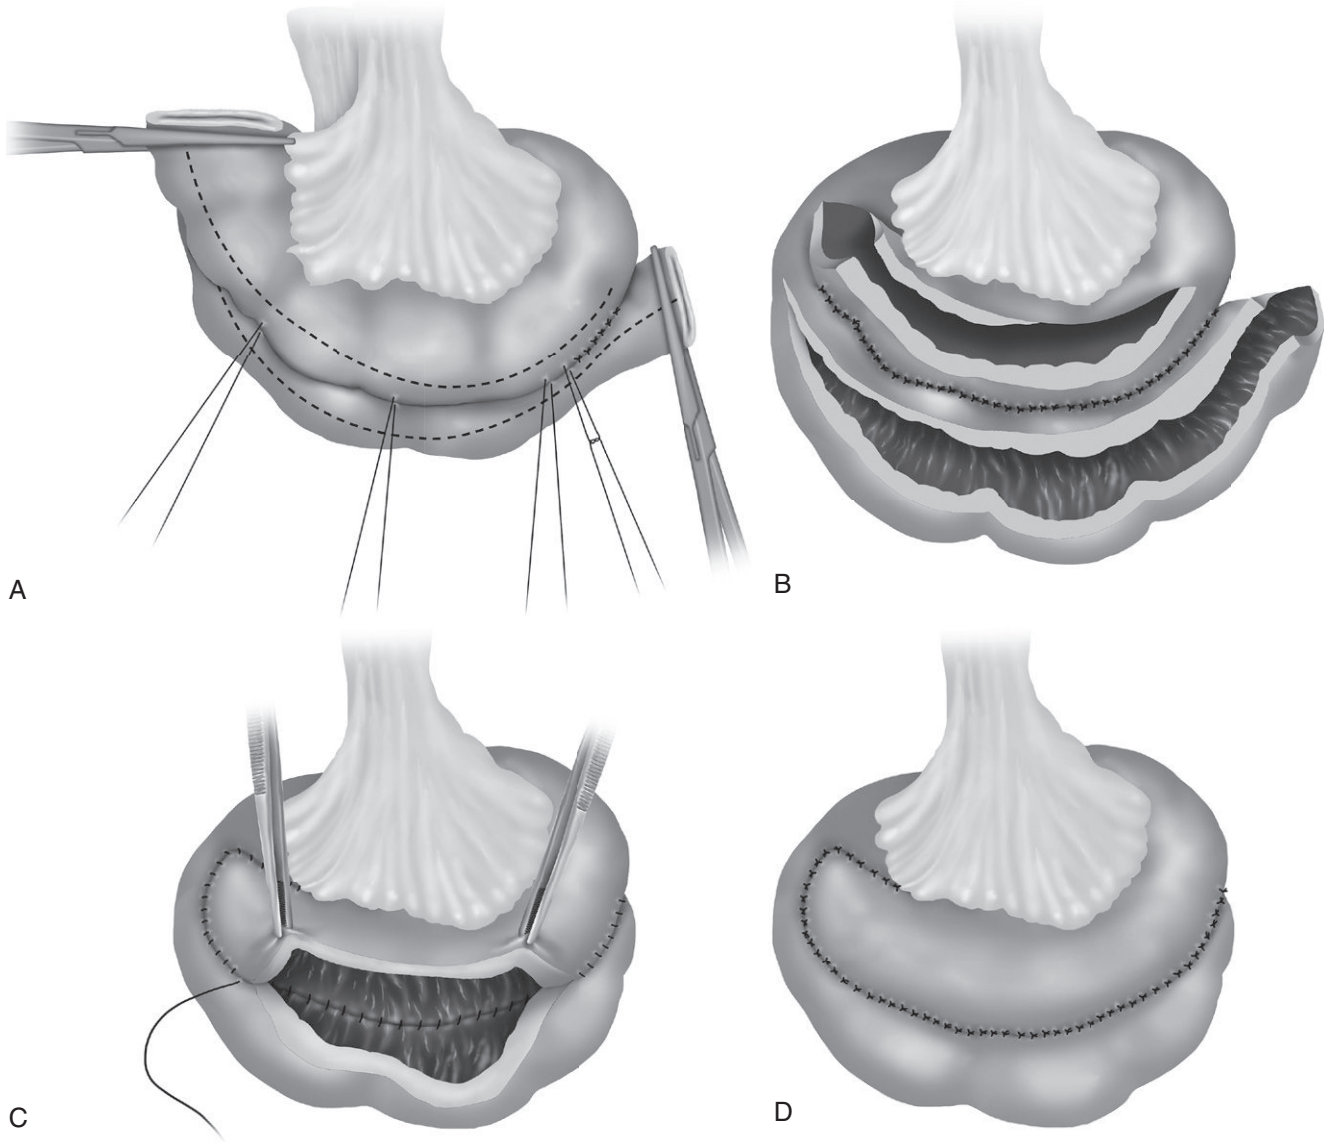

FIGURE 4 **A** to **D,** Side-to-side isoperistaltic strictureplasty. *(Modified from Maggiori L, Michelassi F: How I do it: side-to-side isoperistaltic strictureplasty for extensive Crohn's disease,* J Gastrointest Surg *16:1976-1980, 2012.)*

Long-Term Outcomes

The meta-analysis from 2007 reported an overall symptomatic recurrence rate of 39% with a median follow-up period of 107 months. In this study, recurrence on a previous strictureplasty requiring surgical management occurred in only 10% of cases, which compares favorably with results obtained with small bowel resection. Yamamoto and associates have suggested that strictureplasty may induce a higher recurrence-free survival rate than intestinal resection. Endoscopic, radiologic, and histopathologic evaluations after strictureplasty have indeed highlighted complete CD regression at strictureplasty site in several reports. The mechanism associated with such inflammation regression remains unknown.

Reports of development of small bowel adenocarcinoma arising at the site of strictureplasty have been documented. To date, four cases of such complication have been published, including one reported by the senior author. The risk of neoplastic transformation after strictureplasty is assumed to be low and not sufficient enough to dissuade surgeons from performing those techniques.

Long-term results associated with the side-to-side isoperistaltic strictureplasty technique were reported by a multicenter study in 2007. This study showed that only 14 of 184 total patients needed surgery for recurrent disease at the side-to-side isoperistaltic strictureplasty site, after an average follow-up period of 35 months. Recurrences occurred mostly at the inlet and at the outlet of the side-to-side strictureplasty, leading some authors to suggest the addition of a Heineke-Mikulicz strictureplasty at the inlet and the outlet of the side-to-side strictureplasty during its original construction.

SUMMARY

Crohn's disease is a chronic and recurrent panintestinal inflammatory disorder. Surgical treatment is indicated to address complications of the disease or failure of medical treatment. Symptom alleviation expected from the procedure should be balanced with potential postoperative morbidity and long-term side effects. In this

context, strictureplasty for CD-related small bowel stenosis has been shown to be a safe and effective solution, relieving obstructive symptoms without any bowel sacrifice.

Different strictureplasty procedures have been described to address different settings of CD. The choice of strictureplasty techniques should be made based on the length and the number of strictures.

THE MANAGEMENT OF SMALL BOWEL TUMORS

Hiroko Kunitake, MD, and Richard Hodin, MD

OVERVIEW

Small bowel mucosa comprises approximately 75% of the length and 90% of the absorptive surface area of the digestive system, yet only 2.8% of new digestive system cancers each year occur in the small intestine. The American Cancer Society estimates that each year, more than 8000 new small bowel malignancies are found, and approximately 1100 people die of their disease.

Several reasons for the low incidence of small bowel tumors have been proposed, including the rapid transit of contents through the small bowel, lower bacterial load, high amount of lymphoid tissue, rapid turnover of epithelial cells, and decreased inflammation owing to the liquidity and alkaline nature of small bowel contents.

Signs and symptoms of these tumors are usually nonspecific and include abdominal pain, weight loss, nausea, vomiting, occult bleeding, and obstruction or perforation. Vague symptoms, limited findings on examination, and failure to obtain or correctly interpret diagnostic tests have all been implicated in delaying the diagnosis of small intestine cancers, and because of this, more than 50% of patients have nodal or distant metastases at the time of presentation.

Diagnosing small bowel tumors has historically been difficult due to limited means of gaining access to distal portions of the small bowel. Common methods have included small bowel follow-through, enteroclysis, computed tomographic (CT) scans, magnetic resonance enterography, upper endoscopy, and push enteroscopy. Wireless capsule endoscopy and double-balloon endoscopy have become increasingly more common. Capsule endoscopy allows painless endoscopic imaging of the whole small bowel, and it has become the standard diagnostic approach for patients with obscure gastrointestinal bleeding, often a presenting symptom of small bowel tumors. However, it is contraindicated for patients with suspected or documented intestinal obstruction, and it does not allow for tissue sampling or interventional therapies in the small bowel. Double-balloon enteroscopy allows for direct inspection of most or all of the small intestine, with better visualization of the duodenum and proximal jejunum compared with capsule endoscopy as well as the option of tissue biopsy and therapeutic intervention. The treatment of small bowel neoplasms has not changed significantly over the past two decades, and surgery continues to be the primary therapy in most cases.

CARCINOID/NEUROENDOCRINE TUMORS

Tumor Characteristics

Gastrointestinal carcinoid tumors, more recently referred to as neuroendocrine tumors, are the most common malignancy of the small bowel. They include a diverse range of slow-growing neoplasms arising from various cells of the neuroendocrine system. Carcinoids can occur anywhere along the gastrointestinal tract; 45% occur in the small intestine, most commonly in the ileum. Up to one third of cases of small bowel carcinoid tumors are multifocal, and more than 50% of patients have nonlocalized disease at the time of diagnosis. Gastrointestinal carcinoid tumors, especially those of the small intestine, are also often associated with other cancers. Synchronous or metachronous noncarcinoid cancers occur in approximately 29% of patients with small intestinal carcinoid tumors. Carcinoid tumors synthesize, store, and release a variety of polypeptides, biogenic amines, and prostaglandins. Most jejunal and ileal carcinoids are serotonin-producing enterochromaffin-cell tumors. The majority of duodenal carcinoids are gastrin-producing G-cell tumors (two thirds) followed by somatostatin-producing D-cell tumors (one fifth). Most small intestine carcinoid tumors occur sporadically, but others may occur in the background of an inherited neoplasia

syndrome such as multiple endocrine neoplasia type I (MEN1) or neurofibromatosis type 1 (NF1).

Clinical Presentation

Patients with carcinoid tumors may present with abdominal pain and obstructive symptoms. Carcinoid tumors may act as a lead point for intussusception, and they can also elicit an intense desmoplastic reaction, causing adhesions of intestinal loops and stricturing of the bowel. Fibrosis around mesenteric metastases can cause contraction of the mesentery or fixation of the mesentery to the retroperitoneum, leading to kinking and obstruction via fibrous bands. Encasement of mesenteric vessels by tumor can lead to venous stasis and even ischemia in portions of the small bowel. Duodenal carcinoids (Figure 1) are often identified incidentally or because of symptoms from hormone or peptide production, but they may also arise in the periampullary region and obstruct the ampulla of Vater, causing jaundice.

Approximately 35% of carcinoids of the small intestine are associated with carcinoid syndrome. Carcinoid syndrome is caused by the release of metabolically undegraded vasoactive amines into the systemic circulation. Because vasoactive amines are efficiently metabolized by the liver, carcinoid syndrome rarely occurs in the absence of hepatic metastases. Exceptions include circumstances in which venous blood draining from a tumor enters directly into the systemic circulation (e.g., pelvic or retroperitoneal involvement by metastatic or locally invasive small bowel carcinoids, or extensive bone metastases). Carcinoid syndrome is associated with flushing, abdominal pain and diarrhea, bronchoconstriction, and carcinoid heart disease, manifested by endocardial fibrotic plaques and thickening and fibrosis of the tricuspid and pulmonary valves, and to a lesser extent the mitral and aortic valves.

Diagnosis

Biochemical diagnosis of carcinoid tumors may be achieved by measurement of 5-hydroxyindolacetic acid (5-HIAA) in a 24-hour urine sample or by serum analysis of chromogranin A (CgA), which is believed to be a superior screening test. However, false-positive plasma levels of CgA may occur in patients on proton pump inhibitors. Common imaging studies for localizing carcinoid tumors include abdominal CT, magnetic resonance imaging (MRI), somatostatin receptor scintigraphy (octreotide scan), and positron emission tomography (PET). Octreotide scanning is a useful initial imaging method, with a diagnostic sensitivity estimated to be as high as 90%.

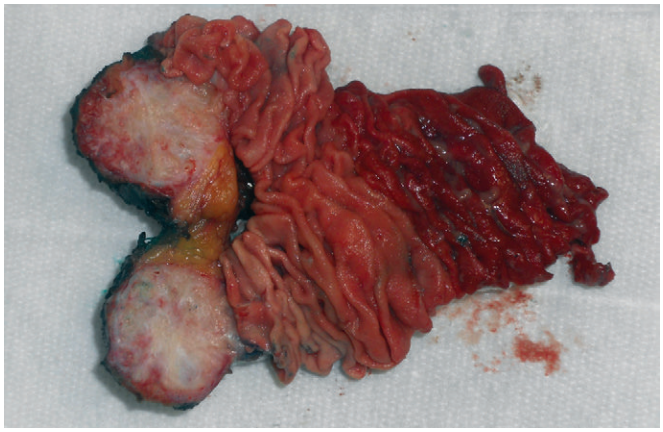

FIGURE 1 Small bowel neuroendocrine tumor.

Treatment

Surgery remains the only potentially curative therapy and is the most effective treatment for averting both local tumor effects, such as obstruction and bleeding, and symptoms caused by the secreted bioactive agents. Because metastatic spread to regional lymph nodes is common, small bowel carcinoids warrant an en bloc resection with extensive lymphadenectomy and wide resection of the mesentery. The abdomen should be carefully inspected for multicentric lesions and liver metastases. If liver metastases are identified, the primary tumor should still be resected to diminish later complications such as obstruction, perforation, and bleeding. Hepatic metastases may be managed with surgical resection, hepatic artery embolization, cryoablation, radiofrequency ablation, or liver transplantation. In the case of duodenal tumors, lesions less than 1 cm may be resected endoscopically, and lesions smaller than 2 cm may be excised locally. Tumors larger than 2 cm should be treated with full-thickness excision and regional lymphadenectomy, even with negative imaging, because of the high rate of lymph node metastases for these tumors. If the tumor is in proximity to the ampulla, a pancreaticoduodenectomy may be necessary to obtain complete resection.

The role of surgery in metastatic disease is not well defined, but resection of bowel, mesenteric tumors, lymph node and hepatic metastases, and fibrotic areas may improve symptoms and quality of life. Extensive resections of metastatic disease may even prolong survival, though it is estimated that 90% of the disease needs to be resected to achieve palliation. Tumor debulking may also improve the efficacy of pharmacologic therapy by reducing the bioactive substances secreted. If future treatment with octreotide is anticipated, a prophylactic cholecystectomy should be considered given the association between the long-term treatment with somatostatin analogs and the development of biliary symptoms and gallstones.

Long-acting and depot formulations of somatostatin analogs have been shown to be highly effective in controlling carcinoid syndrome symptoms, resulting in significant improvement in quality of life with relatively mild adverse effects. Routine preoperative administration can also prevent carcinoid crisis, which is characterized by excessive cutaneous flushing, hyperthermia, shock, arrhythmias, and bronchial obstruction. Aside from octreotide, which is associated with delayed progression of small bowel carcinoid, no treatment has proven antitumor activity. Chemotherapy seems to be of limited value, and the role of interferon is controversial. Peptide receptor radionuclide therapy may have cytoreductive activity in patients with somatostatin (SST) receptor–expressing tumors, but randomized controlled trials are lacking. Various therapies targeting vascular endothelial growth factor (VEGF), platelet-derived growth factor receptor (PDGFR), and mammalian target of rapamycin (mTOR) are now in development.

Overall, the 5- and 10-year survival rates for well-differentiated small bowel carcinoids is 65% and 49% in localized disease; 71% and 46% for regional disease; and 54% and 30% for distant disease, respectively. Age greater than 55 years, male sex, primary tumor size greater than 1 cm, and distant metastases negatively affect outcome.

ADENOCARCINOMA

Tumor Characteristics

Adenocarcinoma is the second most common malignancy of the small intestine, comprising approximately 37% of small bowel cancers. It occurs most often in the duodenum and decreases progressively throughout the rest of the small intestine. An exception to the predominantly proximal location is in patients with Crohn's disease. Seventy percent of the adenocarcinomas that arise in Crohn's disease are located in the ileum, the most common site of chronic inflammation. Small bowel adenocarcinoma is also associated with a

variety of other diseases and syndromes, including celiac disease, familial adenomatous polyposis, hereditary nonpolyposis colorectal cancer, and Peutz-Jeghers syndrome.

Clinical Presentation

Symptoms of small bowel adenocarcinoma are frequently nonspecific, leading to significant delays in diagnosis. More than 50% of patients are found to have advanced disease (stage III or IV) at presentation, 24% have distant metastases, and approximately 30% have nodal involvement. Patients with ampullary adenocarcinoma often present earlier in their disease course because of symptoms that result from biliary obstruction.

Diagnosis

Periampullary lesions can be diagnosed by upper endoscopy, endoscopic ultrasound, and magnetic resonance cholangiopancreatography. Cancers distal to the ligament of Treitz are more amenable to video capsule endoscopy and double-balloon endoscopy. Advanced adenocarcinomas may appear on barium contrast studies as "apple core" lesions: short, annular, narrowed portions that show evidence of mucosal ulceration and appear rigid and unchanging with compression. CT features of adenocarcinoma are similar to those seen on barium studies; abrupt transitions and irregular shouldered overhanging margins are typical. After intravenous contrast administration, these mucosal-based soft-tissue lesions demonstrate enhancement. CT is advantageous over conventional barium studies for detection of extramucosal spread, lymphadenopathy, and distant metastases. CT enterography and MR enterography are emerging as valuable imaging techniques for accurate diagnosis of small bowel adenocarcinoma (Figure 2).

Treatment

The primary treatment and only potential for cure for small bowel adenocarcinoma continues to be surgical resection. Tumors of the first and second portions of the duodenum require pancreaticoduodenectomy. For tumors arising in the third and fourth portions of the duodenum, segmental resection is preferred over pancreaticoduodenectomy as long as a margin-negative resection can be obtained. Jejunal and ileal tumors require segmental bowel resection with a wide resection of the lymph node–bearing mesentery. An ileocolectomy is indicated for tumors of the distal ileum.

Patients with locally advanced, unresectable, or metastatic small bowel adenocarcinoma may benefit from palliative surgical resection of the primary tumor to prevent bowel obstruction or bleeding. In some advanced cases, intestinal bypass may be needed to relieve obstruction. For tumors in the duodenum, palliation may be achieved by endoscopic placement of an intraluminal duodenal stent. There are no widely accepted criteria for selecting patients for neoadjuvant therapy, nor any standard chemotherapy regimens. However, neoadjuvant therapy is sometimes used in patients with bulky or locally advanced tumors. Similarly, there is a paucity of data demonstrating the benefit of adjuvant chemotherapy, although patients with completely resected, lymph node positive small bowel adenocarcinoma are selectively being offered chemotherapy based on principles established for colorectal cancer. Cytoreductive surgery and intraperitoneal hyperthermic chemotherapy have also been reported to be successful in a handful of highly selected patients with peritoneal carcinomatosis.

A recent SEER registry analysis of 4518 cases from 1988 to 2007 demonstrated that 5-year disease-specific survival was 65% for stage I, 55% for stage II, 40% for stage III, and less than 10% for stage IV disease. However, in the subset of these patients who had 8 or more lymph nodes evaluated, the 5-year disease-specific survival markedly improved to 80% for stage I, 70% for stage II, 45% for stage III, and 10% for stage IV disease. These data suggest that a portion of stage I or II small bowel adenocarcinomas are undergoing inadequate lymph node evaluation and consequently are being understaged (and undertreated). Factors negatively affecting survival for small bowel adenocarcinoma include male sex, age greater than 55 years, tumor location in the duodenum or ileum (compared to jejunum), and the presence of distant metastases.

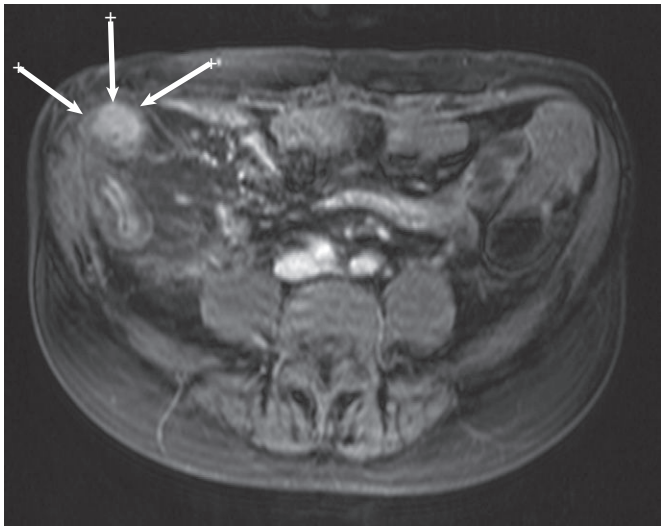

FIGURE 2 MRI showing a small bowel adenocarcinoma *(arrows)* in a Crohn's patient.

GASTROINTESTINAL STROMAL TUMORS

Tumor Characteristics

Gastrointestinal stromal tumors (GISTs) are the most common nonepithelial neoplasm of the small bowel. They originate from the interstitial cells of Cajal or their precursors and can occur anywhere along the GI tract. They are most frequently found in the stomach (60%) and the small bowel (30%), and within the small bowel, they are most likely to be located in the jejunum. The majority of GISTs (>90%) express the CD117 antigen, part of the KIT transmembrane receptor tyrosine kinase that is the product of the KIT (also denoted c-kit) protooncogene. Mutation in the KIT gene leads to an abnormally activated KIT protein and enables oncogenic signaling in the cell. A subset of GISTs lacking KIT mutations has activating mutations in the related receptor tyrosine kinase, platelet-derived growth factor receptor alpha (PDGFRA). These findings led to the development of effective systemic therapies in the form of tyrosine kinase inhibitors (TKIs), such as imatinib that block signaling via KIT and PDGFRA and inhibit tumor proliferation.

Most GISTs arise sporadically. Hereditary GIST is a rare, autosomal dominant genetic disorder, with the majority attributable to germline KIT mutations and a small percentage due to germline mutation in PDGFRA. GISTs may also arise in the setting of the autosomal dominant disorder neurofibromatosis type I (NF1) or as part of Carney's triad (GIST, paraganglioma, and pulmonary chondromas) or Carney-Stratakis dyad (GIST and paragangliomas).

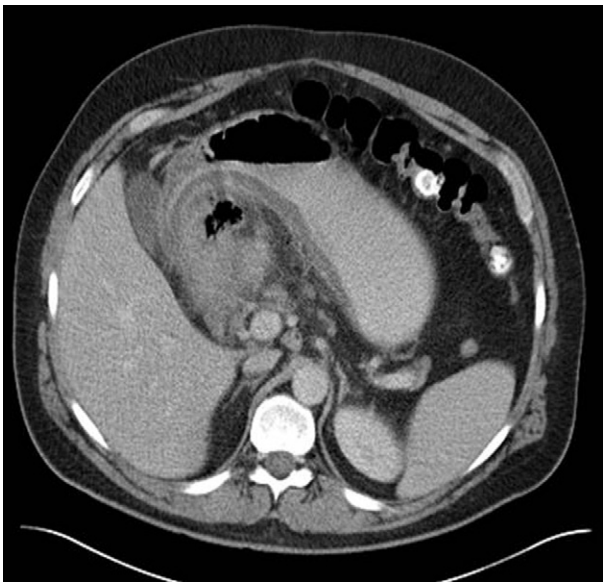

FIGURE 3 Duodenal perforated astrointestinal stromal tumors.

GISTs associated with both syndromes have a chronic, yet indolent course.

Clinical Presentation

Presenting complaints include obstructive symptoms, abdominal discomfort, early satiety, and abdominal distension due to the space-occupying nature of these masses. Most GISTs arise within the muscular wall of the GI tract, and they can grow into the mucosa to form solid subserosal, intramural, or polypoid intraluminal masses. Alternatively, they can protrude outward and form external masses attached to the outer aspect of the gut. GISTs may grow to a massive size prior to presentation, with a median tumor size of 7.5 cm. Bleeding can occur when GISTs erode through the bowel wall or result in intraperitoneal rupture (Figure 3).

Diagnosis

On upper endoscopy, GISTs may appear as a submucosal mass with smooth margins with a normal overlying mucosa. Performing preoperative biopsy for tissue diagnosis is generally discouraged, especially if the tumor is easily resectable. GISTs are soft, fragile masses, and biopsies increase the risk of tumor hemorrhage and dissemination. Biopsy may be appropriate when planning neoadjuvant therapy with imatinib, whether for localized, potentially resectable lesions whose surgical morbidity would be improved by tumor size reduction or for unresectable or metastatic lesions.

Radiographic evaluation often includes CT of the abdomen and pelvis with contrast. Attention should be given to the liver and peritoneum, the most common sites of metastases. Chest CT can be performed to assess for rare lung metastases. Staging and determination of surgical resection is generally based on CT findings. The characteristic finding is of a smooth and well-circumscribed mass in the bowel wall that demonstrates exophytic growth. Larger GISTs may demonstrate central necrosis or hemorrhage.

The clinical behavior of GISTs is highly variable. Virtually all GISTs, especially those larger than 1 cm, have malignant potential. Tumor size and mitotic rate are the two major criteria used to define the risk of aggressive behavior (Table 1).

TABLE 1: Risk of aggressive behavior in GISTs

	Size (largest dimension)	Mitotic count
Very low risk	<2 cm	<5/50 HPF
Low risk	2-5 cm	<5/50 HPF
Intermediate risk	<5 cm 5-10 cm	6-10/50 HPF <5/50 HPF
High risk	>5 cm >10 cm	>5/50 HPF Any mitotic rate

GISTs, Gastrointestinal stromal tumors; *HPF,* high-powered field.
Fletcher CD, Berman JJ, Corless C, et al: Diagnosis of gastrointestinal stromal tumors: a consensus approach, Hum Pathol *33(5):459–465, 2002.*

Treatment

Treatment depends on the extent of disease. For localized disease, resection is the primary therapy and should consist of segmental resection of the affected bowel. Periampullary tumors may require pancreaticoduodenectomy. Tumors with adjacent organs adherent to the mass must have all disease resected en bloc. The abdomen should be thoroughly explored for peritoneal and liver metastases. Because GISTs rarely metastasize to lymph nodes, routine lymphadenectomy is not recommended. The goal is complete gross resection with an intact pseudocapsule and negative microscopic margins. Careful handling of these tumors is critical to avoid rupture and tumor dissemination. Some evidence has suggested that patients whose complete resection is complicated by tumor rupture have a shortened survival compared with those who do not have tumor rupture.

Preoperative administration of imatinib should be considered for marginally resectable GISTs in patients whose surgical morbidity would be improved by reducing the size of the tumor preoperatively. Postoperative treatment with imatinib has been shown to prolong recurrence-free survival and is considered a standard approach following complete resection of all small bowel GIST tumors larger than 3 cm. The optimal duration of treatment is still not clear, but it is recommended that patients with intermediate- to high-risk GISTs be treated for a minimum of 36 months. Imatinib should also be given postoperatively to patients with incomplete resection, recurrent disease, and/or metastatic disease.

Patients with unresectable or metastatic GISTs should be treated with imatinib, and because disease progression has been reported to follow the cessation of imatinib therapy, these patients are often treated with tyrosine kinase inhibitor therapy indefinitely, as long as the disease does not progress and patient tolerance permits. The majority of patients treated with imatinib ultimately experience disease progression after an initial response because of the development of delayed imatinib resistance at a median of 18 to 24 months. The oral tyrosine kinase receptor sunitinib malate is generally given to patients who progress on imatinib.

The decision to operate for metastatic or recurrent GIST should be tailored to each patient and limited to patients with stable or shrinking tumors while on tyrosine kinase inhibitor therapy or for limited disease progression, especially for those lesions that appear potentially easy to resect. The 5-year overall observed survival for patients with a small bowel GIST undergoing resection is 40%. Factors that negatively affect prognosis include larger tumor size, high mitotic index per high-powered field, tumor rupture, male gender, age greater than 55 years, metastases, poorly differentiated tumors, and involved margins.

NON-HODGKIN'S LYMPHOMA

Tumor Characteristics

Gastrointestinal lymphomas are the most frequently occurring extranodal lymphomas. Primary lymphomas of the small intestine consist of a variety of non-Hodgkin's lymphoma subtypes that vary significantly in tumor behavior, response to chemotherapy, and prognosis. Most gastrointestinal lymphomas are of B-cell origin, including diffuse large B-cell lymphoma, mantle cell lymphoma, B-cell lymphoma of mucosa-associated lymphoid tissue (MALT) type, follicular lymphoma, Burkitt lymphoma, and immunoproliferative lymphoma. MALT tumors can be associated with *Helicobacter pylori* infection, and primary treatment includes eradication of *H. pylori*, often leading to complete histologic remission. The distribution of lymphoma in the small intestine parallels the distribution of lymphoid follicles, with the lymphoid-rich ileum representing the most common location. Lymphomas are characteristically bulky tumors, and approximately 70% of them are larger than 5 cm in diameter at presentation.

T-cell lymphomas of the small intestine are more common than B-cell lymphomas and are typically associated with celiac disease. Most enteropathy-associated T-cell lymphomas (EATL) are located in the proximal small intestine. The diagnosis of small bowel lymphoma should be entertained in celiac patients who do not improve on a gluten-free diet or who develop recurrent gastrointestinal symptoms, anemia, or weight loss. Finally, patients with human immunodeficiency virus and low CD4 count are at risk for developing B-cell gastrointestinal lymphomas, which often have a high grade of malignancy and a poor prognosis.

Clinical Presentation

The clinical presentation of patients with lymphoma of the small intestine differs according to the histologic tumor type. Abdominal pain is the most frequent symptom of all types, occurring in approximately two thirds of patients. Other symptoms include gastrointestinal (GI) bleeding, intestinal obstruction or perforation, or a palpable abdominal mass. Patients with EATL often present with acute bleeding, obstruction, or perforation.

Diagnosis

Radiographic evaluation may include a CT scan, which characteristically demonstrates multiple, large tumors and bowel wall segments with homogenous thickening and a normal or enlarged lumen (Figure 4). Diagnosis of lymphoma requires a tissue biopsy so that studies including immunohistochemistry, flow cytometry, and cytogenetic and molecular genetic evaluation can be performed. These allow classification of the lymphoma and ultimately determine optimal treatment and prognosis. One of the major reasons to biopsy ulcerating or nodular lesions in the small bowel remains assessment for lymphoma because this may change the management from surgical to medical. Taking multiple endoscopic biopsies provides sufficient material to diagnose lymphoma in nearly all cases.

The Ann Arbor staging system used for most lymphomas is considered to be inadequate for the staging of GI lymphoma since it does not incorporate information on the depth of tumor invasion, that is known to affect prognosis. Several other staging systems have been proposed, and the most widely accepted is the Lugano staging system (Table 2).

Treatment

Optimal treatment of GI lymphoma remains poorly defined. The treatment of nongastric MALT lymphoma depends principally upon the stage of disease at diagnosis. Treatment of small intestinal MALT lymphomas diagnosed at an early stage with antibiotics directed against *Campylobacter jejuni* or *H. pylori* may lead to regression. Most patients ultimately relapse and present with an aggressive high-grade histology requiring radiation therapy and/or combination chemotherapy. Most patients with diffuse large B-cell lymphoma are treated with combination chemoimmunotherapy regimens such as R-CHOP with or without radiation therapy. Surgery is reserved for patients with complications such as perforation or obstruction or intractable bleeding.

EATL is almost always of high-grade histology. Prognosis is poor and worse than that of other intestinal lymphomas. Treatment consists of combination chemotherapy that can be followed by autologous hematopoietic cell transplantation. Systemic chemotherapy is

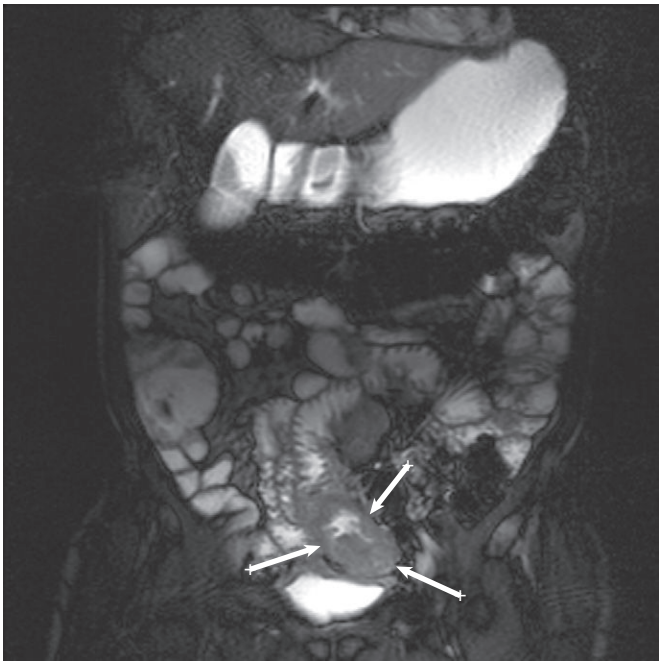

FIGURE 4 Lymphoma involving the ileum.

TABLE 2: Lugano staging system for gastrointestinal lymphomas

Stage I—The tumor is confined to the gastrointestinal tract. It can be a single primary lesion or multiple noncontiguous lesions.
Stage II—The tumor extends into the abdomen. This is further subdivided based upon the location of nodal involvement.
Stage II_1—There is involvement of local nodes (perigastric nodes for gastric lymphoma or paraintestinal nodes for intestinal lymphoma).
Stage II_2—There is involvement of distant nodes (paraaortic, paracaval, pelvic, or inguinal nodes for most tumors; mesenteric nodes in the case of intestinal lymphoma).
Stage IIE—The tumor penetrates the serosa to involve adjacent organs or tissues.
Stage III—There is no stage III disease in this system.
Stage IV—There is disseminated extranodal involvement or concomitant supradiaphragmatic nodal involvement.

Rohatiner A, d'Amore F, Coiffier B, et al: Report on a workshop convened to discuss the pathological and staging classification of gastrointestinal tract lymphoma, Ann Oncol *5:397, 1994.*

the treatment of choice for mantle cell lymphoma. However, if the tumor is localized, chemotherapy followed by radiation may be curative. Chemotherapy is the mainstay of treatment of Burkitt lymphoma, but resection may be an option for isolated lesions or may be required to alleviate symptoms or avoid perforation during chemotherapy.

METASTASES

Secondary neoplastic involvement of the intestine is more common than primary small intestinal neoplasia, most frequently from melanoma, lung cancer, and breast cancer. Metastases to the small bowel can occur via direct invasion, hematogenous or lymphatic spread, and intraperitoneal seeding. The most common presentation of metastasis is small bowel obstruction, although ascites, mesenteric ischemia, perforation, and bleeding can also be seen. Unfortunately, small bowel metastases indicate an advanced stage of the primary neoplasm, so treatment usually is focused on alleviating symptoms. Small bowel obstructions are treated in the standard fashion: with nasogastric decompression, bowel rest, and intravenous hydration. Failure of conservative treatment necessitates surgical intervention, typically resection of obstructed or intussuscepted bowel with primary anastomosis.

Patients with diffuse carcinomatosis are high-risk operative candidates who must be medically optimized prior to undergoing surgery. In those patients whose tumors are so advanced that definitive treatment cannot be performed, placement of a gastrostomy tube or an ostomy for decompression may be considered. Before any surgery, however, it is useful to repeat tumor staging to define the patient's prognosis.

BENIGN TUMORS

Similar to their malignant counterparts, benign small intestine tumors often are undetected. Those patients who are symptomatic most commonly present with abdominal pain and bleeding. Despite their benign nature, endoscopic or surgical resection is usually indicated to obtain adequate tissue for diagnosis and to reduce the risk of subsequent complications, such as bleeding and obstruction.

Adenomas

Three types of small intestine adenomas have been described: simple villous, tubular, and Brunner's gland adenomas. In general, they may develop as single or multiple lesions, both sessile and pedunculated, and are found most commonly in the duodenum. Villous adenomas carry the highest risk of malignant transformation. Malignant cells are found in as many as 42% of duodenal villous adenomas, with an adenoma-carcinoma sequence similar to that of colorectal cancer. Patients with familial adenomatous polyposis have a significantly higher prevalence of duodenal adenomas, as well as a much greater risk of duodenal adenocarcinoma. Tubular adenomas are less likely to undergo malignant transformation. Brunner's gland adenomas exhibit benign proliferation of the Brunner's glands, with scattered ductal and stromal elements.

Ampullary adenomas most commonly present with painless jaundice related to the mass effect on the ampulla and sometimes with pruritus or cholangitis. MRCP and percutaneous transhepatic cholangiography will show findings suggestive of biliary obstruction at the ampullary level, but endoscopic retrograde cholangiopancreatography (ERCP) has the advantage of permitting direct visualization of the ampulla, biliary decompression via an internal stent if necessary, and biopsy of the ampullary mass.

Although endoscopic evaluation is a common and useful means of evaluating these tumors, endoscopic biopsies have been shown to miss malignancies. Treatment of small intestinal adenoma varies by their pathology, and local excision may be appropriate for small tumors. For villous tumors of the duodenum, treatment recommendations vary from local excision to pancreas-sparing duodenectomy to pancreaticoduodenectomy. Patients whose tumor has no features that raise concerns for malignancy, such as ulceration, severe dysplasia on preoperative biopsy, or dilation of pancreatic and common bile duct, may be treated with local excision; if any of the aforementioned worrisome traits are present, pancreaticoduodenectomy should be considered.

Because of the high rate of tumor recurrence with local excision (up to 30% at 5 years) and the potential for recurrence as invasive cancer, regular endoscopic surveillance postoperatively is required. Villous tumors of the duodenum that recur after local excision call for pancreaticoduodenectomy. Patients with familial adenomatous polyposis and duodenal tumors showing high-grade dysplasia should undergo either pancreas-sparing duodenectomy or pancreaticoduodenectomy.

Lipomas

Small intestinal lipomas are benign tumors that arise from the submucosal adipose tissue and expand with compression of the lumen. They are most commonly found in the ileum. Histologic features include collections of mature adipose tissue and fibrous tissue strands. Symptoms, when they do occur, are usually related to obstruction, bleeding, and/or intussusception. Lipomas are seen on CT as a homogenous mass with the density of fat. On barium studies they appear as smooth, radiolucent, well-circumscribed intramural masses whose size and form change with peristalsis and pressure. Small, asymptomatic lipomas can be treated conservatively, whereas symptomatic lipomas or those greater than 2 cm should be resected.

Hamartomas

Hamartomatous polyps consist of a smooth muscle core arising from the muscularis mucosa and extending into the polyp. They usually occur in multiples and in varying sizes and shapes. Hamartomas are characteristic of Peutz-Jeghers syndrome, an autosomal dominant condition. They occur throughout the bowel and in varying number, from solitary polyps to hundreds coating the intestine. The polyps can cause abdominal pain, intussusception, obstruction, and GI bleeding. Endoscopic polypectomy reduces polyp-related complications and the risk of needing future operative polypectomy. If a laparotomy is performed either emergently for obstruction/intussusception, or electively for the removal of large or symptomatic polyps, intraoperative endoscopy and "clean sweep" polypectomy should be undertaken. There are a number of potentially promising agents for reduction of polyp burden in Peutz-Jeghers syndrome, but none of these are in routine clinical use.

Hemangiomas

Vascular tumors account for 7% to 10% of all benign small bowel tumors. They can be solitary or multiple, and in the small intestine, the jejunum is the most common site of involvement. Occult chronic GI bleeding and iron deficiency anemia are the most common forms of presentation. Hemangiomas can be classified as cavernous (most frequent), capillary, or mixed-type, according to the diameter of the involved vessel. Microscopically, they consist of numerous dilated, irregular, blood-filled spaces or sinuses lined by layers of endothelial cells. They can vary in size from a few millimeters to several centimeters. They are usually localized in the submucosa but can be infiltrative and affect the entire thickness of the intestinal wall, as well as the mesentery, retroperitoneum, or pelvis.

Preoperative diagnosis is difficult. MRI and, more recently, capsule endoscopy have been useful means of identifying these lesions. Complete surgical resection is the procedure of choice, particularly when a solitary lesion is found. For appropriately sized and located lesions, endoscopic sclerotherapy or angiographic embolization may also be used.

The Management of Diverticulosis of the Small Bowel

Kyla P. Terhune, MD, and John L. Tarpley, MD

Diverticulosis of the small bowel is often overlooked because its presentation may be similar but its prevalence pales in comparison with diverticulosis of the large bowel (15% to 40% of those older than 40 years are reported to have colonic diverticula). However, three small bowel diverticula merit particular consideration: duodenal, jejuno-ileal, and Meckel's. These may present acutely or chronically, and management varies depending on location, acuity, and patient age. Descriptions of small bowel diverticula can be categorized by structure or cause: (1) congenital or acquired; (2) true (all three layers) or false (mucosa, submucosa); and (3) location (duodenal or jejuno-ileal). Most duodenal and jejuno-ileal diverticula are false or pseudodiverticula, pulsion phenomena related to increased intraluminal pressure and intestinal dysmotility with consequent herniation of mucosa and submucosa through muscular defects. These occur at the points of entrance or exit of blood vessels, the vasa recta, located on the mesenteric border of the small bowel. Perhaps 5% of adults over 40 years of age harbor duodenal diverticula, with incidence rate increasing with age, but only about 1% has jejunal or ileal pseudodiverticula and about 2% a Meckel's. Although Meckel's diverticula can be described with these descriptors, it is a specific entity unto itself, defined as a congenital true diverticulum that is a result of incomplete closure of the omphalomesenteric or vitelline duct during gestation.

The objective of this chapter is to address the practical approaches to small bowel diverticula, partitioning them by duodenal, jejuno-ileal, or Meckel's. A description of the characteristics of each is followed by proposed guidelines for surgical management: nonoperative or operative, with or without endoscopic or interventional techniques.

DUODENAL DIVERTICULA

Duodenal diverticula are fairly common in adults, and because they are rarely symptomatic, the true incidence and prevalence rates are likely underestimated. Most are detected incidentally on imaging studies, upper endoscopy, occasionally at operation or at postmortem examination. Frequently reported incidence rates are approximately 5% with radiologic contrast studies, 15% with upper endoscopy, and up to 20% in some autopsy reports. The incidence rate rises with increasing age and affects more women than men. Two thirds of cases reside in the periampullary region, located mostly on the medial wall (Figure 1). Duodenal diverticula sometimes are stated to produce symptoms 5% to 10% of the time when present. Symptoms may be the result of inflammation of the diverticulum, perforation, bleeding, or compression of the biliopancreatic ducts. Resist the temptation to "do something" for the asymptomatic, incidentally discovered duodenal diverticulum. As one of the authors says, "Don't poke a skunk."

Occasionally, duodenal diverticula are symptomatic and present with abdominal pain, both acute and chronic. Acute presentations can be the result of diverticulitis, bleeding, pancreatitis, and biliary obstruction. Location of the diverticulum and surrounding structures determines the symptoms from compression. In patients with diverticula immediately adjacent to the ampulla of Vater, the biliopancreatic ducts usually enter the duodenum at the superior margin rather than through the diverticulum. In addition, diverticula on the medial wall of the duodenum are, in reality, embedded in the pancreas. Diverticula in proximity to the ampulla increase in importance during endoscopic procedures, especially endoscopic retrograde cholangiopancreatography (ERCP). The likelihood of an unsuccessful study or, even worse, an iatrogenic injury with duodenal perforation can accompany such efforts when a duodenal diverticulum is present.

Chronic presentations of small bowel diverticular disease can be the result of bleeding or stasis-related steatorrhea with bacterial overgrowth. However, even when symptomatic, diverticula should be addressed operatively only after much reflection given the historically high morbidity and even mortality rates associated with operative management. Patients should instead "earn" their operation, and the physician should be as certain as possible that the diverticulum is causal to the presentation.

When a duodenal diverticulum has been determined to be the source, the least intervention that accomplishes a good outcome is the aim. Nonoperative options in these usually elderly patients include bowel rest, antibiotics, parenteral nutrition, endoscopic treatment, and interventional radiologic (IR) techniques. For patients with a perforation, one can consider IR percutaneous drainage. For patients with bleeding, endoscopic coagulation options or IR angioembolization are options.

In the past, direct attack on the offending bleeding, inflamed, or perforated diverticulum was the strategy. Now, this is reserved for emergent situations and failure of nonoperative interventions because surgical intervention often comes with significant morbidity and mortality, including high recurrence rates and duodenal fistulae

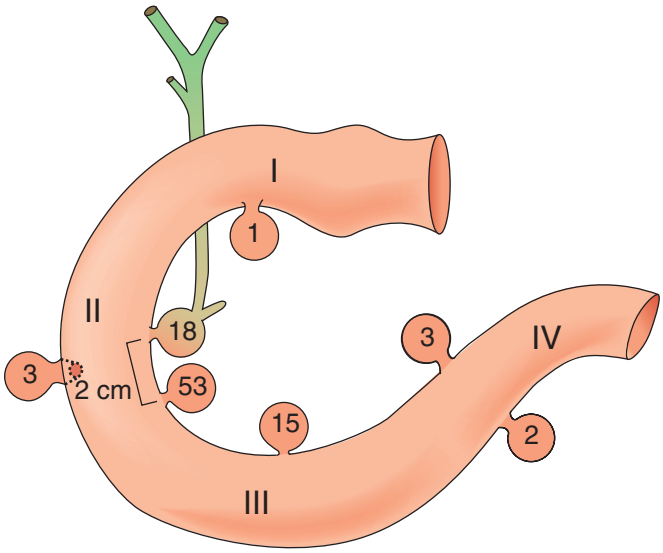

FIGURE 1 Distribution of 95 duodenal diverticula within the four portions of the duodenum. *(From Eggert A, Teichmann W, Wittmann DH: The pathologic implication of duodenal diverticula,* Surg Gynecol Obstet *154:62-64, 1982.)*

formation. When operative intervention is necessary, it consists of open laparotomy with generous Kocher's maneuver, followed by diverticulectomy, duodenal resection, inversion, or drainage (Figure 2). Anatomically, most of the diverticula are against and into the head of the pancreas, one of the primary reasons for difficulty and consequent morbidity. It is imperative to know the relationship between the duodenal diverticulum and the biliary system, particularly the ampulla. After the Kocher's maneuver and anterolateral duodenotomy for exposure, one can either place a probe retrograde via the papilla or pass a Fogarty biliary or red rubber catheter anterograde through an opening in the cystic duct or via the common duct to define the anatomy. The challenge is to identify the diverticulum, protect key structures, and then either resect or invert the diverticulum. One then closes the duodenum in two layers with absorbable suture for the inner layer and nonabsorbable sutures for the outer layer, taking care not to compromise the diameter of the bowel. Historically, with a large diverticulum, a serosal patch technique or Roux-en-Y duodenojejunostomy was at times used to thwart narrowing of the lumen. Safer alternatives to resection or inversion of the diverticulum include diversions of the biliary or alimentary stream. These indirect or flanking procedures such as a Roux-en-Y hepaticojejunostomy or a Roux-en-Y duodenojejunostomy as advocated by Silen and more recently Mathews are worthy of consideration and often safer and more effective (Figure 3).

A second type of duodenal diverticulum that is rare but worth describing is a congenital anomaly often referred to as an intraluminal duodenal diverticulum. It can lead to duodenal obstruction, bleeding, and acute pancreatitis. This rarely encountered entity is a variant of an intestinal web, caused by incomplete recanalization of the duodenum, appearing to develop in utero at approximately the 7th week of gestation when a partial duodenal diaphragm forms and elongates, forming a diverticulum. With entrapment of food, peristalsis, and distension, this "diverticulum" increases in size. Radiographically, the region appears as a "windsock" or "thumb of a glove" and resides in the lumen of the duodenum. Other coexistent gastrointestinal congenital abnormalities can be found in up to 40% of patients who also have intraluminal duodenal diverticula. Operative intervention is necessary because the "diverticulum" should be excised; for planning, it is again important to understand the

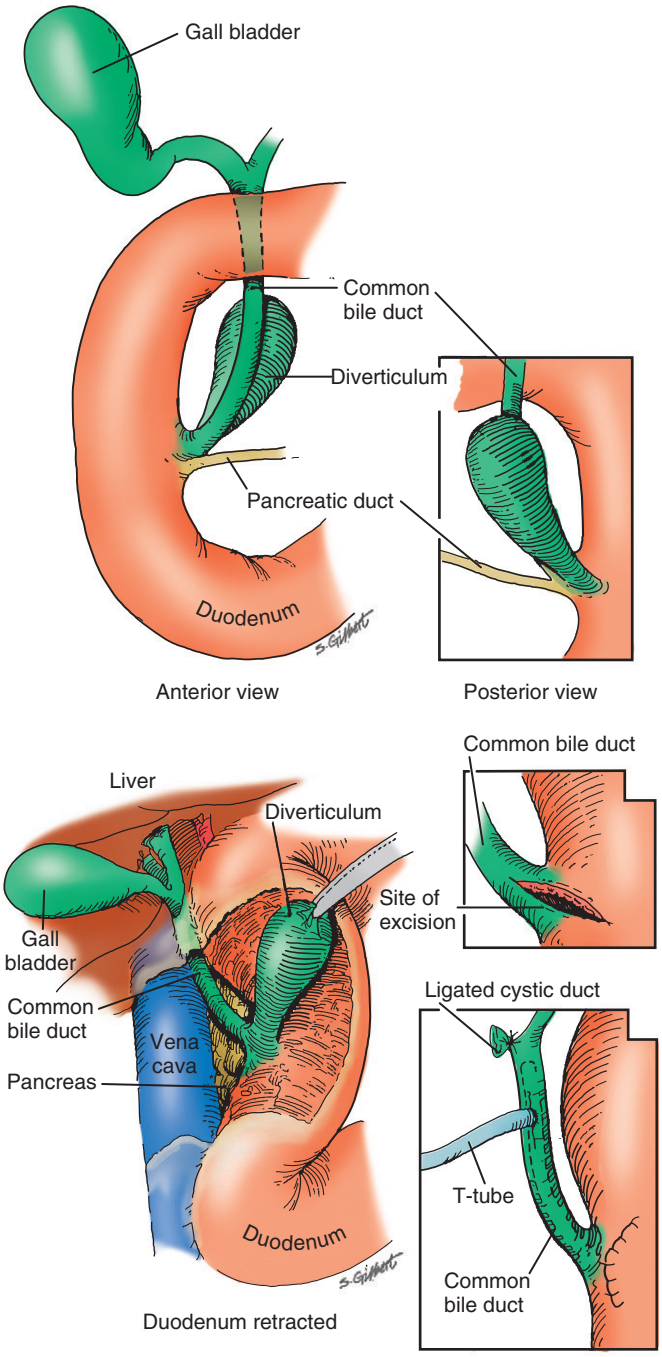

FIGURE 2 Usefulness of the Kocher's maneuver in demonstrating duodenal diverticula. *(From Jones TW, Merendino KA: The perplexing duodenal diverticulum,* Surgery *48:1068, 1960.)*

anatomic relationship of surrounding ductal structures. The common bile duct and pancreatic duct usually empty into the diverticulum near its attachment to the duodenal wall at the proximal extent of the diverticulum. The approach is similar to that described previously, with an anterior duodenotomy and careful preservation of the ampulla of Vater. This is followed by a subtotal resection of the intraluminal diverticulum. Endoscopic approaches have also been reported recently, but currently laparotomy with excision via duodenotomy is recommended.

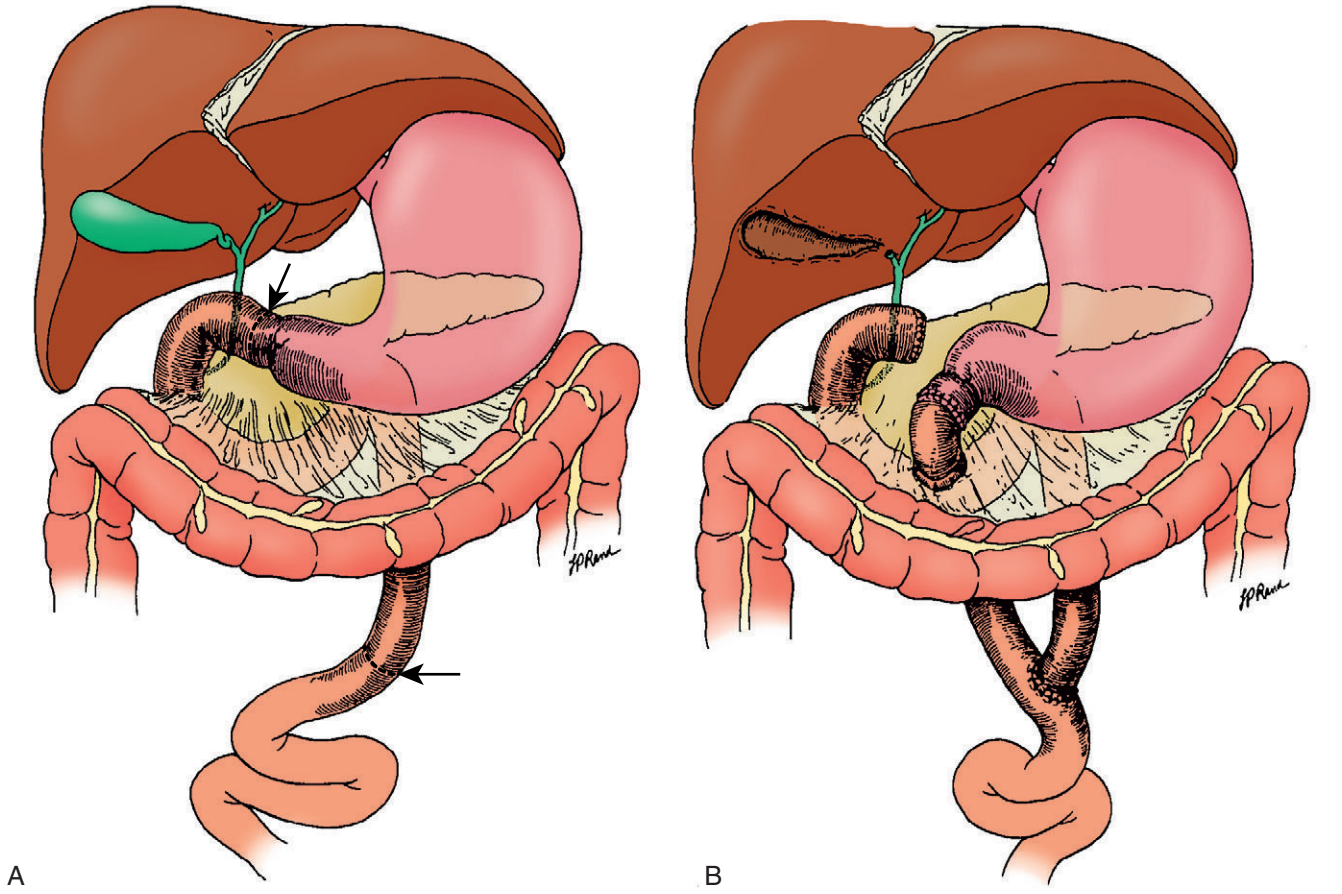

FIGURE 3 Duodenojejunostomy for pancreaticobiliary complications of duodenal diverticulum. **A,** Anatomy before reconstruction. *Arrows* point to dotted lines that indicate proposed sites of division of the intestine. **B,** Anatomy after reconstruction. The gallbladder has been removed. The Roux limb has been brought through the mesocolon, the duodenojejunostomy completed, and the mesentery closed. *(From Critchlow JF, Shapiro ME, Silen W: Duodenojejunostomy for the pancreaticobiliary complications of duodenal diverticulum.* Ann Surg *202:56-58, 1985.)*

JEJUNO-ILEAL DIVERTICULAR DISEASE

Similar to duodenal diverticula but even less frequent, jejuno-ileal diverticula are also false diverticula. Usually in the elderly and multiple in number, diverticula are stated to be seven times more frequent in the jejunum than in the ileum (Figure 4). In the evaluation of patients with chronic symptoms, detection of lesions may be noted with computed tomographic (CT) scan, enteroclysis, push enteroscopy, double-balloon endoscopy, and capsule endoscopy. Jejuno-ileal diverticulitis is an overlooked cause of acute abdominal pain in the elderly and can be confused with colonic diverticulitis, appendicitis, and other entities on the long list of candidates for the differential diagnoses of the acute abdomen. Similarly, patients with a subacute or chronic presentation can be confused as having inflammatory bowel disease, tuberculosis, and even neoplasms. Acute complications from jejuno-ileal diverticula are infrequent but, just as in duodenal disease as described previously, may occur from inflammation, perforation, obstruction, and bleeding. The approach to operative intervention is similar, but because these lesions are not proximately associated with the biliopancreatic tract, the danger of injury to surrounding structures is decreased.

Acute inflammation in the setting of jejuno-ileal diverticulosis can result in uncomplicated diverticulitis, microperforation with phlegmon or abscess formation, and free perforation without containment resulting in generalized peritonitis. The CT scan can prove most helpful in detecting inflammation, stranding, presence of other

FIGURE 4 Multiple large jejunal diverticula located in the mesentery in an older patient with obstruction from an enterolith. *(From Evers BM, Townsend CM Jr, Thompson JC: Small intestine. In Schwartz SI, editor:* Principles of surgery, *ed 7, New York, 1999, McGraw-Hill, p 1248.)*

diverticula, bowel-wall thickening, microperforations with focal extraluminal air, abscesses, and other features not dissimilar to the more frequent colonic diverticular disease. Symptomatic patients often have an accompanying leukocytosis, although this is sometimes absent in the elderly. Chronic symptoms include abdominal pain, stasis, bacterial overgrowth, and malnutrition. In the symptomatic

but nonperitonitic case with a failed trial of nonoperative management with bowel rest, antibiotics, and decompression, the operative treatment is a judicious segmental resection of the involved segment of small bowel with enteroenterostomy. One should not attempt to remove all diverticular disease but instead resect the portion responsible for the current illness.

MECKEL'S DIVERTICULUM

Meckel's diverticulum (Figure 5) is the most common congenital anomaly of the alimentary tract, with a reported prevalence rate of 1% to 4% in the general population. As noted previously, this is the result of incomplete closure of the omphalomesenteric or vitelline duct during gestation. Most Meckel's diverticula remain asymptomatic over the course of a patient's lifetime but may be discovered incidentally at operation or with an imaging study. When symptomatic, it is the result of bleeding, bowel obstruction, diverticulitis, and, very rarely, neoplasia. Meckel's diverticulum is affectionately taught early in medical school as the "Rule of Twos:" it is usually found within 2 feet of the ileocecal valve, in 2% of the population, with two possible heterotopic mucosae (gastric or pancreatic), two times as prevalent in men compared with women, wherein only 2% (0.5 to 2.0%) become symptomatic, usually within the first 2 years of life. When symptomatic in the pediatric population, it is often from bleeding, as secretions from the heterotopic gastric mucosa within the Meckel's diverticulum ulcerate the ileal mucosa on the mesenteric border, opposite the diverticulum. This bleeding may be acute or chronic. If suspected, one can use Meckel's scintigraphy, with technetium-99m pertechnetate, which then is concentrated and secreted by the heterotopic gastric mucosa (Figure 6). Although it has a sensitivity of approximately 85% in children, it shows the presence of gastric mucosa so is less useful in adults where the gastric mucosa may be atrophic.

FIGURE 5 Common presentation of a Meckel's diverticulum projecting from the antimesenteric border of the ileum. *(From McKenzie S, Evers BM: Small intestine. In Townsend CM Jr editor:* Sabiston textbook of surgery, *ed 19, Philadelphia, 2012, Elsevier Saunders.)*

On rare occasion, IR has a diagnostic role during active bleeding for localization or confirmation. A persistent right vitelline artery arising from the superior mesenteric artery or a nonbranching embryonic ileal artery may be encountered. Treatment for bleeding incited by a Meckel's diverticulum requires a segmental ileal resection so that both the Meckel's diverticulum and the ileal ulceration are removed. When the resection is for symptoms other than bleeding, a simple V-shaped diverticulectomy with transverse closure of the ileum can be performed.

Most children who undergo an operation for a Meckel's diverticulum are under 4 years of age. In a recent national study directed by B.T. Campbell of Hartford, Conn, with an administrative database from 43 freestanding, not-for-profit U.S. children's hospitals, 815 children underwent Meckel's diverticulectomy over a 24-month period. The boy:girl ratio was 2.3:1, and half of the children (53%) needed operation before their 4th birthday. Children less than 2 years of age had the highest incidence rate of Meckel's diverticulectomy. The most common presentations for primary (intentional, directed for the Meckel's diverticulum, not incidental) resection were obstruction (30%), bleeding (27%), and intussusception (19%) in children under 18 years old.

In adults, diverticulitis and obstruction are more likely presentations of a symptomatic Meckel's diverticulum, although both acute and chronic bleeding can occur. The presentation of Meckel's diverticulitis is virtually indistinguishable from acute appendicitis. In fact, it is recommended that when acute appendicitis is suspected but not found operatively, one should run the terminal ileum to exclude Meckel's diverticula. Obstruction can be secondary to a residual fibrous band or cord from the obliterated omphalomesenteric duct with creation of an intestinal volvulus. Other obstructive etiologies include ileo-ileal or an ileo-colic intussusception with the Meckel's diverticulum as a lead point. Rarely, a Meckel's diverticulum becomes incarcerated in an inguinal hernia, known as Littre's hernia.

Resection of the incidentally found Meckel's diverticulum depends on patient age, circumstances of the procedure, and whether the risk of resection is higher or lower than the likelihood of subsequent symptomatology. In the multiinstitutional study from Hartford, 40% of the Meckel's resections in the 815 patients under age 18 years were performed as a secondary procedure after the Meckel's was discovered during an operation for another diagnosis. A study from Seattle by Soltero and Bill in the 1970s argued that the likelihood for

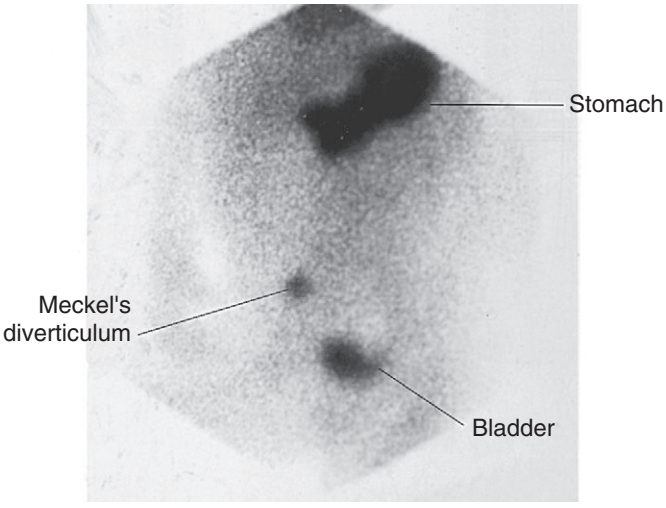

FIGURE 6 ^{99m}Tc-pertchnetate scintigram from a child with a Meckel's diverticulum clearly differentiated from the stomach and bladder. *(From McKenzie S, Evers BM: Small intestine. In Townsend Jr CM editor:* Sabiston textbook of surgery, *ed 19, Philadelphia, 2012, Elsevier Saunders.)*

a Meckel's becoming symptomatic in an adult was only 2% but the projected morbidity for resection may be as high as 12%. Cullen and associates from the Mayo Clinic in 1994 challenged the practice of ignoring an incidentally found Meckel's and quoted a 6.4% likelihood of symptoms from a Meckel's over a lifetime. Noting a low complication rate from the removal of the Meckel's diverticulum itself as opposed to that of the primary operation, they recommended removal at any age up to 80 years, as long as no additional conditions made removal hazardous. From a meta-analysis of 244 studies, Zani and colleagues reported increased morbidity associated with incidental resection over no treatment and determined that more than 700 patients with incidental Meckel's diverticulum required resection to avoid one Meckel's-related death. Thus, general practice is to resect incidentally found Meckel's diverticulum in children but not in adults.

SUMMARY

In summary, small bowel diverticula are rarely symptomatic, as they are in continuity with the lumen and thus function as a part of the small bowel lumen. On occasion, a diverticulum can become secondarily inflamed, perforate, cause obstruction, or bleed. Bleeding from false diverticula of the duodenum, jejunum, and non-Meckel's ileum arises from blood vessels along their perimeter associated with the vasa recta; bleeding in association with a Meckel's diverticulum results from ulceration secondary to acid secretion from heterotopic gastric mucosa. Asymptomatic diverticula, including incidentally found Meckel's diverticula in the adult, should be left alone. In cases of acute or chronic symptoms associated with the pulsion diverticula, one must ask whether the option for observation and nonoperative management exists. Intraluminal duodenal diverticulum, a congenital anomaly associated with web formation, and symptomatic Meckel's diverticula should be resected. With symptomatic pulsion diverticula (duodenal or jejuno-ileal), operative management is sometimes required. Understanding the anatomic relationship of the diverticulum to surrounding structures, particularly to the biliopancreatic anatomy in the case of the duodenal diverticulum, is imperative. When considering any operation for a patient with a complication from a duodenal diverticulum, be mindful of the counsel of Emperor Augustus: *Festina Lente,* or "Make haste slowly."

Motility Disorders of the Stomach and Small Bowel

John Clarke, MD

OVERVIEW

Motility disorders of the gastrointestinal (GI) tract are most commonly encountered by surgeons in two of the following circumstances: either postoperatively or as a consequence of functional or directed denervation. Paralysis of the small intestine commonly manifests in patients undergoing manipulation of the abdominal viscera during laparotomy (especially during colectomy). Primary motility disorders of the GI tract are less commonly encountered in the realm of surgery, but they require a surgeon's evaluation because they are included in the differential diagnosis of surgical conditions and may require surgical intervention. As a rule, most cases of GI motility disorders may require surgical intervention when the symptoms are debilitating and unresponsive to medical management. This chapter is a review of the different motility disorders of the stomach and small bowel, with emphasis on surgical management.

MOTILITY DISORDERS OF THE STOMACH

Gastroparesis

Gastroparesis is a syndrome characterized by delayed gastric emptying in the absence of mechanical obstruction. The hallmark symptoms are nausea, vomiting, abdominal pain, early satiety, and postprandial sense of fullness. Symptom severity can be assessed with the Gastroparesis Cardinal Symptom Index (GCSI), which is a validated scale to assess symptom severity, although symptom severity is

not a reliable predictor of the degree of gastric emptying impairment. Other symptoms may include bloating, uncontrolled reflux, postprandial hypoglycemia, and weight change.

These symptoms can range from mild to severe and can be described within a classification scheme of gastroparesis. Three categories have been proposed: mild (grade 1), compensated (grade 2), and severe (grade 3). In grade 1 gastroparesis, symptoms are easily controlled and nutrition is maintained with a regular diet or with minor modifications. In grade 2 gastroparesis, symptoms are partially controlled by pharmacotherapy, dietary modifications are required, and patients rarely require hospital admission. In grade 3 gastroparesis, symptoms are refractory to medical therapy, oral nutrition intake is compromised, and patients may require frequent hospital admissions.

The incidence and prevalence of gastroparesis are controversial. The best data to date suggest that the age-adjusted incidences of definite gastroparesis are 2.4 for men and 9.8 for women per 100,000 person-years, and the prevalences per 100,000 persons are 9.6 for men and 38 for women. In all subsets of gastroparesis, there is a gender imbalance; women are affected in much greater numbers than are men. Some sources quote a female/male ratio of involvement of as high as 7:1.

Gastroparesis is a heterogeneous disease with distinct causes, the most common being idiopathic factors (36% to 49% of cases), diabetes mellitus (25% to 29%), and postsurgical factors (7% to 13%). Idiopathic gastroparesis is currently the most common subset at presentation. A potential autoimmune or postinfectious origin has been a subject of speculation, but the exact cause remains unknown, and active research to better understand involved mechanisms is ongoing.

Although diabetes is classically associated with gastroparesis, diabetic patients represent less than one third of patients with gastroparesis in most series. Approximately 10% to 15% of patients with gastroparesis have upper GI symptoms consistent with potential gastroparesis; however, the true prevalence of gastroparesis in patients with diabetes remains unclear. In tertiary referral centers, a delay is documented in more than 50% of diabetic patients referred for gastric emptying studies; however, this relationship may not exist in community settings. Gastroparesis can affect patients with both type 1 and type 2 diabetes. Usually, symptoms develop after at least 10 years of having documented diabetes, and these patients usually have some other sign of end-organ involvement, such as retinopathy, neuropathy, or nephropathy. Diabetic gastroparesis can cause severe symptoms and hence lead to nutritional compromise, impaired glycemic control, and poor overall quality of life, independent of other confounding factors such as age, smoking, alcohol, or type of diabetes.

The surgical procedure for gastroparesis that may be most commonly encountered in clinical practice and leads to reversible or irreversible vagal injury is fundoplication. Loss of extrinsic vagal stimulation reduces the capacity of the stomach to empty, whether in the fasting or postprandial state, and leads to gastroparesis and possible bezoar formation. Other surgical procedures that are implicated include the Billroth II gastrectomy, botulinum toxin injection for medical treatment of achalasia, variceal sclerotherapy, and lung or heart transplantation. Measuring the plasma pancreatic polypeptide may help establish the diagnosis of vagal injury; however, this is not often required in clinical practice as confirmation of vagal injury may not change management and the diagnosis can usually be established from clinical history. The plasma pancreatic polypeptide level normally increases by at least 25 pg/mL in the first 20 minutes after sham feeding, as a result of cephalic vagal stimulation. In cases of vagal injury, this increase may be blunted or absent.

Medications that have been implicated in gastroparesis include narcotics, α_2-adrenergic agonists (clonidine), tricyclic antidepressants, calcium channel blockers, dopamine agonists, muscarinic anticholinergics, and octreotide. Of interest, intermittent or prolonged use of erythromycin, which is known to accelerate gastric emptying, may cause vomiting and upper abdominal discomfort, which can mimic symptoms of gastroparesis.

Gastroparesis can also be secondary to other causes, such as connective tissue diseases (typically scleroderma), viral illnesses (Norwalk virus and rotavirus), iatrogenic causes (medications, postsurgical status), infiltrating diseases (amyloidosis), thyroid dysfunction, metabolic abnormalities (hypokalemia, hypomagnesemia, hyperglycemia), and neuromuscular disorders.

In view of the varied causes implicated in gastroparesis, exact predictions regarding prognosis can prove difficult, although it has been suggested that patients with connective tissue disorders and the subset of patients with idiopathic gastroparesis with predominant symptoms of abdominal pain, have a worse prognosis. In addition, it has been noted that emptying of solids is more often compromised than that of liquids. Patients with poor tolerance of a liquid diet have a more unfavorable outcome.

Evaluation of Gastroparesis

Gastroparesis is often suspected from the history and physical examination findings and is subsequently confirmed with the appropriate diagnostic tests. Although no routine laboratory tests aid in the diagnosis, they may be helpful for ruling out secondary causes of gastroparesis. The basic laboratory tests to obtain include measurements of hemoglobin, fasting plasma glucose level, thyroid-stimulating hormone concentration, total serum protein, and albumin to assess the nutritional state of the patient or presence of metabolic abnormalities. If potential rheumatic disease is highly suspected, an antinuclear antibody titer can be measured. A plain radiograph of the abdomen could also reveal any evidence of bowel dilatation.

As symptoms of gastroparesis are nonspecific, upper endoscopy is necessary to rule out mechanical obstruction or significant mucosal disease. Endoscopy also allows for the detection of potential retained food (or bezoar formation). The finding of retained food on endoscopy is more specific for gastroparesis, but sensitivity is lower, and the absence of retained food on endoscopy does not guarantee normal findings of a gastric emptying study. If obstruction is highly suspected, an upper GI series or small bowel follow-through may be performed to rule out a mechanical process.

The "gold standard" for the diagnosis of gastroparesis is the gastric emptying scintigraphy. In the United States, this is the most standardized, simplest, and most widely available technique to document postprandial gastric stasis. In this test, the patient ingests a low-fat egg-white meal labeled with technetium 99 m and sulfur colloid and then undergoes scintigraphy immediately and 1, 2, and 4 hours after ingesting the meal. Many centers may perform studies of shorter duration; however, a 4-hour study has more optimal performance characteristics and is specifically recommended by joint consensus of the American Neurogastroenterology and Motility Society and the Society of Nuclear Medicine. Gastric emptying scintigraphy has 62% sensitivity and 93% specificity when performed 4 hours after meal ingestion. Medications that affect gastric emptying should be discontinued 48 to 72 hours in advance, and the blood glucose level in diabetic patients should be less than 275 mg/dL (and ideally normal) on the day of the test. In clinical practice, abnormal values are higher than 10% retained at 4 hours and higher than 60% retained at 2 hours. Approximately 20% of patients with symptoms suggestive of abnormal gastric emptying and normal 2-hour emptying parameters have abnormal emptying parameters at the 4-hour time point. At some centers, intravenous prokinetic agents may administered after 4 hours to determine whether the patient is a "responder" or "nonresponder," although this is not standard of care at the present time.

Liquids often empty from the stomach normally despite the presence of solid retention, which helps document the presence of gastric stasis, and its severity is most commonly assessed by evaluation of the gastric emptying of solids. Liquid-phase gastric emptying tests

can be performed with the use of water labeled with a different isotope, indium 111–diethylenetriaminepentaacetic acid, (^{111}In-DTPA) and technetium 99 m (^{99m}Tc) . This test helps identify the small group of patients who may have altered liquid emptying with a normal solid-phase emptying and persistent nausea, although the clinical significance of this pattern remains unclear.

Other tests that can be used to assist the diagnosis of gastroparesis include the stable isotope breath test, wireless motility capsule (SmartPill), and antroduodenal manometry. The stable isotope breath test is not currently available in the United States, but it is commonly performed in Europe and other parts of the world and has certain potential benefits that will probably lead to more widespread use, including (1) lack of radiation exposure and (2) lower cost. This test is an indirect measure of gastric emptying. The patient ingests a solid meal labeled with carbon 13 (C^{13}) and another substance, such as C^{13} octanoic acid, C^{13} acetate, or C^{13}Spirulina (*Arthrospira platensis,* a plant-based protein source). When the C^{13}–labeled meal is emptied from the stomach, it is rapidly absorbed in the small intestine and metabolized in the liver to $C^{13}O_2$, which is exhaled from the lungs and subsequently detected in the breath test. Breath samples are collected 45, 90, 120, 150, and 180 minutes after meal ingestion. Accuracy and specificity of the stable isotope breath test are comparable with those of scintigraphy; however, the results may be less accurate in cases of malabsorption, liver disease, or lung disease, all of which may hinder the excretion of C^{13}-labeled foods.

The wireless motility capsule provides the opportunity to directly measure gastric emptying time and stomach contractile adequacy. The indigestible capsule has temperature, pressure, and pH sensors and is ingested with a meal or a standardized nutrient bar (e.g., SmartBar). As the capsule traverses the GI tract, it detects changes in pH and measures phasic pressure amplitudes. Gastric emptying time for a nondigestible solid is measured as the characteristic change in pH between the stomach and small intestine. In addition, the pattern and amplitude of contractions immediately before gastric emptying may provide useful information regarding gastric contractile adequacy and potentially may help distinguish patients with heightened gastric contractions from those with a more flaccid stomach. Emptying of the capsule appears to be correlated reasonably well with gastric emptying, as demonstrated by scintigraphy, and this technology has been approved by the U.S. Food and Drug Administration (FDA) as a valid means of evaluating gastric emptying. The wireless motility capsule also has the benefit of enabling clinicians to view whole-gut transit, potentially allowing detection of pan-gastrointestinal motility disorders that may alter therapy; however, at present this technology is expensive and insurance coverage is limited, and although vast amounts of information are derived with regard to gastric and small bowel pressure parameters, normative data to put that information in context are limited.

Antroduodenal manometry is often suggested as an additional modality to assess patients with scintigraphic evidence of gastric stasis and without an identifiable cause. It is an invasive technique that involves insertion of a water-perfused or solid-state multilumen manometry catheter placed through the nose. The proximal catheter port is placed in the distal antrum, and the distal catheter port is placed in the duodenum. This placement can be performed either under fluoroscopic guidance or through endoscopy. Antroduodenal manometry helps differentiate patterns of myopathic origin (low-amplitude contractions), as observed in amyloid deposition and scleroderma, from patterns of neuropathic origin (normal-amplitude contractions with abnormal contractile response), as observed in diabetes mellitus and idiopathic autonomic neuropathy. Although this technology provides helpful diagnostic information, the degree to which this information alters management of patients with gastroparesis remains unclear. For this reason, this study is offered in only select tertiary referral centers and in not widely available.

Management of Gastroparesis

Management of gastroparesis can be divided into four components: supportive measures, including hydration and dietary modifications; optimizing glycemic control in diabetic patients; medical therapy; and surgical therapy.

First-line therapy for these patients remains dietary modification. Usually, fat delays gastric emptying, and nondigestible fibers in fruits and vegetables are emptied poorly because they require effective interdigestive antral motility, which is absent in patients with gastroparesis. For these reasons, patients are usually recommended low-fat diets without nondigestible fibers in small quantities and frequent meals. Because liquid emptying is rarely affected, noncarbonated fluids can be taken throughout the meal, and proper liquid caloric supplementation can be used in lieu of a solid diet. In severe cases in which the patient is severely malnourished (>10% unintentional weight loss in the past 6 months) or is unable to maintain weight by oral intake alone, enteral access via jejunostomy or gastrojejunostomy tube is considered. It is of utmost importance that diabetic patients maintain glycemic control at all times because hyperglycemia results in antral hypomotility and delay in gastric emptying, and it appears to attenuate the efficacy of prokinetic drugs.

Prokinetic and antiemetic medications can be tried when dietary modification alone has not been successful. Antiemetics that can be used include phenothiazines, antihistamines, and 5-HT_3 antagonists (granisetron or ondansetron). For outpatients who have difficulty taking oral medications, rectal suppositories (promethazine) or transdermal agents (scopolamine) can be considered, as absorption may be more readily achieved. If patients are hospitalized, intravenous formulations may have more rapid onset and produce a more predictable response.

Prokinetic therapy is often touted as the mainstay of medical therapy for gastroparesis, but evidence to support efficacy is limited. Metoclopramide is the only medication that is endorsed by the FDA for treatment of gastroparesis in the United States; however, it is approved only for short-term use (up to 12 weeks) and has significant potential toxic effects, including tardive dyskinesia in a small percentage of patients who take this drug long term. If metoclopramide is chosen for outpatient use, the liquid formulation may offer more predictable bioavailability, and the dose should be tapered to the smallest amount that controls symptoms. Erythromycin is a macrolide antibiotic that has been shown to significantly increase antral contractions and, for this reason, has been used for treatment of gastroparesis. It may be helpful in a hospital setting for acute use, but long-term use is limited by tachyphylaxis and concern regarding potential toxic effects (including ototoxicity and QT prolongation). Domperidone is not approved in the United States but is frequently used in other countries and works through peripheral dopamine receptors. Comparisons of domperidone with metoclopramide have shown similar efficacy with fewer adverse effects noted in the patients who received domperidone; however, toxicity is not insignificant, and increase in cardiac arrhythmias and QT prolongation have been reported. If the clinician does wish to prescribe this agent in the United States, an Investigational New Drug (IND) application should be obtained from the FDA. Finally, cisapride has the most extensive data with regard to prokinetic use; however, this was withdrawn from the market because of QT prolongation and increased risk of sudden cardiac death. This agent can be obtained on the basis of compassionate use from Janssen Pharmaceuticals (Titusville, N.J.) if desired; however, this is reserved for rare cases in which the potential benefits are believed to outweigh the significant potential cardiac risks.

Neuromodulators have also been used as a potential treatment option for patients with gastroparesis; the rationale is that improvement in visceral sensation may lead to fewer gastroparesis-mediated symptoms. Options available for use include low-dose tricyclic antidepressants (nortriptyline), atypical antidepressants (mirtazapine), or sertraline, which may also have a mild prokinetic effect.

In view of the chronic nature of gastroparesis and the limited medical options available, there has been significant interest in potential alternative and complementary options. Ginger (*Zingiber officinale*) has been shown to accelerate gastric emptying in animals and people and has been used as a treatment for pregnancy-associated nausea, although it has not been studied in gastroparesis per se. Iberogast (an herbal extract) showed efficacy equivalent to that of cisapride for the treatment of patients with functional dyspepsia and gastroparesis in one case series. Acupuncture has been evaluated in idiopathic and postsurgical gastroparesis in small series with good results, although mechanisms remain unclear.

The role of endoscopic therapy at present for gastroparesis is limited. Several large open-label series showed improvement with prepyloric injection of botulinum toxin in approximately 50% of patients with gastroparesis and suspected pylorospasm; however, two small randomized controlled trials showed no difference between the groups that received botulinum toxin as opposed to placebo. Endoscopic placement of a pyloric channel stent has also been reported in a single small pilot study; however, numbers of patients were small, and these data are still very preliminary.

In refractory and severe cases, surgery is often considered after unsuccessful trials of dietary modification and medical therapy. Gastric electric stimulation was given a humanitarian device exemption (HDE) by the FDA for use in patients with gastroparesis and is, at present, the most common surgical procedure performed for these patients. Contrary to expectations, this device involves the use of high-frequency, low-energy settings to modify gastric sensation, but it is not designed to induce gastric contractions or "pace" the stomach. Data with regard to gastric electrical stimulation are controversial. Two randomized controlled trials have been published. Abell and colleagues (2003) showed that high-frequency, low-energy stimulation significantly decreased vomiting frequency and GI symptoms and improved quality of life in patients with gastroparesis. McCallum and colleagues showed that gastric stimulation significantly improved subjective and objective parameters at 1 year, including vomiting frequency, overall quality of life, and 4-hour gastric emptying. However, although both studies showed significant improvement in gastroparesis parameters, neither study demonstrated a convincing difference between the group for which the stimulator was activated and the group for which it was not (although all patients had the device activated at some point in the study and there may have been lingering effects that affected the final measurements). In these studies, as well as several observational series, patients who seemed to derive the most benefit from this procedure were patients with diabetic or postsurgical gastroparesis (as opposed to idiopathic); patients with primary symptoms of nausea, vomiting, or both (as opposed to pain); and patients who were not taking narcotic analgesic drugs.

Gastric electrical stimulation can be performed either laparoscopically or in an open approach. Traditionally, a region 10 cm proximal to the pylorus along the greater curvature is identified, and two leads are placed in the seromuscular layer of the stomach, approximately 1 cm apart. These leads are connected to a separate generator, which is positioned in the subcutaneous layer of the anterior abdominal wall. Intraoperative endoscopy should be performed to ensure that the leads have not perforated the gastric wall. Estimated battery life with the current device (Enterra Neurostimulator; Medtronic, Minneapolis, Minn.) is approximately 7 years, and the generator can be exchanged (without adjustment of the leads) if need be when the battery is depleted. The device can be interrogated and adjusted as needed with a handheld device that is telemetrically connected to the generator.

Other surgical options that have been considered for treatment of refractory gastroparesis include pyloroplasty and complete or subtotal gastrectomy. Although data with regards to pyloroplasty are limited, Swanstrom and colleagues reported 83% clinical improvement in 28 patients who underwent isolated pyloroplasty for treatment of refractory gastroparesis, with significant improvement in symptoms, gastric emptying, and prokinetic use. Completion or subtotal gastrectomy has also been evaluated as a potential option in patients with refractory symptoms in whom other treatment options have failed. Data suggest that patients who do best with this approach are those with continued nausea and vomiting after a prior partial gastrectomy. Symptom improvement has been reported in up to 79% of patients who undergo this procedure; however, other studies have suggested failure rates of more than 50% at 5 years.

Patients unable to maintain adequate caloric intake need aggressive measures for nutritional support, including insertion of an enteral feeding tube (jejunostomy or gastrojejunostomy), and if enteral feeding is not tolerated, total parenteral nutrition is recommended. A venting gastrostomy tube can also be considered, although data supporting its efficacy are limited.

Postgastrectomy Dumping

Rapid transit disorders occur as a consequence of previous gastric and perigastric operative procedures, most commonly any surgery involving a vagotomy. Approximately 25% to 50% of patients undergoing Roux-en-Y gastric bypass, gastrectomy, gastroenterostomy, or vagotomy experience dumping syndrome, but only approximately 5% have symptoms severe enough to require medical or surgical management. Clinically, dumping syndrome can be categorized as early dumping (which affects most patients) and late dumping, although these subgroups may be difficult to distinguish in practice. Early dumping classically manifests with nausea, abdominal pain, diaphoresis, and palpitations approximately 15 to 30 minutes postprandially, followed by diarrhea approximately 30 to 60 minutes later. Late dumping occurs within 1 to 3 hours postprandially secondary to reactive hypoglycemia. After ingestion of a meal, carbohydrates enter the small intestine, inducing the release of glucagon-like peptide–1 (GLP-1), which exaggerates insulin release and thereby leads to hypoglycemia. This results in a surge of catecholamines with subsequent adrenergic symptoms, including lightheadedness, palpitations, diaphoresis, and tremulousness. Late dumping is rare in comparison with early dumping. Patients experiencing dumping syndrome most commonly improve with time and dietary modifications. If the condition is refractory, they might benefit from a trial of subcutaneous octreotide.

Diagnosis of dumping syndrome is made clinically and confirmed by provocation tests. The patient is given 50 g of oral glucose, and several parameters (hematocrit, plasma glucose level, and heart rate) are monitored every 30 minutes for 3 hours. A positive test result shows more than a 3% rise in hematocrit, hypoglycemia (plasma glucose level, <50 mg/dL), or a rise in heart rate of more than 10 beats/min, along with reproduction of the patient's symptoms. Solid-meal scintigraphy assists in documenting rapid gastric emptying. In the ^{13}C–acetic acid and hydrogen breath tests, bacterial fermentation of glucose is a marker for gastric emptying.

The first-line of management remains dietary modification, because symptoms generally improve over time with improvement of dietary habits. Patients are counseled to eat frequent small meals high in protein and fats and with minimal simple carbohydrates. Patients should not drink liquids with solid meals and 2 hours postprandially. It is recommended to add to the diet nonabsorbable polysaccharides such as glucomannan, pectin, and guar gum, which decrease glucose absorption, reduce reactive hypoglycemia, and thus improve dumping symptoms.

In cases in which dumping symptoms persist, medical therapy should be considered. Acarbose (α-glucosidase inhibitor) prevents the digestion of complex polysaccharides and sucrose, which reduces the surge of postprandial plasma glucose. Although acarbose is very efficacious in treating dumping symptoms, it has widely undesirable side effects, including flatulence and diarrhea, because of the fermentation of the unabsorbed carbohydrates. Octreotide (a somatostatin analogue) has been used to slow gastric emptying, inhibit secretion

of insulin and enteric peptides, and attenuate the postprandial hemodynamic changes by splanchnic vasoconstriction and hormonal release. Octreotide is typically administered subcutaneously three times a day, 30 min before each meal. Another formulation often preferred by patients is the depot long-acting octreotide (Sandostatin-LAR), administered monthly. Studies have suggested this to be as effective as the intermittent subcutaneous formulation, and it is preferred by patients because it is administered less frequently.

The rare patient with intractable symptoms may be considered for operative therapy with the goal of delaying gastric emptying. Surgery is not always effective, but its goal is usually to prevent rapid delivery of food to the proximal intestine and re-create gastric reservoir function. Although few studies have been conducted to compare different surgical procedures, conversion Roux-en-Y gastrojejunostomy and antiperistaltic jejunal interposition loops provide the most satisfactory results, depending on the initial surgery that resulted in the dumping syndrome. If a patient underwent pyloroplasty, pyloric reconstruction is recommended. Patients who underwent Billroth II or Billroth I gastrectomies should undergo conversion Roux-en-Y gastrojejunostomy. This tends to slow motility by interrupting the migrating motor complexes and introducing a retrograde jejunal contraction. Although ineffective in 25% of patients, the Billroth II gastrectomy can be converted to a Billroth I gastrectomy to restore the physiologic delivery of meal to the duodenum. The surgeon must emphasize to the patient that the outcome may be suboptimal.

Roux Stasis Syndrome

Roux stasis syndrome is usually encountered in patients after Roux-en-Y gastrojejunostomy. It occurs in approximately 25% to 30% of these patients, affecting predominantly women, and usually in cases in which the Roux limb is longer than 40 cm. The motility disorder most commonly occurs in the gastric remnant and in the distal efferent jejunal Roux limb, resulting in symptoms of nausea, vomiting, and early satiety (indistinguishable from gastroparesis). It can also affect the Roux limb alone, but this is generally a late complication, occurring after months or years. The mechanism is related to the transection of the jejunum from the duodenum. This is believed to separate the jejunum from the natural small intestinal pacemaker (in the duodenum), which leads to the development of ectopic pacemakers in the Roux limb with resultant retrograde contractions.

Diagnosis can be made clinically from a thorough history. It can be confirmed with scintigraphy to document delayed gastrojejunal transit, but because of manipulation of the anatomy, interpretation of the results may be difficult. Manometry theoretically can also be used, although in practice this is not commonly performed. Pancreatic polypeptide response to insulin-induced hypoglycemia (pancreatic polypeptide test) can be used to test for vagal function. Pancreatic polypeptide is secreted from the pancreas in response to vagal nerve stimulation in the cephalic phase of digestion. Pancreatic polypeptide can be measured in the blood after sham feeding. However, after vagotomy, this response is lost.

Prokinetics, antiemetics, and minimal narcotics have been used as medical treatment options for patients with Roux stasis syndrome, with approximately 50% improvement. Cisapride may provide long-lasting symptom relief and improved transit in 40% of patients; however, this is not available commercially in the United States and is available only on the basis of compassionate use from Janssen Pharmaceuticals (Titusville, NJ). Intravenous erythromycin and bethanechol have also been used; however, up to 50% of patients continue to have symptoms despite medical therapy and may ultimately require total or near-total gastrectomy. Total gastrectomy has been successful in 43% of patients in improving symptoms; the prognosis is worse in patients receiving total parenteral nutrition, those with endoscopically observed retained food, and those with nausea.

Postvagotomy Diarrhea

Postvagotomy diarrhea occurs in 20% of patients after truncal vagotomy and can be severe in 4% of these patients. If selective vagotomy is performed, especially if the celiac and hepatic branches are preserved, diarrhea is almost nonexistent. It is difficult to distinguish from dumping syndrome, although distinction is important because of the therapeutic and prognostic implications. Patients typically experience approximately 20 watery bowel movements in a 24-hour period, not related to food intake, and this can occur nocturnally. Signs and symptoms similar to dumping syndrome occur, but unlike dumping syndrome, they usually occur 30 to 60 minutes postprandially.

Pathophysiologic features, although unclear, have been described as a combination of impaired gastric relaxation and bile acid malabsorption. With complete vagotomy, gastric motility is, in addition, altered to gastric acidity, favoring bacterial overgrowth, which leads to diarrhea. In addition, in cases of hepatic and celiac branch denervation, gallbladder contraction and coordination are impaired, causing the enterohepatic circulation to be overwhelmed with bile salts, which themselves trigger a secretory and osmotic diarrhea. High bile salt content in the feces can help in the diagnosis of postvagotomy diarrhea, but it does not exclude other causes of diarrhea.

Dietary modification remains the mainstay of treatment. Patients are instructed to avoid carbohydrate-dense foods and to have small, frequent, low-fat meals. Introduction of bulk-forming agents into the diet, such as fibers, psyllium, or pectin, can be helpful. Pharmacologic agents can be used if the diarrhea persists. Codeine phosphate (60 mg, qd) and loperamide (12 to 24 mg, qd) inhibit GI transit time and have proven efficacy as short-term treatments. Bile salt resins, such as cholestyramine, reduce the bile salt load to the gut and alleviate diarrhea, but their unfavorable side effects and their uncertain long-term benefit limit their use. Octreotide, although used in the past to target bile acid malabsorption, has not proven effective for this indication. If diarrhea is persistent, the entire GI tract should be evaluated with endoscopy. In addition, surgery can be tried, although it is rarely beneficial. Procedures, such as Roux-en-Y conversion or using an interposition segment of antiperistaltic jejunum to slow gastric emptying, may be attempted, although data regarding their efficacy are limited.

MOTILITY DISORDERS OF THE SMALL INTESTINE

Ileus of the Small Intestine

Ileus refers to dysmotility in the bowels in the absence of a mechanical obstruction; such dysmotility results in signs and symptoms similar to those of obstruction. These include bloating, diffuse abdominal pain, abdominal distension, obstipation, constipation, nausea, vomiting, and inability to tolerate oral intake. The term *ileus* originated from the Greek word *eileos,* meaning "twisting."

Ileus can be either normal postoperative ileus or paralytic ileus. If symptoms are less severe and last for up to 5 days after the operation, then ileus is considered postoperative. If the symptoms are protracted and prolonged, then it is called *prolonged postoperative ileus.* It is important to distinguish between mechanical bowel obstruction and ileus because management differs. Intense colicky pain, feculent emesis, or acute pain and distension are more suggestive of small bowel obstruction. Emergency surgical intervention is needed when signs and symptoms of shock are suggestive of bowel ischemia or perforation.

Inhibitory neural reflexes are thought to act locally through noxious spinal afferent signals that increase inhibitory sympathetic activity in the GI tract. Blocking these spinal afferents with epidural

local anesthetics can improve postoperative paralytic ileus. Intestinal manipulation and trauma during surgery leads to an inflammatory response that contributes to ileus. In addition, neurohumoral peptides (nitric oxide, vasoactive intestinal polypeptide, and substance P) are thought to act as inhibitory neurotransmitters in the gut, which slow gut motility. Use of opioids has an inhibitory effect on the GI tract by increasing the resting tone while decreasing gastric motility and emptying, increasing small intestinal periodic spasm, and decreasing propulsive colonic movements, all of which further contribute to the pathogenesis of ileus.

Risk factors for paralytic ileus include narcotic overuse, peritoneal or retroperitoneal inflammation, sepsis, severe pelvic fractures, and spinal cord injury. Ileus can be prolonged by metabolic disturbances such as hypomagnesemia, hypermagnesemia, hypercalcemia, hyponatremia, hypokalemia, and ketoacidosis. Medications other than opioids are implicated in ileus, including anticholinergics, phenothiazines, calcium channel blockers, and tricyclic antidepressants, which are all notorious for adversely affecting gut motility.

When paralytic or prolonged ileus is suspected, plain radiographs of the abdomen may reveal gas in segments of both the small and large bowel. Differentiating obstruction from ileus can be made by contrast studies, or computed tomographic study, which is usually more useful in a nonacute setting because it helps identify other hidden pathologic processes such as abscesses that might be contributing to ileus.

Prevention measures of paralytic ileus have been attempted when its occurrence is anticipated during surgery. The surgeon assesses intraoperative findings, prolonged handling and packing of the bowels, intensive use of narcotics or other antikinetic agents, presence of peritonitis or sepsis, or extensive blood loss, and accordingly decides on the preventive measures used. Nasogastric suction has been commonly used to prevent accumulation of secreted fluids and swallowed gases in the paralyzed gut. Studies have shown that nasogastric tubes increase the risk of aspiration and may cause additional discomfort for patients, and hence may confer a greater risk than benefit.

When the surgeon elects not to place a nasogastric tube, the patient is allowed nothing by mouth. Oral intake is advanced gradually, beginning with sips of water, then adding a liquid diet, then adding solid food in accordance with evidence of resolution of postoperative ileus, such as positive bowel sounds, the subjective feeling of "rumbling," or passage of flatus. In the meantime, the patient is supported with ample intravenous hydration.

Use of epidural analgesia, whether thoracic or high abdominal, has been beneficial in reducing the duration of postoperative ileus. For maximal effect, analgesic placement must block nociceptive afferent signals from the surgical site and be used postoperatively for 48 to 72 hours. In addition, correction of metabolic disturbances (whether electrolytes, minerals, or endocrine) and fluid imbalances is of importance in prevention and management of ileus.

Experimental data suggest that the length of the incision may affect GI motility postoperatively. Perhaps for this reason, minimally invasive surgery appears to be associated with decreased incidence of postoperative ileus, although this observation may be confounded by other factors, such as decreased postoperative opiate burden. The development of prolonged ileus after laparoscopy is unusual and should raise concern for potential occult injury.

Finally, several pharmacologic agents have been assessed to treat ileus. Prokinetic agents such as metoclopramide, cisapride (not FDA approved), and erythromycin have been shown to promote gastric emptying after upper GI procedures; however, they did not show benefit for ileus after abdominal or pelvic procedures. Peripherally acting opioid antagonists such as alvimopan and methylnaltrexone have been used in several studies to assess their effect on management of ileus. To date, the FDA has approved alvimopan only in perioperative care after partial large or small bowel resections with primary anastomosis and not for the treatment of protracted ileus.

Surgeons should always keep in mind that gentle handling of tissue, meticulous attention to hemostasis, and abiding by the principles of wound management during laparotomy or laparoscopy provide the best safeguards against ileus development and reduce the risk of a protracted course. Use of minimally invasive surgery (to decrease incision size and reduce the time the intestines are handled), as opposed to open laparotomy, decreases the likelihood of ileus that much more.

The Management of Short Bowel Syndrome

Heung Bae Kim, MD, and Tom Jaksic, MD, PhD

INTRODUCTION

Throughout the care of patients with short bowel syndrome (SBS), a multidisciplinary approach to management is essential because no one provider has the expertise to care for these complex cases alone. The key focus of medical management should be on the meticulous management of parenteral nutrition (PN) to avoid metabolic and hepatotoxic complications of this life-saving treatment. Enteral feedings should be introduced as early as possible and carefully advanced with observation for signs of feeding intolerance. In general, elemental formulas are preferred over more complex formulas because absorption is better and there are less allergic complications. Breast milk is tried before elemental formulas in neonates with SBS. PN may be weaned as tolerated as long as the patient continues to meet growth and weight milestones. Meticulous attention to care of the central venous line is also critical because repeated line sepsis episodes can lead to worsening of liver function and loss of central venous access sites. The authors use ethanol locks for the long-term outpatient management of SBS because several case series have

shown a decreased rate of line sepsis with this therapy. The management of PN has evolved significantly over the past 40 years since Dr. Dudrick's first report of the use of total PN to support the growth of animals and infants. Commercially available intravenous amino acids, glucose, lipids, vitamins, and trace minerals are provided through a central line to meet patient-specific nutritional requirements. Studies indicate that the avoidance of overfeeding and parenteral lipid restriction (1 g/kg/d or less) is associated with reduced hyperbilirubinemia. Newer experimental lipid formulas that contain fish oil or a combination of fish oil and olive oil may prove to have additional hepatoprotective properties. Studies of growth factors active on the intestine are also ongoing. Glucagon-like peptide-2 (GLP-2) and its longer acting analogue teduglutide appear to facilitate intestinal adaptation, and in one recent trial, the administration of teduglutide was found to reduce PN requirements. A concern with the protracted application of growth factors is the potential induction of intestinal carcinoma.

INITIAL MANAGEMENT OF THE ABDOMINAL CATASTROPHE THAT LEADS TO SHORT BOWEL SYNDROME

The surgical management of SBS usually begins with treatment of the initial condition that leads to acute intestinal loss. In children, SBS is most commonly caused by gastroschisis, intestinal atresia, or midgut volvulus. In adults, additional conditions include Crohn's disease, tumors, or trauma. During these initial operations, the surgeon must not only consider the short-term goals of survival and recovery but also the long-term goal of preserving as much intestinal mucosal surface area as possible. This may require balancing the risks of early aggressive resection of all questionable intestine versus use of a second look laparotomy to allow for complete demarcation of nonviable bowel. In general, if the patient's condition allows, a second look laparotomy often results in preservation of intestine that otherwise appeared nonviable at the initial operation. Intestinal stomas are often necessary to optimize recovery from the initial insult, but the surgeon must balance this against the additional mandatory loss of a small portion of intestine during the future stoma takedown. In general, bowel-preserving surgery is critical to optimize the long-term outcome for patients with SBS.

Once bowel function has been documented, enteral feedings are generally initiated at 10 mL/kg/d and advanced by 10 mL/kg/d until enteral goals are reached. The authors often use nasogastric or gastrostomy tubes to advance feeds because many infants and children with intestinal failure have an oral aversion or swallowing difficulties related to prematurity. Factors that limit the advancement of enteral feedings include vomiting, increased gastrostomy tube output, stool output of more than 2 mL/kg/h, abdominal distention, or skin breakdown from acidic stool output. Promotility agents, postpyloric tube feeds, or fundoplication may be indicated if vomiting and reflux are a major problem. In cases of increased stool output, infection with *Clostridium difficile* and rotavirus should be ruled out because these commonly occur in children with SBS. Once infectious causes of diarrhea have been ruled out, loperamide can be initiated and titrated to effect.

At some point when the patient is of adequate size and comorbid conditions have been minimized, all ostomies should be closed to maximize the mucosal surface area that is exposed to the enteric stream. This also brings the colon back into the enteric stream, which improves reabsorption of both fluids and electrolytes. In some cases, the increased delivery of incompletely digested enteric contents to the colon may lead to significant diarrhea, abdominal pain, perianal skin breakdown, or metabolic derangements. The authors usually recommend a "poop prep" for children in diapers in which stoma contents are placed on the perianal skin within the diaper for 30 minutes at a time several times a day to prepare the perianal skin for diarrhea before stoma closure. This allows for the skin to adapt and may prevent severe diaper rash after stoma closure.

If full enteral autonomy and appropriate growth and developmental milestones are achieved, there is usually no role for additional surgical procedures to treat SBS. The one instance in which surgical management may be useful is when bacterial overgrowth develops and results in intermittent diarrhea, abdominal pain or distention, and D-lactic acidosis. Initial treatment for this usually involves enteral antibiotics for intestinal decontamination. If this fails to improve symptoms, radiographic studies of the intestine are indicated to determine whether segments of dilated intestine might be the cause of stasis. If present, dilated bowel causing symptomatic bacterial overgrowth may be an indication for surgical treatment despite full enteral autonomy.

Despite optimal early surgical and medical therapy, some patients remain dependent on PN to achieve normal growth and development. When progress halts or the patient's enteral tolerance worsens, surgical procedures may be indicated to improve intestinal function and allow for continuation of weaning from PN.

INDICATIONS FOR SURGICAL MANAGEMENT OF SHORT BOWEL SYNDROME

The initial insult that occurs after massive intestinal resection is a loss of mucosal mass, which leads to an inability to absorb sufficient nutrients to maintain normal growth and development. In response to intestinal loss, the remaining intestine adapts with both microscopic and macroscopic changes that occur within the intestine. Although microscopic changes like increases in villus height and crypt depth and proliferation of enterocytes tend to improve intestinal function, the usual macroscopic adaptive response is intestinal dilation. With mild dilation, the intestinal function may improve, but with ongoing massive dilation, the response becomes maladaptive and results in poor intestinal motility and bacterial overgrowth. This dilated bowel does not have normal peristalsis because the increased diameter prevents proper and complete approximation of the bowel walls. Failure of the bowel edges to fully coapt leads to a sloshing motion of the intraluminal contents and disorganized antegrade peristalsis. The goal of intestinal lengthening and tapering procedures is to correct the two major functional problems of adapted short bowel: namely, poor motility and bacterial overgrowth. Once a patient has reached a plateau in the advancement of enteral nutrition and all medical strategies have been exhausted, surgical intestinal lengthening and tapering procedures should be considered. A contrast study should be performed to give an approximation of the residual intestinal length and to define any areas of dilation or stricturing that may benefit from surgical intervention. In addition to definition of the anatomy, preoperative assessment of liver function and other comorbid conditions is critical. Coagulopathy and decreased hepatic synthetic function may preclude any major abdominal surgery, and in these cases, the patient may benefit from direct referral for liver and small bowel or multivisceral transplantation. Insertion of an enteral access tube and liver biopsy should also be considered during the operation, if not already done. It is our practice to use a preoperative antibiotic and antifungal bowel preparation because many of these patients have significant bacterial or fungal overgrowth at the time of surgery that may result in postoperative sepsis from the significant bowel manipulation during surgery.

A number of procedures to improve intestinal function in patients with SBS have been developed over the past 50 years, but only two are widely used today. The longitudinal intestinal lengthening and tailoring (LILT) and the serial transverse enteroplasty (STEP) procedures are both autologous intestinal reconstruction procedures that combine the benefits of intestinal tapering and lengthening with maximal preservation of enterocyte mass. Although both procedures

may be used successfully in select cases with similar outcomes, the STEP procedure has recently gained more widespread popularity among surgeons because of its simplicity and adaptability to bowel that is variably dilated. Both the LILT and the STEP procedures have been shown to improve enteral autonomy in select patients with SBS. With rare exceptions, other procedures, including reversed intestinal segments, intestinal valves, recirculating loops, and isolated bowel segments (Iowa procedure), are of historical interest only and are not discussed further.

LONGITUDINAL INTESTINAL LENGTHENING AND TAILORING

The first paper describing a readily reproducible procedure for intestinal lengthening was reported by Bianchi in 1980. The procedure was initially referred to as intestinal loop lengthening and then later renamed the LILT procedure, although in the modern surgical vernacular, it is commonly referred to as the Bianchi procedure. The initial step of this procedure involves the use of blunt dissection to separate the mesentery into two leaves, each of which supplies blood to half of the intestine. The intestine is then divided longitudinally, with either a surgical stapler or a hand-sewn anastomosis. This results in two separate loops of intestine, each with half the circumference of the original loop. When these two loops are then anastomosed end to end, the result is a doubling of the length and a tapering of the diameter of the intestine (Figure 1). Since its introduction, LILT has been performed worldwide with variable success. In one report of a 6-year follow-up period in 25 patients who underwent LILT, 17 of 18 survivors were able to be weaned from PN and no intraoperative deaths occurred. In another 5-year follow-up study of 13 children who underwent LILT, bacterial overgrowth was eliminated in 8 of 10 patients who had this documented before surgery. At both 1 and 5 years after surgery, 6 of 13 patients (46%) were on full enteral nutrition. In a more recent series from 2006 of 49 patients who underwent LILT, the reported mortality rate was 18%, and 39% of patients were successfully weaned from PN in a mean of 9 months. Bianchi himself reviewed the worldwide experience with LILT in 2006, with a total of 150 patients from eight published studies. Results were varied, with overall survival rate ranging from 30% to 100% and 28% to 100% of patients achieving full enteral autonomy. The most common causes of death in children who underwent LILT were related to progression of PN-associated liver disease and sepsis. Most of the fatal septic episodes occurred in children with long-term central venous catheters. To date, no intraoperative deaths have been reported. Necrosis of one of the divided limbs necessitating surgical resection of the affected bowel has been reported. Reoperation for

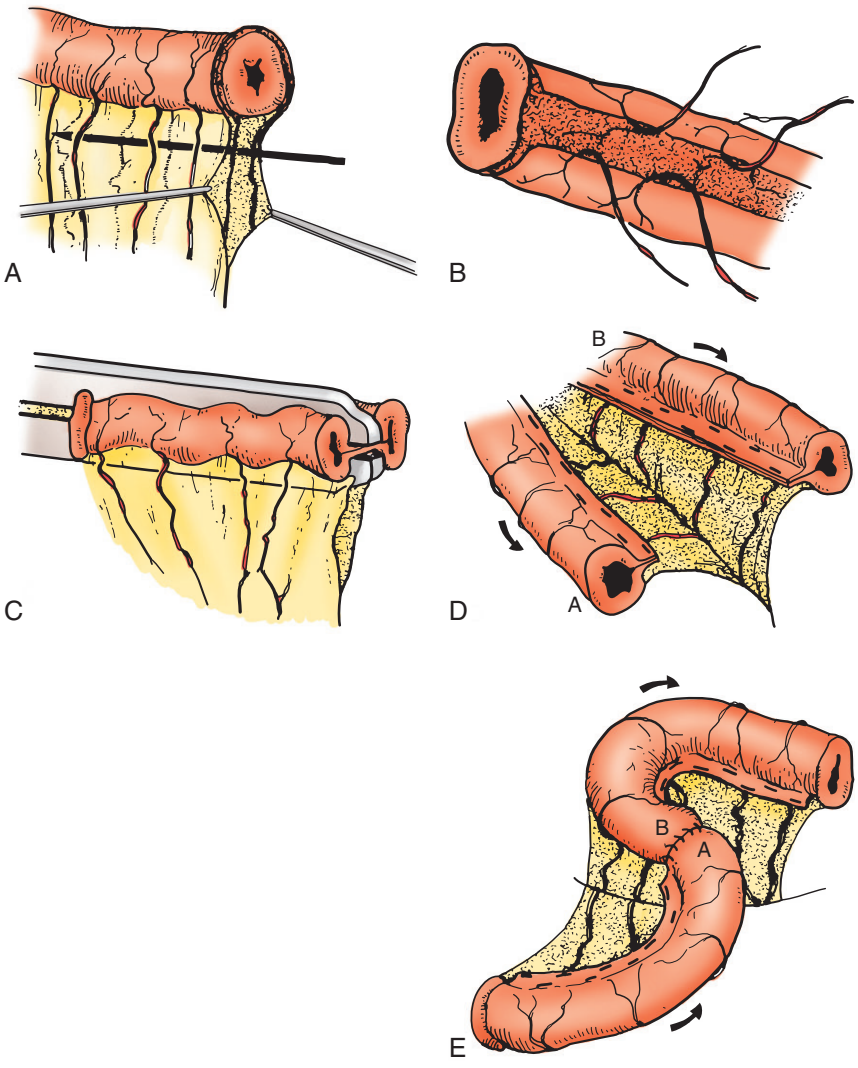

FIGURE 1 Longitudinal intestinal lengthening and tailoring. **A** and **B,** Creation of the mesenteric tunnel. **C** and **D,** Division of the dilated bowel into two hemiloops. **E,** Reanastomosis in an isoperistaltic fashion. *(From Bianchi A: Intestinal loop lengthening: a technique for increasing small intestinal length,* J Pediatr Surg *15(2):145–151, 1980, pp 147, Fig 1.)*

anastomotic strictures, adhesive small bowel obstruction, and interloop fistula formation have been noted. Recurrent dilation is common in the lengthened bowel, sometimes requiring reoperation for additional tapering. In patients who are unable to wean from PN after the LILT procedure, small bowel transplantation has been used as a salvage procedure.

The LILT procedure has undergone technical modifications since its original description in 1980. Bianchi reported a change in his preferred method of bowel division in 1984, opting to use bipolar cautery to divide the bowel in half along the mesenteric and antimesenteric borders, rather than the surgical stapler. A hand-sewn suture line was then used to form the divided bowel into the new hemiloops. A surgical nipple valve has been used in some patients with SBS who lack a maladaptive intestinal dilation response to create a partial obstruction and induce bowel dilation so that the LILT procedure can be performed. This technique was used to induce dilation sufficient to perform LILT in six patients at 3 to 9 months after nipple valve construction. The primary criticism of this method is the possibility of creating a complete bowel obstruction. Bianchi's group has also developed a modification of this dilation model for use in patients with jejunal atresia. They reported placing a tube jejunostomy into the proximal dilated small bowel and a separate tube colostomy into the distal bowel. Jejunal contents were then intermittently refed into the distal bowel, and intermittent occlusion of the jejunostomy tube was used to induce proximal bowel dilation. Another modification of the LILT procedure enables the elimination of two of the three intestinal anastomoses usually required for the LILT. In this modification, the stapling device is be applied obliquely at both the proximal and the distal ends of the LILT segment, tapering the diameter down to the size of the native intestine without completely dividing the intestine as originally described. Once the dilated segment has been divided into two equal-sized tubes, a single hand-sewn anastomosis can be fashioned between the two, thus eliminating both the proximal and distal anastomoses as potential sites of leak or stricture.

SERIAL TRANSVERSE ENTEROPLASTY PROCEDURE

In 2003, Kim and colleagues described a novel intestinal lengthening and tapering procedure called the STEP. As in the LILT procedure, the first description of the STEP procedure was in an animal model of dilated intestine that was obtained with a reversed jejunal segment. Once the intestine was dilated, a stapler was placed on the distal dilated intestine perpendicular to the long axis of the intestine and fired to partially transect the intestine, leaving an approximately 2-cm portion undivided. A second stapler was then applied about 2 cm proximal to this and similarly fired to only partially transect the intestine. This pattern of alternating partial transection of the intestine was carried proximally, maintaining a 2-cm zigzag channel until the length of the staple firings became too short to continue. To accommodate the stapler, a small defect in the mesentery was created at each point of stapler application. The end result was a zigzag pattern to the lengthened and tapered intestine (Figure 2).

These original animal studies showed an immediate 68% increase in the length of intestine after the STEP procedure. Six weeks after the STEP procedure, all animals were noted to have gained weight appropriately and there were no deaths or episodes of bowel obstruction. Subsequent studies in an animal model of SBS showed that the STEP procedure not only increased the length of intestine but also had a beneficial effect on nutrient absorption, bacterial overgrowth, and overall weight gain. In addition, animals that underwent the STEP procedure were found to have higher postoperative levels of serum citrulline, a nonprotein amino acid that is a surrogate for total small intestine enterocyte mass. Though the STEP procedure does not result in an immediate increase in mucosal surface area, the authors hypothesize that by tapering the previously dysfunctional dilated bowel, bacterial overgrowth is reduced and the process of adaptation may be facilitated.

The first human case of the STEP procedure was also reported by Kim and associates in 2003. The patient was a 2-year-old boy who had SBS secondary to gastroschisis with midgut volvulus. He had previously undergone a LILT at age 11 months, which increased his bowel length from 72 to 130 cm, but despite this increase, he remained dependent on PN. At 23 months of age, he returned to the operating room for a STEP procedure. Preoperative imaging had confirmed that the intestine that had undergone the LILT had redilated. Intraoperative measurement revealed 83 cm of dilated intestine that measured approximately 6 cm across. After 26 firings of the stapler, this segment was lengthened to 147 cm, with a channel width of 2 cm. This left the patient with a total small bowel length of approximately 200 cm (Figure 3). Postoperative absorption studies showed a statistically significant increase in serum D-xylose after oral loading. In

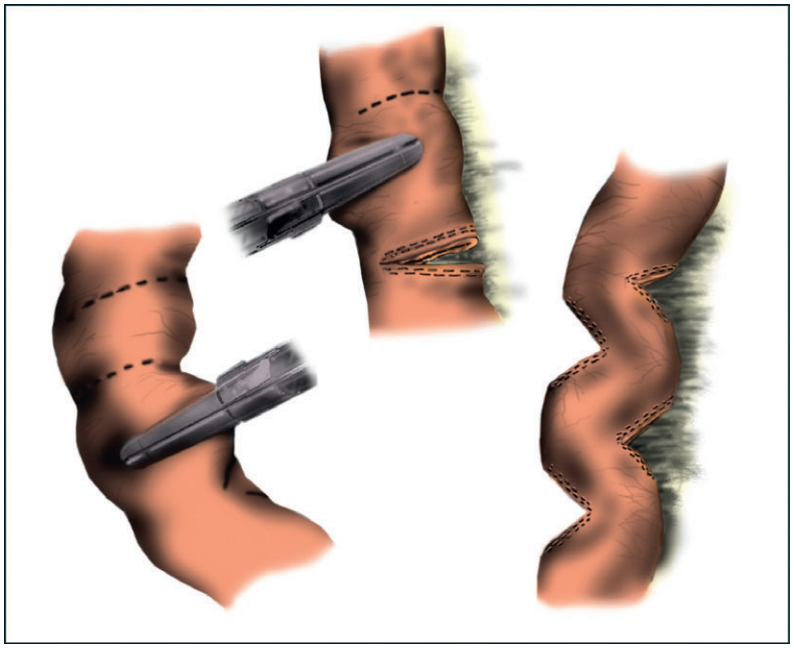

FIGURE 2 Serial transverse enteroplasty. The dilated bowel is flattened, and the stapler is applied perpendicular to the long axis of the bowel, from alternating sides. A small defect in the mesentery was created at each point of stapler application. The end result is a zigzag pattern to the lengthened bowel. *(Adapted from Kim HB, Fauza D, Garza J, et al: Serial transverse enteroplasty (STEP): a novel bowel lengthening procedure,* J Pediatr Surg *38(3):425–429, 2003, Fig 1.)*

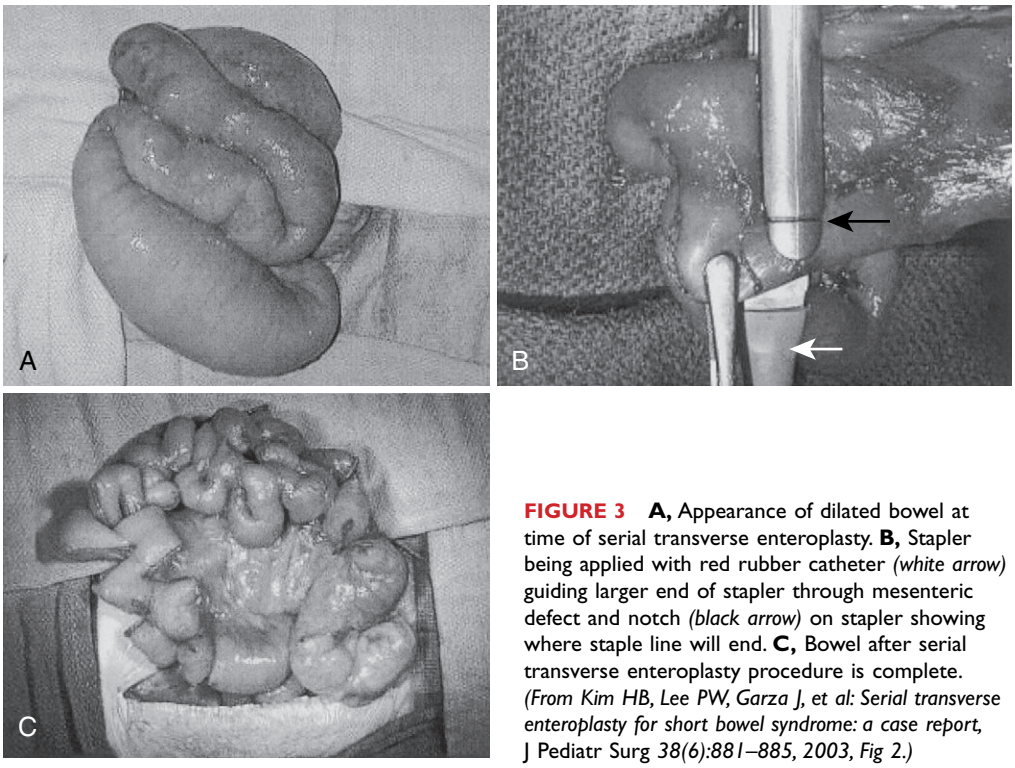

FIGURE 3 **A,** Appearance of dilated bowel at time of serial transverse enteroplasty. **B,** Stapler being applied with red rubber catheter *(white arrow)* guiding larger end of stapler through mesenteric defect and notch *(black arrow)* on stapler showing where staple line will end. **C,** Bowel after serial transverse enteroplasty procedure is complete. *(From Kim HB, Lee PW, Garza J, et al: Serial transverse enteroplasty for short bowel syndrome: a case report,* J Pediatr Surg *38(6):881–885, 2003, Fig 2.)*

addition, 6 months after surgery, the patient had advanced to 50% enteral nutrition.

After these initial reports, the STEP rapidly increased in popularity for the surgical management of patients with SBS who were unable to wean from PN because of dysfunctional dilated intestine. Subsequent reports also described two additional indications for the procedure beyond established SBS with PN dependence. The second published indication for the use of the STEP procedure was to treat newborns with intestinal atresia and marginal bowel length. In these cases, the STEP procedure is used primarily as a mucosa-sparing tapering procedure. When children are born with intestinal atresia, the proximal intestine is very dilated, and when there is a loss of a significant portion of the overall intestinal length, it is critical to save as much of the intestinal mucosa as possible. Rather than performing a standard tapering enteroplasty that results in the removal of a significant portion of the antimesenteric portion of the intestine, the same tapering can be achieved with the STEP, without the need for any intestinal resection. The third published indication for the STEP procedure is for the treatment of recalcitrant D-lactic acidosis that results from bacterial overgrowth. In this report, an 18-year-old woman who previously has SBS from a midgut volvulus developed neurologic impairment from bacterial overgrowth that resulted in elevated serum levels of D-lactic acid. Although she did not need PN, her overall intestine length was marginal and any intestinal resection was undesirable. Preoperative imaging showed a dilated duodenum, which at the time of surgery measured 8 cm in diameter. The STEP procedure was performed on this isolated segment of bowel and resulted in a significant decrease in postoperative episodes of D-lactic acidosis.

Although STEP remains a relatively new procedure, several reported case series with follow-up after STEP have been published and show good short-term and intermediate-term results. To better track STEP outcomes worldwide, a web-based international data registry for patients undergoing the STEP procedure was established at www.stepoperation.org. The first publication from this registry in 2006 summarized the largest experience to date of the STEP procedure, in 38 patients from 19 centers. The indications for STEP included anatomic SBS (n = 29), neonatal jejuno-ileal atresia with marginal intestinal length (n = 3), and bacterial overgrowth (n = 6). In those patients who underwent STEP for SBS, enteral tolerance increased significantly from 31% enteral nutrition before surgery to 67% enteral nutrition after a median follow-up period of 12.9 months after the STEP. Similar to the LILT, all three of the deaths after the STEP procedure were secondary to progressive liver disease and sepsis. Three patients required combined liver-intestine transplant. Complications related to the procedure included ulcer formation along the staple lines and intraoperative leaks from the staple lines. The authors generally recommend that buttress sutures are placed at the apex of each staple line to minimize this risk of leakage. Postoperative small bowel obstructions have also been reported, although most of these have been managed successfully with nasogastric decompression and bowel rest.

After surgery, a nasogastric tube should be left to suction until bowel function has returned. A slow advancement of enteral nutrition then proceeds. Recent data have shown that even after the STEP procedure, enteral advancement may be slow. In a study of 61 patients registered in the International STEP Data Registry who underwent STEP to treat SBS, 31 eventually advanced to full enteral tolerance, but the median time to achieve enteral autonomy was 19 months, with a range of 1 to 44 months.

Similar to LILT, intestinal redilation occurs frequently after the STEP procedure as intestinal adaptation continues. Although repeat LILT is technically not possible after an initial LILT, it has been shown that the STEP procedure may be performed after either the LILT or the STEP, as was clearly shown in the first reported STEP case. The first demonstration of the feasibility of a second STEP procedure was in an animal model; this was quickly followed by the first reported clinical case in 2007. To date, patients have been reported to have had LILT-STEP-STEP, STEP-STEP-STEP, and even STEP-LILT. The limits of repeated procedures have yet to be determined.

CONCLUSION

The last 30 years have seen great advances in the medical and surgical management of children with SBS. The advent of PN has allowed many of these children to survive long enough to develop the bowel adaptation necessary to compensate for their original losses and reach enteral independence. For children who are unable to reach this goal with medical therapy alone, surgical strategies have been devised to both lengthen and taper the remaining intestine. The most commonly performed procedures today are the LILT and STEP. The primary indication for each procedure is to improve the function of dilated poorly functional intestine through intestinal lengthening and tapering in patients who are unable to achieve enteral autonomy despite maximal medical management. Both the LILT and STEP procedures have been reported to increase enteral tolerance, with approximately half of patients achieving enteral autonomy at some point after surgery. However, it must be emphasized that the optimal care for these patient requires a multidisciplinary approach to achieve excellent overall outcomes and that surgical treatment should be limited to select cases in which progression to enteral autonomy is: (1) being hampered by surgically correctable anatomic problems; and (2) not attainable through optimal medical management alone. Application of these surgical techniques without appropriate ongoing evaluation and management may result in poorer than expected outcomes.

The Management of Enterocutaneous Fistulas

Lindsey L. Manos, MPAS, PA-C, and Christopher L. Wolfgang, MD, PhD

OVERVIEW

Management of enterocutaneous (EC) fistulas presents a complex problem that falls on the shoulders of general and gastrointestinal surgeons. At the very least, the successful management of an EC fistula is labor-intensive with regards to nutritional support, fluid and electrolyte management, and wound care. Approximately one third of EC fistulas close spontaneously in patients in whom these factors are controlled. In patients whose fistulas do not close with conservative management, operative care becomes necessary. These operations are often complex procedures that involve bowel resection with reconstruction of the abdominal wall. Overall, the mortality rate of EC fistulas remains approximately 15% to 25% and is typically associated with sepsis, malnutrition, and electrolyte imbalance. Expert management of EC fistulas through conservative measures or definitive surgical repair is necessary to reduce morbidity and mortality and ultimately improve the patient's quality of life.

DEFINITION AND ETIOLOGY

A fistula is an abnormal connection between two hollow epithelial-lined organs or between an epithelial-lined organ and the exterior of the body. This differs from a sinus tract, which is a communication between an infected cavity and the surface of the body. An EC fistula occurs when a communication is present between the alimentary tract and the surface of the skin. Often included within this category is the enteroatmospheric (EA) fistula, which is a communication between the alimentary tract and a nonepithelialized granulating wound (Figure 1). This chapter focuses specifically on EC and EA fistulas. Essentially all of the information presented within this chapter pertains to both EC and EA fistulas, and the terminology throughout states EC fistula only for brevity. Unique to EA fistulas is the wound care and drainage control management; this difference is noted where applicable. Postoperative pancreatic and biliary fistulas are unique entities with some differences in management and are discussed elsewhere.

Most EC fistulas develop after an operation that requires an enteric anastomosis, extensive lysis of adhesions, or removal of infected mesh from a prior hernia repair (Table 1). Note that EC fistulas can spontaneously occur in some conditions such as Crohn's disease, malignant disease, or less commonly diverticular disease. Spontaneous formation accounts for a small percentage of EC fistulas and occurs when underlying conditions such as inflammatory bowel disease or malignancy are present. Poor nutrition, prior radiation therapy, and emergency procedures or trauma are associated with postoperative fistula formation.

PRESENTATION

An EC fistula begins with a disruption in the integrity of the bowel wall that results in the leakage of enteric contents either into the abdominal cavity or from the body surface. A typical presentation often begins with fever and a leukocytosis 3 to 5 days after surgery. On physical examination, a wound infection may be encountered and opened at the bedside. This progresses to efflux of enteric fluid through the wound. Another manifestation is that the patient is found to have an intraabdominal abscess on computerized tomographic (CT) scan. This is managed with the placement of a percutaneous drain, which then goes on to drain enteric contents once the

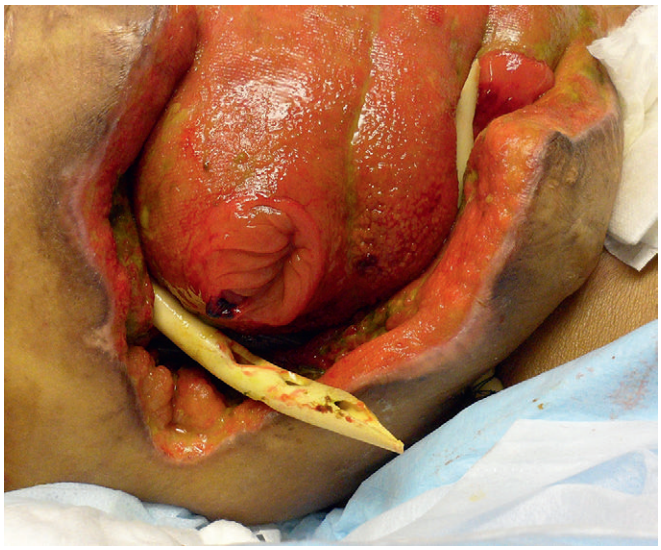

FIGURE 1 Example of enteroatmospheric fistula.

TABLE 1: Common causes of fistula formation

Spontaneous Formation (15% to 25%)
Malignant disease
Radiation therapy
Inflammatory conditions
Inflammatory bowel disease (Crohn's disease)
Bowel obstruction or ischemia
Complicated diverticular disease
Complicated appendicitis
Perforated ulcer disease
Postoperative Formation (75% to 85%)
Oncologic procedures
Bowel resection
Colostomy or ileostomy reversal
Emergent laparotomy (trauma)
Appendectomy
Adhesiolysis

initial infected fluid clears. In the case of spontaneous EC fistula formation, the patient presents with fever, leukocytosis, ileus, and abdominal pain or peritonitis. These findings are typical in inflammatory bowel disease. If the abscess is close to the surface, spontaneous drainage may occur or the placement of a percutaneous drain forms a controlled fistula.

PHYSIOLOGIC EFFECT AND COMPLICATIONS

Fluid and electrolyte imbalances, malnutrition, and sepsis are the most common complications associated with EC and EA fistulas. Undrained or incompletely drained collections can be associated with ileus, peritonitis, or even sepsis. Once the infection is cleared through either intentional drainage or spontaneous efflux, the septic complications often resolve and give way to the other long-term problems. For example, the inability to feed through the enteric tract and loss of protein-rich fluid can result in malnutrition if not already present. Fluid loss results in dehydration and electrolyte abnormalities. The extent of fluid and electrolyte imbalance is directly related to the composition and volume of the fistula output. EC fistulas are characterized as low output (<200 mL/d), moderate output (200 to 500 mL/d), or high output (>500 mL/d; Table 2). Colonic fistulas tend to be low output; small bowel fistulas tend to be moderate to high output and are therefore associated with a higher degree of dehydration. The location also affects the composition of the output and degree of electrolyte imbalances. Proximal fistulas within the duodenum tend to have an output high in bicarbonate and can lead to a metabolic acidosis. Nearly all fistulas have output that is high in potassium, which leads to hypokalemia.

MANAGEMENT

The management of an EC fistula is complex and requires a detailed, stepwise approach to achieve successful closure. The ultimate goal of management is to reestablish the continuity of the patient's alimentary tract while limiting the morbidity and mortality. Approximately one third of EC fistulas close with supportive care and without operative management. The remainder need operative intervention. Achieving metabolic stability and control of sepsis in the first few hours to days of fistula formation is crucial for patient stabilization. Instituting a plan for controlling fistula output and achieving adequate nutritional support is necessary to resuscitate the patient and so that a definitive plan for closure can be developed (Table 3).

Stabilization and Sepsis Control

Sepsis control is imperative in the initial phase of fistula management. The lack of complete source control of the sepsis can lead to rapid multisystem organ failure or even death. In all cases, the principle to eliminate the source of infection is the same. For cases in which the initial abscess spontaneously drains, this may be as simple

as débridement of the wound and adequate conduit for egress of the collection. Percutaneous drainage is often necessary for deeper infections. This can be done through image-guided drainage of the abdominal abscess. Antibiotics alone are seldom sufficient in clearing the infection and should only be used as an adjunct to drainage in patients who display sepsis. Unnecessary use of antibiotics creates drug-resistant bacteria and only compounds the complexity of future management. Antibiotic therapy should be maintained for approximately 4 to 7 days or until the sepsis clears. CT scanning should be used liberally with percutaneous drain upsizing used as needed until source control is completed. Operative source control in this phase is often not necessary and may even complicate the problem by creating more enterotomies, completely disrupting an anastomosis, or converting a contained abscess into widespread abdominal sepsis. The exception to this general principle is in the case of a retained foreign body, such as nonabsorbable mesh within the area of the fistula or abscess cavity. When this is present, good source control becomes unlikely, and the foreign body also interferes with subsequent closure of the fistula.

Resuscitation and Nutritional Support

By the time an EC fistula presents, the patient has typically endured multiple stresses, such as a malignant process, inflammatory bowel disease, or a surgical procedure including a complicated postoperative course. On presentation, the patient can be expected to have a decrease in lean muscle mass, anemia, dehydration, and suboptimal nutritional status.

Fluid resuscitation should begin with several liters of isotonic crystalloid solution and transfusion of red blood cells to improve oxygenation in patients who are severely anemic. The type of replacement fluid and electrolyte repletion should be tailored to the type and volume of fistula output as described previously and serum electrolyte status as measured with laboratory assessment. Electrolyte abnormalities of Na, K, Mg, and phosphate are common. These disturbances must be addressed, with special attention paid to relatively rapid correction of hypokalemia and hypophosphatemia, which are important for normal cardiac and respiratory muscle function. Metabolic acidosis may be present in duodenal fistulas and requires replacement of sodium bicarbonate.

Both enteral and parenteral nutrition have a role in the management of EC fistulas and should be used to achieve optimal nutritional support. Baseline nutritional needs are 20 kcal/kg/d of carbohydrate and fat and 0.8 g/kg/d of protein. These requirements can increase to approximately 30 kcal/kg/d and 1.5 to 2.5 g/kg/d in the setting of high-output fistulas. The route for nutrition delivery is based on caloric needs, patient symptoms, and fistula output. Enteral feeding is the physiologically preferred method, and numerous studies performed in the setting of various conditions have shown a benefit to enteral feeding with regards to healing, nutrition, and immune function. Enteral nutrition also supports the intestinal tract with regards to maintaining function while also preserving the integrity of intestinal mucosa. The drawback to this approach is that the initiation of enteral feeds may be associated with increased fistula output or in some cases is simply not tolerated because of ileus or obstruction. In these cases, total parenteral nutrition (TPN) is often necessary in the management of a fistula. Moreover, TPN is often needed in the interim between initiation of enteral support and achievement of caloric goals.

In the authors' practice, all patients start on enteral feeds once the ileus has resolved. If the fistula output does not increase to the level of a high-output fistula, and if it is tolerated, enteral feeds are continued and TPN is discontinued. A bulking agent, such as psyllium, may be added to assist in output control. Antimotility agents and octreotide, a long-acting somatostatin analog, may also help to control output. Although octreotide use has shown no proven benefit, it offers a potential decrease in fistula output by inhibiting secretion of various gastrointestinal hormones. In the authors' experience, some high-output fistulas are converted to medium or low output with the use of octreotide, which makes fluid and electrolyte management easier. If these measures do not work, the authors then revert to TPN to reduce the output.

When a trial of enteral feeds is initiated in a patient who has been on long-term TPN, one must be careful to assess for refeeding syndrome. This condition results in metabolic and fluid abnormalities, especially hypophosphatemia, on reintroducing enteral feeding. Refeeding syndrome typically presents in the first 4 days of renourishment. The chance of refeeding syndrome is reduced through the gradual reinstitution of enteral feeds while weaning the TPN.

Wound Care

Maintenance of skin integrity through control of fistula output and proper wound care is a crucial aspect of successful management. Involvement of skilled nursing staff or an enterostomal therapist can help to ensure that optimal wound care is received, especially in the outpatient setting.

H_2-receptor antagonists, proton pump inhibitors, and sucralfate can suppress acid production to decrease the acidity of the effluent. These medications can potentially limit corrosive effects on skin and assist in acid-base and electrolyte regulation but have shown no benefit with associated wound closure.

Although these pharmacologic agents may assist in controlling the volume of output, the corrosive properties of the effluent are actually most detrimental to skin integrity. Skin barriers (solid wafers, powder, paste, and sealants), adhesives (liquid, aerosol, and double-faced adhesive sheets or discs), dressings, and pouches (one-piece or two-piece appliances) are all useful for protecting the patient's skin and containing effluent.

Vacuum-assisted closure (VAC) dressings are frequently used to manage nonfistula wounds. VAC dressings promote formation of healthy granulation tissue and limit frequent dressing changes. Some studies suggest that applying VAC dressings to EC fistula wounds can assist in effluent management and promote wound healing. However, concerns continue to exist with this method. Effluent confined under VAC dressing sponges can potentially impair wound healing and place the patient at an increased risk of wound infection. Different sponge types are available to prevent this, such as standard VAC GranuFoam, GranuFoam Silver and WhiteFoam (Kinetic Concepts, Inc., San Antonio, Tex). However, VAC dressings are not accepted as standard of care for EC fistula wound management at this time. In the setting of deep EA fistulas, VAC dressings provide constant suction, which reduces contact between the peritoneum and fistula contents. In superficial EA fistulas, split thickness skin grafts can be done around the fistula site and a VAC dressing applied. VAC dressings placed around the fistula site keep effluent away from granulating tissue. When graft healing has progressed, skin barriers and stoma control appliances can replace VAC dressings.

SURGICAL MANAGEMENT

Spontaneous closure of EC fistulas is seen in approximately one third of patients in the first 4 to 6 weeks after formation. In those patients who do not have spontaneous closure, surgical repair is necessary. The operations to repair EC fistulas can be some of the more challenging, unforgiving, and time-consuming operations for the general surgeon. The operation is usually characterized by difficult entry into the abdomen, extensive adhesiolysis, removal of embedded mesh, bowel resection, and complex abdominal wall reconstruction. The tissue encountered is often suboptimal because of malnutrition and chronic inflammation. Not surprisingly, the risk of postoperative wound infection, anastomotic dehiscence, and even reformation of a fistula is not insignificant.

The timing of operation for EC fistula is critical in maximizing the chances of success. First and foremost, electrolyte imbalances need to be corrected and nutrition must be optimized before operation. In general, with the use of aggressive nutritional support, most patients can achieve serum albumin levels of greater than 3 g/dL, which should be the goal before operative intervention. The passage of time itself also plays an important role in preparing the surgical field. With time, the adhesions among bowel loops and other abdominal viscera become soft and filmy, which allows easier dissection and minimizes the chances of inadvertent enterotomy or serosal tear. In addition, the inflammation surrounding a fistula resolves and involves less of the surrounding structures, thus reducing the potential need for resection of adjacent bowel loops. In general, at least 12 weeks should pass from fistula formation to operative intervention. Unless other circumstances, such as uncontrolled sepsis or failure to progress, force an earlier operation, this amount of time should be the minimal wait period. In patients who are doing nutritionally well and have good control of fistula output, waiting an additional 4 to 6 weeks optimizes the chances of a good outcome even further. If a skin graft was placed on a granulation tissue bed, it should pass the "pinch-test" before operation. This test is performed by pinching the skin graft and elevating it off of the underlying tissues. The ability of the graft to elevate from the bowel shows that the surgeon will be able to separate the skin from the viscera at operation.

The operation for fistula takedown is often extensive, and ample preparations should be made. Patients should have appropriate intravenous access to allow resuscitation of the significant insensible fluid loss from the relatively long operative time. A Foley catheter should be placed, and an arterial line should be considered for monitoring hemodynamics and resuscitative effort. In patients who undergo an extensive abdominal operation combined with a complex abdominal wall reconstruction, consideration should also be given to a postoperative intensive care unit (ICU) bed for ongoing resuscitation and monitoring of respiratory function.

The operation should begin with a generous incision away from the EC fistula itself and in virgin tissue if possible. The abdomen should be entered sharply, and care should be taken to avoid injury to the bowel, which is almost always adherent to the previous incision, particularly in the area of the fistula. Once the abdomen is entered, the viscera should be completely freed from each other with extensive adhesiolysis. A thorough inspection of all of the abdominal viscera should be made. In particular, assessment for an obstruction downstream of an EC fistula is important. Often, most of the abdomen is normal appearing, and the area of the fistula is apparent from dense thick adhesions, inflammatory rind, and associated phlegmon. The authors typically separate all structures and leave the fistula attached to the abdominal wall for the very last part of the dissection. In this way, an assessment can be made of the relative location of the fistula on the bowel and any other involved structures before resection. This is important to minimize the length of resected bowel. It is not uncommon that a "single" fistula is often made up of multiple loops of small bowel that are physically close but are separated by a long linear distance. A decision must then be made to resect these enterotomies as a single segment with one anastomosis or multiple segments with several anastomoses, keeping in mind the need to balance the development of short gut syndrome with the added risk of a complication added by each additional anastomosis.

The closure of a fistula almost always involves a bowel resection and anastomosis. Direct suture closure of the dissected fistula tract has been described but is seldom possible in practice. Often the fistula involves a significant portion of the bowel circumference or is surrounded by scarred abnormal bowel and simple closure is not possible. The exceptions to this are fistulas created by a percutaneous drain that inadvertently traverses bowel or a surgically created fistula such as a tube jejunostomy. These can often be dissected and stapled or oversewn.

Once the gastrointestinal portion of the operation is complete, attention must be turned to closure of the abdominal wall. This also carries complex problems not seen with most simple closures. Often the takedown of the fistula requires a full-thickness resection and débridement of scarred and inflamed abdominal wall. The area of resection can be quite large, especially if it includes previously placed mesh. In many cases, the amount of abdominal wall resected precludes a primary closure and an abdominal wall reconstruction must be performed. A few important principles that apply to abdominal closure after EC fistula takedown should be pointed out. At the very least, EC fistula closures are clean-contaminated cases and the use of nonabsorbable meshes such as proline should be avoided. If primary closure cannot be achieved, the midline can often be medialized with a component wall separation. This is often reinforced with an underlay of a biologic material, such as xenograft of bovine or porcine acellular dermis. Further reinforcement can be gained by quilting an overlay of absorbable mesh onto the anterior fascia. Closure of a large defect with these measures is associated with a high risk of subsequent incisional hernia but is superior to the risk of infecting nonabsorbable mesh. With this in mind, a decision should be made on how complex of a closure should be performed at the fistula reversal. A component separation "burns bridges" for future definitive repairs and should not be undertaken if the judgment is that it will not be definitive. The principle of "live to fight another day" applies.

SUMMARY

Enterocutaneous fistulas are a common, complex problem in the surgical patient population. Diligent control of sepsis, electrolyte imbalance, fistula output, and nutrition management can significantly reduce the patient's morbidity and mortality. A patient's course can be optimized through definitive surgical repair when spontaneous closure does not occur.

Preoperative Bowel Preparation: Is it Really Necessary?

Pamela A. Lipsett, MD, MHPE, FACS, FCCM

OVERVIEW

Among elective surgical procedures, elective resection of the colon has the highest rates of surgical site infection (SSI), often at or above 20% when postoperative surveillance is continued for 4 weeks after surgery and strict definitions of infection are applied. No doubt this is related to the fact that the colon contains more than 10^{12} colony-forming units (CFU)/g bacteria that can be released and contaminate the surgical site when the surgical procedure opens the lumen of the bowel. Mechanical bowel preparation (MBP) combined with oral antimicrobial agents was designed to reduce infections after colorectal surgery. However, the routine use of intravenous systemic antibiotics during surgery has brought into question the necessity of preoperative oral antibiotics. Further, evidence-based reviews have routinely called for surgeons to eliminate MBP as lacking evidence to support its usefulness. Moreover, incomplete MBP has been associated with a paradoxical increase in complications, such as intraoperative contamination of the operative field with liquefied bowel contents. Thus, it is reasonable to consider whether MBP should be used in addition to systemic antibiotics, whether MBP should be combined with oral antibiotics, or whether both should be abandoned.

HISTORICAL BACKGROUND

In the 1930s, with mortality rates of 10% to 12% and SSI as high as 80% to 90% after colon resection, it seemed logical to focus on reducing microbial contamination by cleansing of the colon of gross fecal material. Further, some surgeons believe that reduction of the mass of colon contents allows for enhanced manipulation of the colon, ease of stapler use, and palpation of tumors. Edgar Poth noted that MBP reduced the burden of total bacteria in the colon but that it did not reduce the concentration of bacteria. He believed that it was essential to reduce the microbial concentration by MBP for intraluminal antibiotics to have any effect on the mucosal concentration of bacteria. In addition, Nichols and associates similarly concluded that MBP alone had no impact on microbial concentration in the colon. Thus, one can conclude that no clinical or microbiologic evidence supports MBP alone as a method to reduce SSI rates for elective colon surgery.

MECHANISM OF ACTION OF ORAL ANTIMICROBIAL AGENTS

Magnesium citrate, sodium phosphate, enemas, polyethylene glycol (PEG), and whole-bowel irrigation clear the colon of solid fecal components but do not influence the species or concentration of organisms in residual fluid within the colon at the time of operation. Early experience with oral antimicrobial prophylaxis did not adequately consider the importance of both aerobic and anaerobic bacteria in the colon. However, the combination of an antianaerobic agent with neomycin resulted in a significant reduction of both *Escherichia coli* and *Bacteroides fragilis* species in the colon. In the surgically resected colon, oral antibiotics produce a 4-log to 5-log decrease in the concentrations of both aerobic and anaerobic bacteria. Further, the use of an oral preparation with neomycin and erythromycin base both quantitatively and qualitatively reduces evidence of intraluminal and mucosal wall microflora. No doubt, the reduction in bacterial concentration coupled with a reduction in SSI began the modern era of bowel preparation in elective colorectal surgery.

MECHANICAL BOWEL PREPARATION

Early preparations of MBP used dietary limitations, cathartics, and enemas and lasted 48 to 72 hours. Oral cathartics traditionally use isotonic PEG solution or hyperosmolar insoluble salts that contain magnesium or phosphate. Many studies of various preparations for colonoscopy have concluded that various preparations are effective: 4L PEG, 3L PEG, 2L PEG, or 45-mL and 90-mL preparations of sodium phosphate, However, in several studies, sodium phosphate–based preparations are better tolerated with less patient nausea, emesis, bloating, and cramps. Acute phosphate nephropathy has been rarely reported with the use of some oral sodium phosphate for bowel cleansing (Fleet Phospho-soda or Fleet ACCU-PREP, CB Fleet, Inc., Lynchburg, Va.) but not others (Osmo-Prep, CB Fleet, Inc., Lynchburg, Va.). The use of PEG solutions may be slightly favored for colonoscopy, with perhaps a slight advantage of proximal colon cleansing, but these advantages have not been measured in elective colon surgery.

IS MECHANICAL BOWEL PREPARATION STILL WARRANTED?

If evidence-based reviews, systematic reviews, metaanalyses, and national (Canadian) guidelines for the use of MBP were examined for their recommendations about the use of MBP in elective

colorectal surgery, this section would simply say: MBP can be safely omitted. The Cochrane review in 2011 by Guenaga and colleagues examined 5805 patient outcomes and showed that no differences were found in anastomotic leakage rate for low anterior resection (MBP, 8.8% vs 10.3%; odds ratio [OR], 0.88 [0.55,1.40]), colon surgery (MBP, 3.0% vs 3.5%; OR, 0.85 [0.58,1.26]), and SSI (MBP, 9.6% vs 8.5%; OR, 1.15 [0.95,1.42]). Yet, in 2006, a multinational audit of 1082 patients from 295 hospitals in both Europe and the United States revealed that 86% to 97% of patients received preoperative MBP. These surveys indicate that a large gap exists between the evidence surrounding the use of MBP and surgeon practices. Can this gap be explained by lack of awareness of the evidence, or is there more behind the reluctance of surgeons to abandon this practice?

Much of the published evidence suggests that MBP does not reduce SSI or other infectious risks with elective colorectal surgery. Certainly, MBP is unpleasant for patients. Further, in traumatic injury with unprepared bowel, systemic antibiotics alone have complication rates that are considered acceptable. Trials conducted in Europe suggest that when broad-spectrum systemic antibiotics are used, MBP alone provides no advantage in important infectious clinical outcomes. Aside from potential patient concerns and complaints about MBP and dehydration that may be induced with colon cleansing, some adverse effects of MBP have also been identified. First, histologic evidence suggests that cleansing with PEG is associated with depletion of the superficial mucous layer and epithelial cells and severe infiltration of both lymphocytes and neutrophils in the wall of the large bowel. In an interesting report by Wren and colleagues, in which all 304 patients received cathartics and intravenous antibiotics but some patients also received oral antibiotics, *Clostridium difficile* infection was higher in patients who received oral antibiotics (7.4%) versus those who did not (2.6%). Although this single-center report did show an increase in *C. difficile* infection, additional reviews did not support this conclusion.

Despite the lack of efficacy of MBP alone, several authors have suggested that the combined role of MBP and oral antibiotics be reexamined. For example, Lewis showed a reduction in SSI from 17% in the oral placebo group to 5% among those receiving oral neomycin (2 g) and metronidazole (2 g) at 7:00 PM and 11:00 PM the night before surgery. Importantly, the bowel preparation with sodium phosphate was complete by 6:00 PM. Randomized controlled studies with 100 or more patients showed a summary odds reduction with systemic antibiotics, MBP, and oral antibiotics of 0.47 (95% confidence interval [CI], 0.16 to 0.77). Finally, in a naturalistic experiment from the Michigan Surgical Quality Collaborative-Colectomy Best Practices Project, data on MBP and *C. difficile* outcomes were prospectively collected. A total of 49.6% of the 2011 elective colectomies that were performed over 16 months received MBP and no oral antibiotics, and 36.4% received both MBP and oral antibiotics. First, these data show that real-life surgeons still believe in and use MBP. In this report, patients receiving MBP and oral antibiotics were less likely to have any SSI (4.5% vs 11.8%; $P = 0.0001$), to have an organ space infection (1.8% vs 4.2%; $P = 0.044$), or to have a superficial SSI (2.6% vs 7.6%; $P = 0.001$). Patients receiving bowel preparation with oral antibiotics were also less likely to have a prolonged ileus (3.9% vs 8.6%; $P = 0.011$) and had similar rates of *C. difficile* colitis (1.3% vs 1.8%; $P = 0.58$). Although these data are not from a randomized controlled trial, they are real-world experiences that suggest a possible benefit of combining systematic antibiotics with MBP and oral antibiotics.

SUMMARY

Significant controversy remains with respect to the value of MBP and oral antibiotics, alone or in combination. Evidence suggests that MBP does not provide incremental value in the decrease of SSI. However, studies have not examined whether value is provided in colon manipulation, ease of stapler use, and palpation of tumors with MBP. Perhaps the greatest benefit of MBP may well be when used in combination with oral antimicrobial agents. Although the topic of MBP and oral agents may be closed for some, perhaps additional clinical studies to investigate the best agent for MBP in the setting of oral antimicrobials, the timing of MBP and oral agents, and the best oral agents to be used remain valid research questions in providing the best outcomes for our patients after colorectal surgery. However, no additional trials of MBP alone are needed; we know that alone, MBP has no benefit for SSI prevention.

The Management of Diverticular Disease of the Colon

Paula Ferrada, MD, FACS, and
Rao R. Ivatury, MD, FACS

Diverticular disease of the colon is very common with advancing age and is higher in prevalence in countries with Western diets. The two important complications of this condition are inflammation and bleeding. In both of these clinical situations, newer concepts of diagnosis and management have emerged in recent years.

DIVERTICULITIS: CLINICAL PRESENTATION

Diverticulitis is defined as inflammation or infection associated with diverticula and is manifested clinically in about one third of patients with diverticula. The process through which a diverticulum becomes inflamed has been linked to obstruction of the diverticula and venous congestion, ultimately leading to perforation. The extent and localization of this perforation determines the clinical behavior of the disease. Small perforations can remain well localized, contained by the pericolic fat and mesentery, leading to small abscesses, and larger perforations result in more extensive abscess formation, remotely in the mesocolon and in the pelvis. Fecal peritonitis results if the perforation is freed into the general peritoneal cavity and may present as life-threatening sepsis (Figure 1).

Hinchey and colleagues described a grading system to reflect the degree of perforation:

- Stage I: Confined pericolic abscess.
- Stage II: Distant abscess (retroperitoneal or pelvic).
- Stage III: Generalized peritonitis caused by rupture of a pericolic or pelvic abscess, noncommunicating with bowel lumen because of obliteration of diverticular neck by inflammation.
- Stage IV: Fecal peritonitis caused by free perforation of a diverticulum (communicating).

MANAGEMENT

Mild cases of diverticulitis, even with the presence of small abscesses (Hinchey I) can be treated conservatively, with antibiotics (aerobic and anaerobic coverage; e.g., combination of ciprofloxacin and metronidazole). Clinical improvement is monitored with serial monitoring of the patient's temperature, abdominal findings, and white blood cell count (WBC). Once these values are normal, patients are progressed on their diet and encouraged to eat a high-fiber diet to avoid recurrent symptoms. Patients with more severe symptoms and those who do not show improvement on outpatient therapy are admitted for intravenous antibiotics and gradual progression of diet. Responders may be discharged after a brief hospital stay.

After resolution of symptoms and signs (diminished tenderness, reduction of leukocytosis), the patient can be treated as an outpatient with oral antibiotics and follow-up. Older patients should be followed with a colonoscopy to rule out malignant lesions in the colon. Larger abscesses (Hinchey II) may be amenable for computed tomographic (CT) scan or ultrasound-guided percutaneous drainage (PCD). However, even after a successful conservatively treated episode, complications such as excessive scaring and strictures or fistulas to hollow organs may still ensue. In the absence of these complications, surgery may be deferred.

Role of Elective Surgery in Acute Uncomplicated Diverticulitis

Elective colectomy was previously recommended after the first bout of diverticulitis. The Standards Task Force of the American Society of Colon and Rectal Surgeons (ACCRS) recommended colectomy after one to two episodes of uncomplicated diverticulitis and after one episode of complicated diverticulitis. More recent studies began to question this recommendation. In a retrospective cohort study from 12 Kaiser Permanente hospitals, among 2551 patients, 185 (7.3%) had elective colectomy and 2366 (92.7%) did not. In a mean follow-up period of 8.9 years, only 13.3% had recurrence after nonoperative treatment. Only advanced age and higher comorbidity was associated with recurrence. Interestingly, percutaneous abscess drainage was not associated with a higher recurrence rate.

Many authorities suggest that younger patients with diverticulitis requiring hospitalization should have an elective colectomy because the disease is more virulent in these patients. In a statistical model that analyzed the probabilities of clinical events and costs from a large cohort, the group from Seattle concluded that performing colectomy after the fourth episode (rather than the second episode) resulted in 1% fewer deaths and 2% fewer colostomies and saved $5429 per patient. The data were similar for older patients as well. Other studies also challenged the concept of an interval sigmoidectomy after diverticulitis, concluding that morbidity and mortality rates are not significantly different between patients with multiple episodes of diverticulitis compared with those with one or two prior attacks. There appears to be a consensus now that elective colectomy after the first episode of diverticulitis should no longer be a routine practice, regardless of age.

Complicated Diverticulitis

Complicated diverticulitis is defined as diverticulitis associated with abscess formation, free perforation, fistula formation, or stenosis. Not all intraabdominal abscesses need drainage. For pericolic and intramesenteric abscesses, initial management with intravenous antibiotics and close observation may be appropriate, reserving PCD for patients with failure to improve rapidly from a clinical standpoint. The threshold for PCD, however, should remain low, if the patient does not show evidence of sepsis control. Once drainage is established, drains may be removed after clinical symptoms improve and output is minimal or ceases. After successful nonoperative management, patients should be referred for colonoscopy to rule out malignant lesions in the colon.

Role of Elective Surgery in Acute Complicated Diverticulitis (Pericolic Abscess, Hinchey I and II)

The necessity for elective interval resection after successful PCD of pericolic abscesses is controversial. Although recommended by most leaders, several smaller series confirm that drainage of smaller mesocolic abscesses can be the definitive treatment without subsequent sigmoid resection.

Role of Elective Surgery in Acute Complicated Diverticulitis After Successful Treatment

The current indications for elective sigmoidectomy after initial successful nonoperative treatment are recurrent episodes of

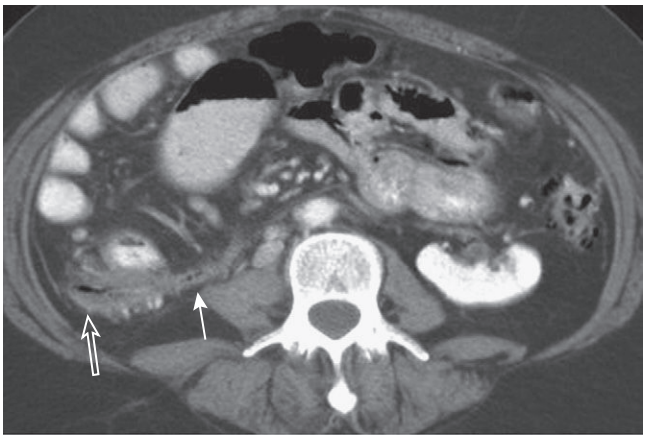

FIGURE 1 Computed tomographic scan of a patient with right lower quadrant abscess *(open arrow)* as a result of perforated sigmoid diverticulitis. The *closed arrow* shows the normal-appearing appendix. *(From Yu J, Fulcher AS, Turner MA, et al: Helical CT evaluation of acute right lower quadrant pain: part II, uncommon mimics of appendicitis,* Am J Roentgenol *184(4):1143–1149, 2005.)*

diverticulitis in patients with immunosuppression or transplant and in those who had pelvic abscess drainage and recovered from it. Diverticular fistulae arise when the inflamed colon erodes into adjacent organs, thus causing a fistulous connection. The most common fistulae are colovesical fistulae, and the presenting symptoms are pneumaturia and fecaluria. The finding of air within the bladder on CT scan is considered pathognomonic. Less commonly fistulas are to other structures within the pelvis: ureter, prostate, fallopian tubes, or uterus. In these patients, preoperative colonoscopy is helpful to rule out malignant lesions. Occasionally, diverticulitis may result in chronic inflammation and stenosis of a segment of sigmoid colon. Such diverticular strictures, if significant and causing increasing constipation, are an indication for surgical resection.

All these patients must have bowel preparation, both mechanical and chemical, before surgery. Concurrent comorbid conditions must be evaluated before surgery and the patients optimized for surgery. The surgical procedure of choice is resection of sigmoid colon up to the level of proximal rectum and colorectal anastomosis.

Current literature strongly supports the superiority of laparoscopic resection and hand-assisted primary anastomosis. In a sigma trial from Europe (a prospective, multicenter, double-blind, parallel-arm, randomized trial), 104 patients were randomized for these two methods. The conversion rate to open operation on initial laparoscopic attempts was 19.2%. Laparoscopic resection took longer ($P = 0.0001$) but caused less blood loss ($P = 0.033$). Mortality rate was 1%. Significantly more major complications were seen in open resection (9.6% vs 25.0%; $P = 0.038$), along with more pain on the visual analog scale, and in systemic analgesia requirement ($P = 0.029$). The short form–36 questionnaire showed significantly better quality of life for the laparoscopy group. At the 6-month follow-up evaluation, no significant differences in morbidity or mortality rates were found. Two patients died of cardiac causes (overall mortality, 3%). Late complications occurred in seven of the laparoscopy group and in 12 of the open group and consisted of three incisional hernias, five small bowel obstructions, four enterocutaneous fistulas, one intraabdominal abscess, one retained gauze, two anastomotic strictures, and three recurrent episodes of diverticulitis. Nine of these patients underwent additional surgical interventions. The total morbidity in these 6 months was significantly less for the laparoscopy group (9 vs 23; $P = 0.003$).

Role of Emergent Surgery in Acute Complicated Diverticulitis

Free Perforation: Purulent and Fecal Peritonitis (Hinchey Stages III and IV)

Peritonitis from free perforation of the diverticula presents with a clinical picture of sepsis, exhibiting signs such as tachycardia, high or very low WBC, hypotension, hyperthermia or hypothermia, peritoneal signs, renal failure, hyperglycemia, and occasionally, frank septic shock. Early, aggressive, goal-directed therapy for sepsis should focus on appropriate oxygen delivery, early initiation of broad coverage antibiotic therapy, and source control with immediate laparotomy, all the time with a careful assessment of the physiologic reserve of the patient.

Critical Care Management and Resuscitation

Starting with the management of an appropriate airway, ensuring adequate ventilation, and continuing with fluid resuscitation are lifesaving measures for these patients in extremis. Placement of a central line, optimization of mixed venous saturation (SvO_2) and central venous pressure (CVP) to guide fluid resuscitation, and early initiation of antibiotics to cover gram-negative and anaerobic organisms are the essential elements of preoperative therapy.

Surgical Management

Emergent operative management is the treatment of choice for patients with perforated diverticulitis. The abdomen is explored with a long midline incision, the intraperitoneal pus and feces are evacuated, and the offending perforation in the sigmoid is controlled with staples, sutures, or clamps. The abdomen is thoroughly irrigated with saline solution, ensuring manual evacuation of stool. Resection of the perforation-bearing segment of the colon (perforectomy) is the preferred procedure in most cases. The safest option in treatment of severe sepsis and generalized purulent or fecal peritonitis is limited resection with colostomy and closure of the distal rectum (Hartmann's procedure) or creation of a mucous fistula. Hartmann's resection is preferred by the authors because it obviates the need for extensive mobilization of the distal colon and avoids violating tissue planes in the pelvis that make the next operation more difficult.

Abbreviated Laparotomy in Unstable Conditions

Massive volume resuscitation and vasopressor therapy is often needed, especially in patients whose conditions are hemodynamically challenged because of severe purulent or fecal peritonitis resulting in acidosis and septic shock. In such cases, the current strategy of abbreviating the laparotomy, rapid perforectomy leaving the colon in discontinuity, abdominal wash out to evacuate pus and feces, and temporary abdominal closure with application of any variation of the vacuum assisted closure (VAC) system constitute the so-called damage-control surgery. The advantages of this approach are the avoidance of continuing operative trauma and resuscitation in the intensive care unit (ICU) with fluids, antibiotics, and, if necessary, vasopressors. Once the goals of correction of acidosis and septic shock are accomplished, usually within 24 to 48 hours, patients are returned for definitive resection, colostomy, and Hartmann's pouch, or in very rare instances, colocolic anastomosis.

Colostomy Versus Colocolostomy

The decision to perform a primary anastomosis with or without an ileostomy or to perform a sigmoid colostomy and Hartmann's pouch hinges on overall stability, the degree and type of peritonitis, and the condition of the colon. In general, Hinchey IV cases with fecal peritonitis are poor candidates for this approach. Patients with

hemodynamically stable conditions with purulent peritonitis may be treated with primary anastomosis and a diverting loop ileostomy. Primary anastomosis, in general, is reserved for the most favorable conditions, including a stable condition and well-vascularized ends of colon. Tension on the anastomotic line must be avoided, if necessary with splenic flexure mobilization. Intraoperative colonic lavage may be an adequate substitute for lack of preoperative bowel preparation. Constantinides and associates analyzed 15 recent series with a random effects model and sensitivity analysis to control for heterogeneity of confounding variables. They showed a significantly reduced postoperative mortality rate of 4.9% in resection-anastomosis versus a rate of 15.1% with Hartmann's procedure (odds ratio [OR], 0.41). In emergency operations, matched for severity of peritonitis (Hinchey >II), no difference in mortality rates was seen between these two procedures (14.1% vs 14.4%). Most of the recent literature supports a proximal defunctioning loop ileostomy if there is any doubt about the integrity of the anastomosis, a concept supported by the European Association of Endoscopic Surgeons.

Laparoscopic Irrigation and Drainage for Hinchey II and III

This provocative approach to Hinchey II and III cases is being reported with frequency. In a prospective study reported by Myers and colleagues in 2008, 92 patients with Hinchey grade II pelvic abscess (n = 25) or grade III (n = 67) were treated with laparoscopic irrigation of the peritoneal cavity with 4 L of warm saline solution and the placement of two Penrose drains in the vicinity of perforation along with antibiotic therapy. Eighty-seven had resolution of disease, and only two had recurring pelvic abscesses; one of these had Hartmann's resection. The mortality rate was 3%, 3 of 92 (two from multi-organ failure and one from pulmonary embolism [PE]). The authors noted no recurrence of the disease after a follow-up period of 3 years. Multiple centers are beginning to accumulate experience with this approach that deserves a careful consideration in the future (Table 1).

The optimal strategy for surgical treatment for diverticulitis, whether elective or emergent, depends on a host of factors related to the patient, the disease, the environment, and the surgical team. These are nicely summarized in the graphic described by Bauer (Figure 2).

SUMMARY AND CONCLUSION

The management of diverticulitis appears to have undergone revision in recent years because of a better understanding of the natural history of the disease. Elective sigmoidectomy is deferred in most patients and is reserved for patients with immunocompromise or transplant and for the more severe forms of complicated diverticulitis. Laparoscopic approaches are playing an increasing role both in emergency situations and for elective sigmoid resection.

DIVERTICULAR BLEEDING

Diverticular bleeding is the most common cause of significant lower gastrointestinal (GI) bleeding, defined as bleeding into the bowel lumen from a source that is distal to the ligament of Treitz. Approximately 15% of patients with colonic diverticulosis experience bleeding, which may range from minor to severe and life threatening. Most diverticular hemorrhages stop spontaneously. In general, patients who need more than 4 units of blood in a 24-hour period for hemodynamic stability, who have not stopped bleeding after 72 hours, or who experience rebleeding within 1 week after an initial episode should undergo surgery. Endoscopic treatment may have a role, but large-scale prospective randomized trials are not available.

Diagnosis and Management

1. Resuscitation is performed with ABC (airway, breathing, and circulation) and transfusion as necessary.
2. Upper GI (UGI) bleed must be ruled out with inserting a nasogastric tube and ensuring that there is bile and no blood in the aspirate. Clear fluid is not enough; one has to see bile to be sure that a postpyloric bleed with pylorospasm is not happening. If UGI bleed is not ruled out, an esophagogastroduodenoscopy (EGD) is indicated.
3. Efforts must be made to localize the site of lower GI bleed. The factors that determine the choice of the diagnostic test are the hemodynamic stability of the patient, the bleeding rate, patient comorbidities, therapeutic options, and local expertise available. The various techniques of localization available are colonoscopy; radionuclide scanning, which is highly sensitive (capable of detecting bleeding at rates as slow as 0.1 to 0.4 mL/min); selective mesenteric angiography (less sensitive but offers therapeutic embolization); or, occasionally, a provocative angiography to provoke bleeding with the use of short-acting anticoagulant agents. The recent availability of multidetector CT scan (MDCT), with its increased resolution and faster scanning, allows for identification of extravasation of intraluminal contrast before it is diluted by intestinal contents. MDCT is also noninvasive and can demonstrate acute lower GI bleeding rates as low as 0.2 mL/min. Overall rates of detection and localization range around 50% to 80%. Figure 3 presents an algorithm for the management of lower GI bleeding.

"Blind" subtotal colectomy or resection without localization is associated with a high rebleeding rate of up to 42%. Subtotal colectomy should be reserved for hemodynamically unstable conditions without a localized source of bleeding.

The Management of Chronic Ulcerative Colitis

Sandy H. Fang, MD, and Jonathan E. Efron, MD

INTRODUCTION

Ulcerative colitis (UC) is a chronic mucosal inflammatory bowel disorder (IBD) characterized by remissions and exacerbations. The disease starts with involvement of the rectum (proctitis) and may extend to include the sigmoid colon (proctosigmoiditis) or further contiguous involvement of the colon (proctocolitis). The small intestine is not involved; however, diarrheal stool from severe inflammation in the cecum may cause inflammation in the terminal ileum called backwash ileitis and this may be confused with Crohn's ileitis.

IBD is a multifactorial disorder caused by both genetic and environmental components. A family history of IBD is the most prominent risk factor. UC probands tend to have more relatives diagnosed with UC, and the same holds true for Crohn's disease. Seventy-five percent of patients with UC have perinuclear antineutrophil cytoplasmic antibodies (p-ANCA). Environmental stimuli include increased sugar consumption, low-fiber diet, food allergies, food additives, infectious agents, and shortened breastfeeding time. Cigarette smoking is a protective influence in UC, whereas it is a risk factor for development of Crohn's disease.

Patients usually present with diarrhea and bleeding per rectum. Pain is an uncommon clinical feature except in severe active disease, when inflammation extends to the serosa. After long-term medical therapy, patients may actually present with constipation as opposed to diarrhea.

Diagnosis is made via endoscopy with multiple biopsies. Because inflammation starts in the rectum, proctoscopy or flexible sigmoidoscopy usually provides evidence for the initial diagnosis of UC; however, complete colonoscopy with evaluation of the terminal ileum is necessary to define the extent of disease and to rule out other pathology, such as benign or malignant neoplasia. Colonoscopy is contraindicated in the face of severe inflammation of the colon that may occur during an acute exacerbation, and in these cases, endoscopic evaluation is limited to the rectum and sigmoid colon. Other conditions that cause diarrhea and rectal bleeding must be ruled out, such as infectious etiology (*Clostridium difficile, Campylobacter jejuni, Salmonella enterocolitis, Escherichia coli* 0157:H7, amebiasis), collagenous colitis, and Crohn's colitis. Stool cultures for pathogenic bacteria, ova, and parasites should be sent for analysis.

INDICATIONS FOR SURGICAL THERAPY

Medically Refractory Disease

Medical therapy for UC refers to administration of a variety of immunosuppressive medications, which includes the 5-aminosalicylic acid (5-ASA) compounds, steroids, antipurine or pyrimidine compounds, and antitumor necrosis factor antibodies. However, UC is chronic, often lasting for decades, and patients may see progression to steroid dependence or a disease state that is medically refractory. Intractability to medical treatment is the most common indication for surgical therapy in patients with UC.

Fulminant Colitis and Toxic Megacolon

Severe colitis affects 5% to 15% of patients with UC and is characterized by bloody diarrhea, weight loss, volume depletion, fever, and severe anemia. Fulminant colitis refers to patients with severe colitis with progressive symptoms of toxicity. Attempts at conservative management with bowel rest, parenteral nutrition, parenteral steroids, and broad spectrum antibiotics are necessary. Progression to toxic colitis is indicated by fevers, leukocytosis, and distention, despite maximal medical therapy. Toxic colitis refers to the triad of fever, tachycardia, and leukocytosis in patients with UC. Toxic megacolon refers to patients who have distention of the transverse colon greater than 8 cm in diameter as seen on abdominal x-ray. Toxic colitis or toxic megacolon should be viewed as a surgical emergency because they indicate impending colonic perforation. Urgent or emergent resection is needed. If a patient's condition with fulminant colitis does not improve or deteriorates within 48 to 96 hours of the initiation of therapy, surgery should be considered. Twenty percent to 30% of patients with fulminant colitis need surgical intervention. If perforation ensues, the mortality rate after surgical intervention may be as high as 57%; therefore, surgery is warranted.

Bleeding

The incidence of massive hemorrhage in UC is low, ranging from 0 to 4.5%. However, it accounts for 10% of all urgent colectomies performed for UC. Although colectomy for bleeding is rare, requirement of blood transfusions is common.

Cancer

Risk factors for malignant disease in patients with UC include extensive involvement of the colon and duration of disease. The risk of development of a malignancy in UC is increased as compared with the general population after the patient's disease duration exceeds 10 years. At 10 years, the risk is 2% above the general population; at 20 years, it is 10%; and after 30 and 40 years, the risk increases to 50% and 75%, respectively. Endoscopic surveillance for dysplasia or cancer must begin 8 to 10 years after onset of symptoms or sooner, depending on age of the patient, and be performed on an annual or biannual basis. If a patient also has primary sclerosing cholangitis (PSC) or has a positive family history of colorectal cancer, surveillance should be performed annually. Ideally, the patient should undergo surveillance colonoscopy while in disease remission to minimize the risk of missing a carcinoma because of inflammation. Because cancer may arise from flat mucosa, random serial four-quadrant biopsies should be obtained every 10 cm for a total of 33 biopsies or more as an adequate sampling for dysplasia or cancer.

If biopsy results are positive for high-grade dysplasia or cancer, a patient should undergo proctocolectomy. The risk of an undetected cancer that is found after colectomy for high-grade dysplasia is 42%. In the setting of low-grade dysplasia, patients are encouraged to undergo elective prophylactic proctocolectomy. Unrecognized synchronous colorectal carcinoma is present in up to 20% of individuals who undergo surgery with the initial diagnosis of low-grade dysplasia. If the patient declines surgery, then close surveillance, every 3 to 6 months, is necessary. Polyps should be biopsied as per routine; however, the surrounding mucosa in four quadrants should also be sampled for dysplasia/carcinoma (non–adenoma-like dysplasia-associated lesion or mass [DALM]). Resection of adenomatous tissue

or a polyp is not an absolute indication for proctocolectomy but in conjunction with a DALM lesion is of greater concern. Typically, patients with dysplastic changes have had their colitis for many years and are no longer having inflammatory symptoms. They are having normal bowel movements and therefore are often satisfied with their ileal pouch function. For this reason, patients are often reluctant to undergo surgery.

Stricture formation occurs in 5% to 12% of patients, with 25% of the strictures being malignant. Malignant strictures appear late in the course of disease (61% after 20 years of disease), are usually located proximal to the splenic flexure (86%), and cause large bowel obstructions (100% vs 14% in benign strictures). Thus, proctocolectomy is recommended for stricturing disease in UC.

Extracolonic Manifestations

Hepatobiliary-associated disorders are the most likely to influence surgical management of the colon and rectum in UC. These patients may need orthotopic liver transplantation for primary sclerosing cholangitis. If colectomy is necessitated, formation of a permanent ileostomy is avoided, because of the complications associated with periileostomy varices from portal hypertension. Proctocolectomy for UC is beneficial for erythema nodosum (most responsive), arthritis, and eye diseases (episcleritis, uveitis, iritis, conjunctivitis) but does not affect outcomes for primary sclerosing cholangitis, ankylosing spondylitis, and sacroiliitis.

Growth Failure in Children

Surgery should be considered if children have growth retardation despite maximization of nutritional and medical therapy.

SURGICAL OPTIONS

Many surgical options exist for UC. Each surgical plan is tailored toward the individual patient according to their preoperative comorbidities, functional status, continence, and urgency of the operation. An algorithm to deciding the surgical approach to UC is shown in Figure 1. Patients should have extensive counseling regarding the potential for an ostomy. Several circumstances involve planning for future operations. Patients may need multiple staged procedures because of their disease status or whether they require an emergent operation.

Today, selected patients may be offered a minimally invasive approach. Advocates of the laparoscopic approach cite improved patient comfort, better cosmesis, decreased length of hospital stay, and faster recovery as advantages over the open approach. Studies in minimally invasive ileal pouch–anal anastomosis (IPAA) creation have shown a decrease in adhesion formation and incisional hernias. The many different approaches to minimally invasive proctocolectomy include strict laparoscopy and laparoscopic-assisted, hand-assisted, and single-incision surgery. Specimen extraction or the ileal pouch may be formed through a lower midline incision, Pfannenstiel incision, right lower quadrant incision (the previously marked ileostomy site), or a periumbilical incision. All of the incisions have their benefits. The hand-port incision may also be used for an open approach for the pelvic dissection and pouch creation. Regardless of approach, all patients undergo a standard mechanical bowel preparation, if their condition is stable, and receive perioperative parenteral antibiotics.

INDICATIONS FOR A SUBTOTAL COLECTOMY

A subtotal colectomy with end ileostomy and Hartmann's procedure is the least morbid operation. It is the operation of choice in an emergent situation. It is indicated in moribund patients with fulminant colitis, toxic megacolon, and perforation and in those patients with numerous comorbidities. It is also used for those undergoing a three-stage pouch procedure because they are on high-dose steroids or multiple immunosuppression drugs, are malnourished, or have indeterminate colitis. Patients with indeterminate colitis who the surgeon suspects may have Crohn's disease should undergo the three-stage procedure to allow for complete pathologic evaluation of the colon. For a planned first-stage procedure, it may be an option for those patients wanting to preserve fertility. In men, the risk of damaging the pelvic nerves is reduced by not entering the pelvis with active rectal inflammation. Avoiding the proctectomy in women may prevent pelvic adhesions that may affect fertility.

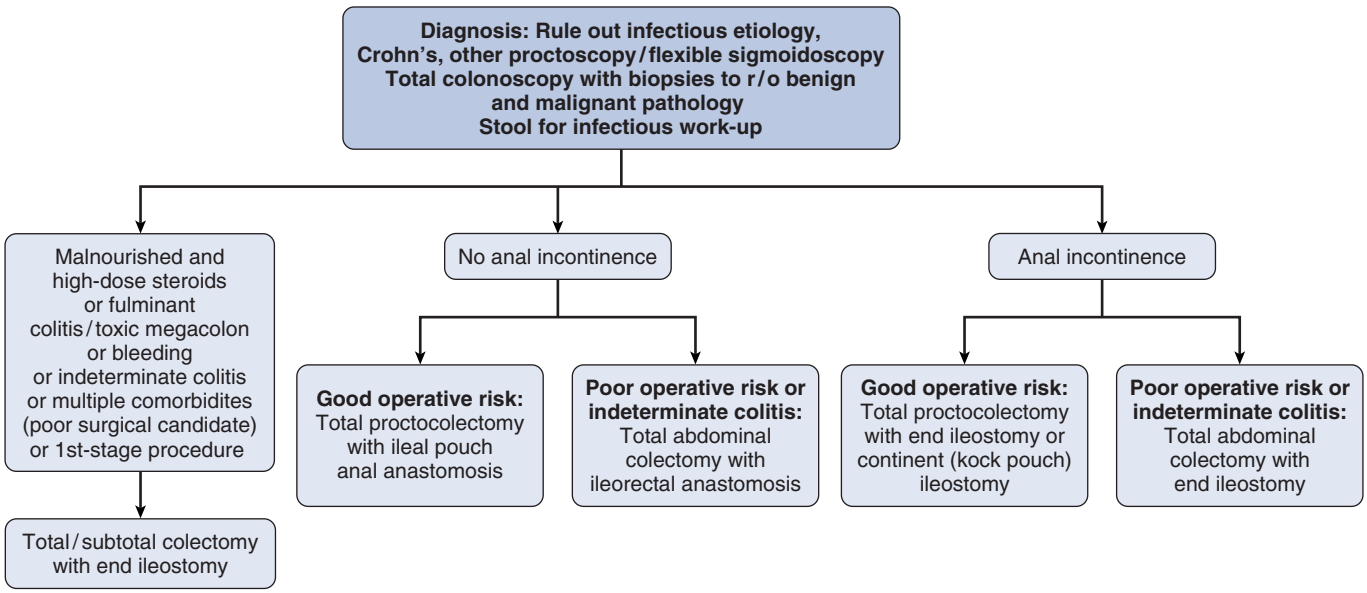

FIGURE 1 Surgical management of chronic ulcerative colitis.

In an emergent situation or when the colon wall is extremely fragile with a high risk of perforation, an open operation should be performed. The lower sigmoid colon is transected with a stapler just above the sacral promontory, leaving a rectal stump. A rectal tube or Foley catheter is left in the rectum to decompress the rectal stump and to prevent perforation of the stump. The Hartmann's pouch may be placed extrafascial, which lowers the risk of pelvic sepsis and subsequently facilitates future pelvic dissection. This is often done by bringing the divided colonic stump up through the most inferior aspect of the midline facial incision and securing the colon in place.

The specimen is submitted for pathologic diagnosis. If the pathology shows UC, a completion proctectomy and IPAA can be planned for a future definitive operation; however, if the pathology shows Crohn's disease and the rectum is without disease, an ileorectal anastomosis may be an option.

A disadvantage of this procedure is that a diseased rectum is left behind. The fate of the retained rectum is not well known. A 10% risk of rectal cancer is believed to exist, so patients need lifelong surveillance of the stump. Other issues include seepage and bleeding. Massive bleeding is rare, but when it occurs, it may require completion proctectomy. Most of these patients proceed on to completion proctectomy with IPAA.

SURGICAL PROCEDURES

Total Colectomy

Laparoscopic

The patient is placed in the modified lithotomy position. Both arms are tucked at the patient's side, and the patient is secured to the operating room table. For the minimally invasive approach, access is secured through an umbilical port with a Hasson technique. All ports are placed under direct visualization, and the right-sided ports include a 12-mm trocar placed 4 fingerbreadths superomedial to the anterior superior iliac spine with a 5-mm port located 4 fingerbreadths cranial in the right upper quadrant and two left-sided 5-mm ports placed to mirror the right-sided ports. As an alternative, a suprapubic port may be placed instead of the more cranial ports.

The omentum is swept above the transverse colon and liver. The small bowel is tucked to the right side of the abdomen. The patient is positioned in steep Trendelenburg position with the right side down. To mobilize the left colon, the surgeon first incises the peritoenum overlying medial aspect of the sigmoid mesentery starting at the sacral promontory and going up toward the inferior mesenteric artery. The mesentery of the sigmoid and descending colon is dissected off the retroperitoneum, identifying the left ureter and gonadal vessels. The base of the inferior mesenteric artery is isolated and divided either with a vessel-sealing device, clips, or an endovascular stapler. The mesentery to the colon is dissected free from Gerota's fascia up to the splenic flexure. The lateral peritoneal attachments, the white line of Toldt, are divided entering the previously dissected plane up to the splenic flexure. The splenic flexure is mobilized entering the lesser sac, and the omentum is freed from the transverse colon with the use of a vessel-sealing device. Shifting the patient into the reverse Trendelenburg's position helps facilitate transverse colon mobilization.

Placing the patient in slight Trendelenburg's position with the table tilted to the left allows the surgeon to perform the mobilization of the right colon. The ileocolic artery is isolated at its origin from the superior mesenteric artery, freeing it from the duodenum and retroperitoneum. The right colon mesentery is mobilized off of the retroperitoneum, identifying the right ureter. The lateral peritoneal attachments are divided entering the previously dissected plane, and the mesentery based on the superior mesenteric artery is completely freed up to the duodenum. The hepatic flexure is mobilized by dividing the colohepatic ligament and omentum with a vessel-sealing device. To prevent bacterial translocation, the colon mesentery is transected last to minimize time that necrotic colon is intracorporeal. The entire colonic mesentery is divided last using a vessel-sealing device or isolating individual vessels such as the right, middle, and left colic vessels with clips or laparoscopic staplers. If an ileal J pouch is performed, the small intestine mesentery must be completely mobilized off of the duodenum to provide maximum reach to the pelvis.

Open

The left colon is mobilized off the white line of Toldt, with care taken to identify and lateralize the left ureter and gonadal vessels. The splenic flexure is mobilized, entering the lesser sac and either dividing the omentum below the gastroepiploic artery, thereby resecting the omentum, or mobilizing the omentum off of the transverse colon in the avascular plane that exists between the two structures.

The right colon is mobilized along the white line of Toldt, identifying the right ureter and gonadal vessels. The hepatic flexure is mobilized by dividing the colohepatic ligament. Complete mobilization of the superior mesenteric artery to its base is necessary, completely exposing the C loop of the duodenum. This is to facilitate reach of an ileal J pouch to the anus. The mesentery to the entire colon is divided down to the sacral promontory. The terminal ileum is divided with a stapler.

Proctectomy

Laparoscopic Approach

The surgeon and the assistant operate on the left and right side of the patient, and a monitor is placed between the patient's legs. The patient is placed in steep Trendelenburg position and in a neutral position with respect to the tilt. In a female patient with a uterus, positioning the uterus to the anterior abdominal wall is often helpful. A suture on a Keith needle is passed into the abdomen, through the abdominal wall just above the pubis. It is passed through the body of the uterus and then back up through the abdominal wall and sutured in place with a bolster. This elevates the uterus and adnexa out of the pelvis and helps facilitate the anterior dissection of the rectum. The rectum is initially retracted superiorly, and the peritoneum is incised over the sacral promontory, with care taken to identify the pelvic nerves and mobilize them off of the mesorectum. The presacral space is entered, and dissection is continued inferiorly in this avascular plane. Rectal mobilization is facilitated by providing adequate traction and counter traction to help identify the correct plane of dissection. Posterior mobilization of the rectum is continued down through Waldeyer's fascia to the levator sling. The lateral avascular plane is identified inferiorly in the previously dissected presacral space. Mobilization is often completed with electrocautery or a vessel-sealing device. Retracting the rectum inferiorly and applying counter pressure with graspers on the vagina or seminal vesicles and prostate allows for the anterior dissection. Dissection is complete at the level of the anorectal ring. This is confirmed with digital examination with cross clamping of the distal mobilized rectum.

At this point, the rectum is divided with a stapler if a J-pouch anastomosis is to be performed. This can either be performed with laparoscopic staplers or a small Pfannenstiel incision may be made above the pubis to facilitate placement of a thoracoabdominal (TA) stapler. Great care must be taken in women to ensure the vagina is kept free from the staple line and that there is approximately 1 cm of mobilized rectum distal to the staple line to allow a safe double-stapled IPAA. The colon and rectum are then removed through either a periumbilical or suprapubic incision. If a mucosectomy is required or the patient is undergoing an intersphincteric dissection, the perineal dissection is initiated after completing the rectal mobilization. In this case, the specimen is often removed via the anus.

Open Proctectomy

The sacral promontory is identified and entered, with care taken to mobilize the hypogastric nerves from the mesorectal fascia. The St. Mark's retractor is then placed in the pelvis, and dissection is continued posteriorly in the avascular plane of the presacral space. Mobilization posteriorly should continue past Waldeyer's fascia to the levator ani muscles. Lateral rectal dissection is facilitated with lateral retraction of the pelvic sidewall with the St. Mark's retractor while the surgeon places medial traction on the rectum and mesorectal fascia. The anterior dissection is completed last, again with the St. Mark's retractor to retract the anterior structures anteriorly while the surgeon applies counter pressure on the rectum. The dissection is complete with the rectum fully mobilized to the levator ani muscles. The level of division is confirmed with digital palpation through the anus while clamping the distal rectum. The rectum should be divided at a level to allow room for stapling of the pouch to the anus, typically 1 to 2 cm above the dentate line. Great care is taken not to incorporate anterior or lateral structures into the staple line. Anterior retraction with the St. Marks retractor helps facilitate rectal division. In women, digital examination of the vagina before firing a TA stapler should be performed to ensure the vagina is not incorporated in to the TA staple line. If a mucosectomy is required or the patient is undergoing an intersphincteric dissection, the perineal dissection is initiated after completing the rectal mobilization.

Perineal Approaches to Remove the Distal Rectum

These dissections are enhanced by the use of a self-retaining retractor to efface the anus. For patients who are undergoing resection with permanent ileostomy, an intersphincteric dissection of the distal rectum and anus is favored. This allows the perineum to be closed with a complete muscular tube and significantly reduces the risk of perineal wound complications. An exception is when the operation is performed in a patient with a low rectal cancer where an abdominoperineal resection is required.

Intersphincteric Proctectomy

A lone star retractor or other self-retaining retractor is sutured to the perineum, and the anus is effaced. A skin incision is created in the intersphincteric groove. The intersphincteric dissection is carried out in the avascular plane, preserving the external sphincter and the levator ani muscles. This avascular plane allows for easy dissection and is initiated in the posterior aspect of the anus extending laterally, reserving the anterior dissection to last. One continues in this plane proximally until the abdominal pelvic dissection is reached and the peritoneal cavity is entered. The entire specimen is removed through the perineum. An omental pedicle flap can be rotated into the pelvis to fill the dead space if it has not been resected with the specimen. Closed suction drains are positioned in the pelvis, and the perineal wound is closed in layers, with all muscular layers closed with absorbable suture. After both abdominal and perineal incisions are closed, a Brooke ileostomy is matured in the right lower quadrant at a previously marked ideal site.

Complications

Postoperative complications include intestinal obstruction, delayed healing of the perineal wound, sexual dysfunction (including postoperative infertility), and issues related to the ileostomy. Patients who present with a chronically draining perineal wound should be investigated for retained mucosa, foreign bodies, and Crohn's disease. Sexual dysfunction after a low pelvic dissection in men consists of impotence, retrograde ejaculation, or both; in women, 30% have dyspareunia. Complications related to the ileostomy include dehydration, skin irritation, stomal stenosis, prolapse, and hernias.

Proctocolectomy with Ileal Pouch–Anal Anastomosis

Proctocolectomy with IPAA (TPC with IPAA) is the procedure of choice for many patients with UC. It eliminates all active disease and eventually leaves the patient stoma free. Patients on average stool six times a day with liquid or pasty stools. This stool consistency requires patients to have normal sphincter tone for continence. Patients who have poor anal continence are not candidates for IPAA and require an end ileostomy.

An ileal pouch performed in patients with middle or distal rectal cancers is controversial. Adjuvant radiation therapy should be performed before pouch creation because postoperative radiotherapy is associated with radiation enteritis and poor pouch function and consequent failure. Finally, in patients with UC with a cecal cancer, a long segment of distal ileum with its associated mesenteric vessel may need to be resected, precluding the formation of a tension-free IPAA.

Typically, the ultimate goal of the TPC with IPAA is accomplished through staged procedures. In a select group of patients, a single-stage procedure may be performed by an experienced surgeon. Most often, patients undergo a two-stage procedure: (1) TPC with IPAA and diverting loop ileostomy; and (2) reversal of the ileostomy. Those who go through a three-stage procedure ([1] subtotal colectomy and end ileostomy; [2] restorative proctectomy with ileoanal pouch anastomosis and diverting loop ileostomy; and [3] reversal of ileostomy) usually are malnourished patients receiving high-dose steroids and are too sick to undergo a total proctocolectomy. Those with fulminant colitis or toxic megacolon have been shown to have a high risk of intraabdominal sepsis; thus, simultaneous IPAA should not be performed at the initial operation because of the high risk of pouch failure.

The patient's positioning and mobilization of the colon and rectum are as described previously. The terminal ileum is transected flush to the cecum, making sure to preserve the ileal branch of the ileocolic vessels. The rectum is transected just above the levator ani muscle. The root of the small bowel mesentery is mobilized to the level of the ligament of Treitz.

J-Pouch Creation

In the laparoscopic technique, the terminal ileum may be exteriorized through the planned diverting loop ileostomy site, a small Pfannenstiel's incision, or a midline incision. Otherwise, the J-pouch is formed through the hand-port or open incision. The J pouch should be 15 to 18 cm in length; the exact length is determined by identifying which point of the antimesenteric edge of ileum provides the maximal reach to the pelvis. Adequate reach for the pouch is confirmed when the distal aspect of the pouch reaches below the pubic symphysis. Sutures are placed to approximate the antimesenteric border of the planned J pouch. A 2-cm curvilinear incision is created at the base of the J. Multiple firings of a linear stapler are used to create the J pouch, usually two or three firings of a stapler 100 cm in length. The tip of the J staple line is oversewn to prevent a leak. The mucosal border of the staple line is inspected to ensure hemostasis and is oversewn if needed (Figure 2).

Ileal Pouch–Anal Anastomosis

A double-stapled pouch–anal anastomosis is thought to provide better postoperative pouch function by maintaining the anal transition zone. It is the preferred method of the authors except in patients with rectal dysplasia or in patients with rectal carcinoma. In those cases, mucosectomy with hand-sewn anastomosis is performed.

Double-Stapled Anastomosis

The curvilinear incision in which the stapler was inserted to create the J pouch is used for the anastomosis. The anvil is inserted into the base of the J pouch and secured with a purse-string suture.

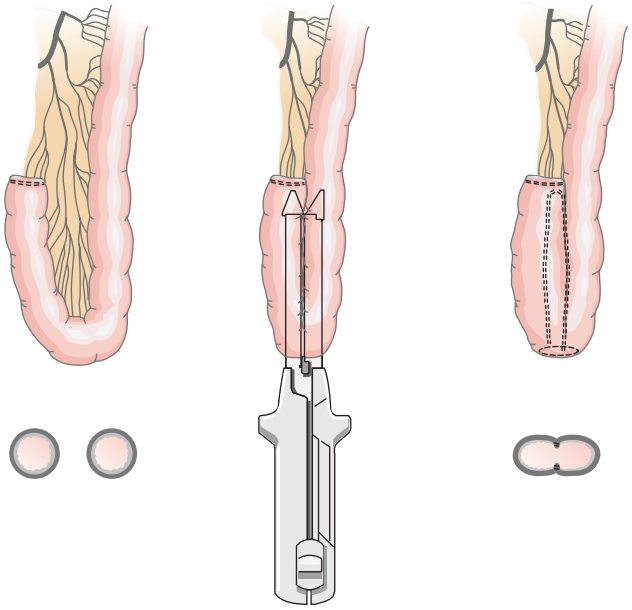

FIGURE 2 Creation of an ileal J pouch with a cutting linear stapler. For replacement of the rectum, a reservoir is created from the distal ileum. The stapler joins two limbs of intestine with staples while dividing the intervening wall. The diameter of the pouch so created is twice as large as the original diameter of the ileum. *(From Townsend CM, Beauchamp RD, Evers BM, Mattox KL, editors:* Sabiston textbook of surgery, *ed 18, Philadelphia, 2008, Elsevier Saunders, pp 1381, Fig 50-33.)*

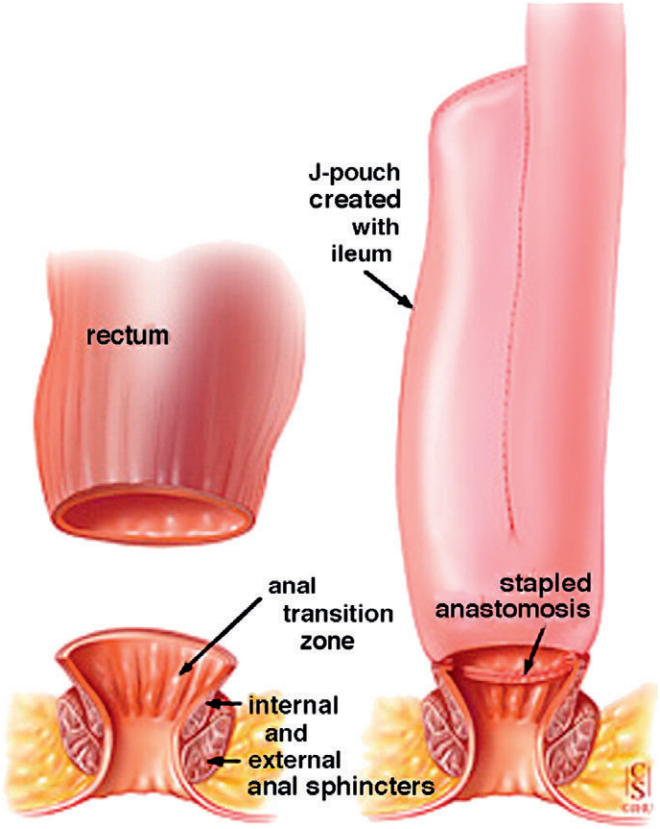

FIGURE 3 Creation of the J pouch. *(From Johns Hopkins Sidney Kimmel Comprehensive Cancer Center website:* http://www.hopkinskimmelcancercenter.org/images/coloncancer/J-pouch2.jpg. *Accessed July 13, 2012.)*

The stapler is inserted transanally, and the pin protruded posterior to the rectal staple line (Figures 3 and 4) Great care must be taken to ensure the pouch is not twisted on its mesenteric pedicle and that anterior structures, most commonly the vagina, are not incorporated into the anterior or lateral staple line. These are key points whether a laparoscopic or open procedure. A loop ileostomy is then formed 40 cm from the ileal pouch at a previously marked location in the right lower quadrant.

Mucosectomy and Hand-Sewn Anastomosis

The mucosa from the anal canal and the distal rectum are removed transanally with the specimen. After the surgeon has completed the abdominal and pelvic dissection, attention is turned towards the anus. A self-retaining retractor is secured to the perineum, and the anus is effaced. Normal saline solution or lidocaine with 1% epinephrine is injected in the submucosal space to help to identify the correct plane of dissection. The mucosa is elevated with electrocautery, generating a circular tube of tissue, and initiating the dissection at the dentate line. The peritoneal cavity is entered posteriorly, dividing the muscularis above the level of the puborectalis sling. The rectum is completely divided, and the specimen is removed. The ileal pouch is brought down to the anus with an empty sponge stick or Babcock clamp. The long instrument is passed through the anus to grasp the pouch, creating a hand-sewn anastomosis. Great care is made to keep the correct orientation of the pouch to avoid twisting the pouch on its vascular pedicle. The pouch is sutured to the anus, anastomosing to the denuded anorectal cuff with interrupted absorbable sutures placed circumferentially. A closed suction drain is placed in the presacral space behind the pouch, and the pouch itself is drained. A loop ileostomy is formed 40 cm from the ileal pouch at a previously marked site in the right lower quadrant.

The risk of the inflammation and dysplasia of the anal transitional zone left behind in a double-stapled technique is low, but present. Similarly, in a mucosectomy procedure, there is a risk of inadvertently leaving small islands of mucosa. For these reasons, long-term annual examinations and biopsies are recommended for all patients with IPAA regardless of the anastomotic technique. These examinations include pouchoscopy and are biannually performed. Biopsies of any retained rectal cuff or suspicious areas in the ileal pouch are required.

Maneuvers to Ensure Reach of the J Pouch

The J pouch should reach comfortably, without tension, to the anorectum. Maneuvers to achieve lengthening of the ileal mesentery include complete mobilization of the superior mesenteric artery off the retroperitoneum and up to the pancreas (including partially Kocher's maneuver of the duodenum). The ileocolic artery may be divided to increase length, with care taken to maintain collateral flow. Backlighting to outline mesenteric vessels is helpful in identifying mesenteric vessels while working on the mesentery. Scoring the mesentery overlying the superior mesenteric artery helps increase the mesenteric length, as does opening mesenteric windows between collateral vessels near the border of the small intestine. These maneuvers are performed before creating the pouch. After formation of the J pouch, the surgeon should wait 15 minutes to reassess viability of the J pouch.

If the J pouch still does not reach, the procedure is aborted by dropping the J pouch into the pelvis and attempting to suture it to a point on the sacrum or coccyx and create a loop ileostomy. Often the pouch mesentery stretches over time, and in 6 months, the patient can be reoperated on and the pouch anal anastomosis completed.

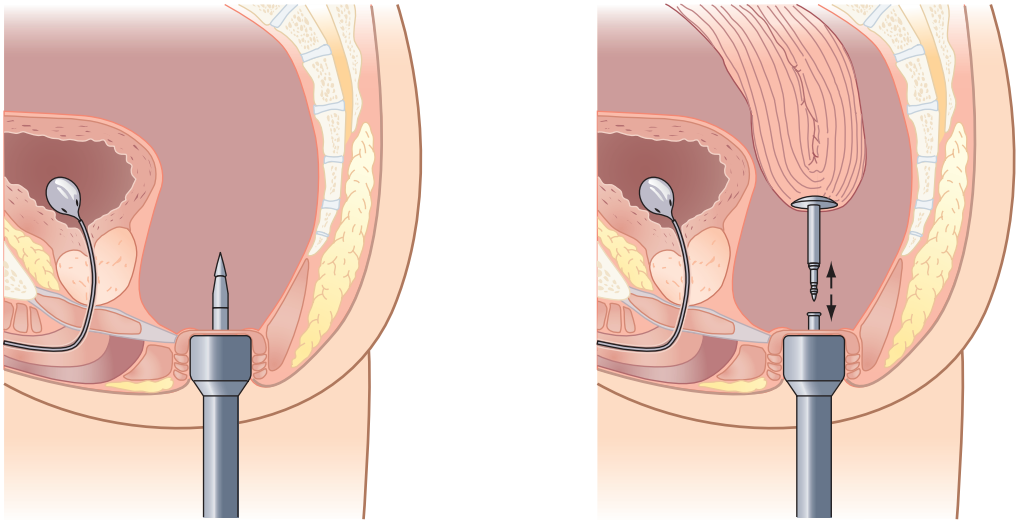

FIGURE 4 Fashioning of stapled ileal pouch–anal anastomosis. *(From Townsend CM, Beauchamp RD, Evers BM, et al, editors:* Sabiston textbook of surgery, *ed 18, Philadelphia, 2008, Elsevier Saunders, pp 1382, Fig 50-34.)*

Other Types of Pouches

An S pouch has two 10-cm to 12-cm limbs and uses its efferent limb (end of the terminal ileum) as the anastomosis to the anus. Evacuation difficulties are high, so functional results are not as beneficial as with a J pouch. The S pouch does provide extra length and therefore is reserved for cases where the J pouch cannot reach. A lateral isoperistaltic H pouch has a long outlet tract with similar sequelae of pouch distention, stasis, and pouchitis issues as the S Pouch. A four-loop reservoir (W pouch) was developed to increase capacity; however, studies have shown there is no difference in reservoir function in terms of incontinence, urgency, and soiling as compared with the J pouch.

Postoperative Course

Before closure of the ileostomy, the pouch should be studied to ensure healing of the pouch and pouch–anal anastomosis. Nonhealing is often manifested by a fistula or abscess. Digital rectal examination is performed to assess sphincter tone and anastomotic stricture or defects. Endoscopy shows the course of healing of the suture lines. The pouch is studied with Gastrografin (Bracco Diagnostics Inc., Princeton, N.J.) to detect evidence of leak, abscess, fistulas, or sinus tracts. Only after confirmation of no abnormality with the pouch should the ileostomy be closed.

Complications

Small bowel obstruction occurs in 20% of patients who undergo ileal pouch operations. Patients also encounter similar issues with sexual dysfunction (including postoperative infertility) and ileostomy complications after a total proctocolectomy. The literature indicates that 5% of patients have pelvic sepsis develop after an IPAA as a result of anastomotic dehiscence (with early or late manifestations as an abscess or fistula) or an infected pelvic hematoma. This rate may be higher, and patients who have pelvic sepsis have a higher likelihood of subsequent pouch failure. Hence, pelvic sepsis should be treated aggressively with intravenous antibiotics and drainage of the abscess. Some studies have shown that pouch failure rates for patients with development of a leak after a hand-sewn anastomosis to be higher than those who had a stapled anastomosis. The incidence rate of pouch-vaginal fistula ranges from 3% to 16%. It requires surgical correction either through an abdominal or perineal approach. Ileoanal anastomotic stricture occurrence rates vary from 5% to 38%. Management includes finger dilation or repeated dilations with anesthesia and, rarely, a transanal approach with excision of the stricture and pouch advancement.

The most frequent long-term complication is pouchitis or nonspecific inflammation of the ileal pouch. Medical management with oral metronidazole or ciprofloxacin and probiotics is usually successful, but those with severe medically refractory pouchitis may need diversion or pouch excision.

Colectomy With Ileorectal Anastomosis

The colectomy with ileorectal anastomosis (IRA) is rarely performed for UC. A select group for patients—those who have indeterminate colitis and those who are young with good anal continence and good rectal compliance, with only mild inflammation of the rectum—are considered. It may be considered in young females who want to preserve fertility and avoid a stoma, but it is rare to have a patient with UC who requires surgery but has minimal rectal inflammation. Moreover, the lack of a pelvic dissection reduces the risk of sexual dysfunction. However, patients tend to have more bowel movements per day. In addition, disease and the potential for malignancy are left behind. The risk of malignant disease of the rectum after IRA is approximately 10%. Twenty-five percent of patients after IRA require a proctectomy as a result of severe proctitis. IRA is contraindicated in patients who have moderate to severe inflammation of the rectum, dysplasia, or cancer of the rectum, perianal disease, and known anal incontinence.

Total Proctocolectomy With Continent Ileostomy (Kock's Pouch)

The continent ileostomy was introduced by Kock for patients who did not want to wear an ostomy appliance for a Brooke end ileostomy. A nipple valve is created with intussusception of a portion of ileum into the planned reservoir. The procedure has essentially been abandoned in the management of UC because of the excellent long-term outcomes with the ileal J pouch and the large complication rate associated with the Kock's pouch. These complications include obstruction and incontinence, usually as a result of nipple valve slippage or dysfunction in 50% of patients. Patients develop difficulty with catheterization of their pouch. Surgical reconstruction is the only option for repair. Twenty-five percent of patients also suffer from pouchitis, 25% from intestinal obstruction, and 10% from

pouch fistulas. Most patients with Kock's pouches eventually require resection and formation of an end ileostomy.

CONCLUSION

Many options exist in the surgical management of chronic UC. An approach is tailored according to the individual patient's preferences and their comorbidities and severity of disease.

The Management of Toxic Megacolon

Bashar Safar, MBBS, and
James W. Fleshman, MD, FACS, FASCRS

OVERVIEW

Toxic megacolon (TM) is a serious, life-threatening condition that can result as a complication of ulcerative colitis, Crohn's colitis, and infectious colitides such as pseudomembranous colitis. TM was first described in 1950 by Marschak and colleagues as a complication of colitis, and it is defined as segmental or total colonic distension of 6 cm in the presence of acute colitis and signs of systemic toxicity.

Rapid dilation of the proximal colon produces the radiographic picture. The thickened, severely inflamed distal colon is, however, the segment of colon in which perforation is imminent; moreover, pneumatosis can be seen radiographically. The dilated proximal colon will perforate only if the inflammatory process has weakened the wall of the cecum. Most commonly the point of perforation is the splenic flexure, where a walled-off perforation is found in a phlegmon involving the colon, spleen, and omentum.

Systemic manifestations of toxicity distinguish patients with megacolon from those with colonic dilation due to other causes, such as colonic pseudoobstruction or Hirschsprung disease. Aggressive conservative management is increasingly advocated and may spare some patients an operation. However, prompt recognition of disease severity and surgical intervention may be lifesaving.

INCIDENCE AND ETIOLOGY

TM can result from any disease that causes inflammation of the colon. Although it is most readily recognized as a complication of inflammatory bowel disease (IBD), other causes include pseudomembranous colitis, bacteria *(Salmonella, Shigella, Campylobacter, Entamoeba),* and ischemic colitis (Box 1).

The incidence of the syndrome varies on the basis of the etiology and the study population. The incidence of TM in IBD has been the most extensively reported and has been estimated to range between 1% and 5% of patients with IBD. However, the incidence is believed to be decreasing because of improved medical management of patients with severe colitis. Conversely, pseudomembranous colitis, which occurs in up to 1% of hospitalized patients, is responsible for an increasing number of patients with TM.

Since 2000 *Clostridium difficile* infections were observed to be more frequent, more severe, more refractory to standard therapy, and more likely to relapse than previously described. These observations have occurred throughout North America and Europe and have been attributed to a new strain (BI/NAP1/027) of *C. difficile.* In a 2008 report of *C. difficile* toxic colitis, only 10% of cases required admission to intensive care, and 2.5% required an emergency colectomy. Other causes of TM are exceedingly rare.

The mechanisms responsible for the toxic dilation of the colon are not fully understood and probably involve a combination of factors, including severe inflammation and local mediator release. Inflammatory damage to colonic mucosa due to severe colitis seems to extend into the smooth muscle layer in TM, resulting in damage and paralysis. Bacterial translocation occurs and results in bacteremia and the toxic/septic response.

Nitric oxide generated by severely inflamed smooth muscle cells in the colonic wall may play an important role in dysmotility and atony, resulting in dilation of the colon proximal to the severely inflamed segment, which in turn leads to the development of TM. In fact, *toxic megacolon* may be a misnomer, because the dilated segment is not the toxic segment, nor is it the cause of the syndrome. In the majority of patients experiencing toxicity from colitis, there is minimal dilation. Thus the terms *severe toxic colitis* and *fulminant colitis* are more accurate.

A number of factors can lead to the induction or exacerbation of colonic dysmotility and dilation. These include hypokalemia, antimotility agents, opiates, anticholinergics, antidepressants, barium enema, and colonoscopy. These, combined with an inflammatory process, can be deadly.

DIAGNOSIS

Patients with IBD are at highest risk of developing TM early on in the disease course. Up to one third of patients with IBD develop colonic dilation within 3 months of their diagnosis, and another two thirds do so within the first 3 years. The mean duration of disease before development of TM has been reported to be between 3 and 5 years.

Toxic megacolon must be suspected in all patients who come in with abdominal distension, diarrhea, and systemic toxicity. In patients with IBD, dilation of the proximal, less inflamed colon frequently complicates severe distal colitis. In such cases the diagnosis

is often preceded or accompanied by severe bloody diarrhea, fever, chills, and abdominal pain. Patients are thought to develop TM when massive colonic distension and functional obstruction ensues and results in worsening signs of systemic disease, including tachycardia and hypotension. The physical examination finding is often remarkable for significant abdominal tenderness, localized or generalized.

The diagnosis of toxic megacolon should be suspected on the basis of physical and radiographic findings, so a thorough history and physical examination are crucial. History of previous bouts of IBD (extent of colonic involvement, previous therapy, extracolonic manifestations), recent use of certain medications (broad-spectrum antibiotics, steroids, antimotility agents, chemotherapy), foreign travel, human immunodeficiency virus (HIV) status, and recent barium enema study must be carefully elicited.

Jalan and colleagues (1969) described the best accepted clinical criteria for diagnosis as any three of the following: fever of 101.5° F (38.6° C) or higher, heart rate of 120 beats/min or higher, white blood cell count greater than 10.5×10^6/L, or anemia. Patients should also have one of the following: dehydration, mental changes, electrolyte disturbances, or hypotension.

A plain abdominal radiograph can aid in making the diagnosis and is crucial in following the disease course. Dilation of the ascending or transverse colon is typical and can vary from 6 cm, which is suggestive of the diagnosis, to as much as 15 cm. The absolute width of the colon is not as important as the rate of expansion along with the overall clinical condition. Small bowel as well as gastric distension may also be present and may be a significant predictor of TM and multiorgan dysfunction in severe ulcerative colitis. Thickening and edema of the wall of the transverse and left colon, with a thin trail of luminal air or none at all, is the typical finding on the left side.

An initial computed tomographic (CT) scan of the abdomen and pelvis can confirm the diagnosis and exclude pneumatosis or colonic perforation. In addition, CT scan may be useful to determine the etiology of the colonic dilation and exclude other causes of colonic distension, such as obstructing colon cancer or a diverticular stricture. Pronounced thickening of the colonic wall is more suggestive of *C. difficile* and IBD as the causative factors.

Laboratory tests should be obtained to both confirm the diagnosis and identify any correctable abnormality. Anemia and leukocytosis are frequently present. Electrolyte abnormalities are common, as a result of the severe inflammation, and they lead to increased fluid loss from the colon; salt and water losses can lead to severe dehydration and hypokalemia. Hypoalbuminemia may herald a poor prognosis. Stool samples should be sent for culture, sensitivity, and *C. difficile* toxin assay. Blood cultures should be considered, as bacteremia occurs in up to 25% of patients with TM.

Limited endoscopy may be useful, but incorrect treatment can result in significant harm to the patient. Endoscopy is especially useful in patients with no previous diagnosis of IBD. Complete colonoscopy should be avoided because of the high risk of perforation, but biopsies can identify inclusion bodies in the case of cytomegalovirus colitis; pseudomembranes in the rectum and sigmoid colon suggest *C. difficile* colitis.

THERAPY

Management of patients with TM and severe acute fulminant colitis necessitates a multidisciplinary approach with early surgical consultation. Communication between the admitting team and the surgical team is crucial. Clear management goals should be defined at the time of diagnosis, and criteria for continuing medical management versus surgical intervention should be set out at the outset and communicated to the patient and the patient's family. An aggressive attempt at medical management is warranted; however, in the absence of measurable improvement or any deterioration, surgical intervention should be instituted early to avoid the high rate of morbidity and mortality associated with colonic perforation.

Medical Therapy

All patients with TM should be admitted to the intensive care unit. Bowel rest and decompression with nasogastric tube is recommended, along with frequent clinical assessment by the nursing and medical staff. Complete blood cell counts, electrolyte measurements, and serial abdominal plain radiographs are reviewed every 12 hours initially and then daily as the patient improves. Anemia, dehydration, and electrolyte deficits, particularly hypokalemia, may aggravate colonic dysmotility and should be treated aggressively. All antimotility agents, opiates, and anticholinergics should be discontinued. Patients should be given prophylaxis for both gastric stress ulcerations and deep venous thrombosis. Broad-spectrum antibiotics are recommended to reduce septic complications. Significant improvement in the intensive care management of these patients has led to a significant decrease in morbidity and mortality.

Management of Patients With Inflammatory Bowel Disease

Patients known to suffer from IBD who show signs and symptoms of TM should be managed as mentioned above with the addition of high-dose intravenous steroids. A typical dose is hydrocortisone 100 mg every 8 hours or an equivalent dose of other intravenous steroids. High-dose steroids have not been shown to result in higher risk of colonic perforation.

Aminosalicylic acid products have no role in the management of TM. They are used in patients with mild to moderate disease, and their clinical efficacy is not proven in severe disease. Other immunosuppressive medication, such as cyclosporin and anti–tumor necrosis factor-alpha (TNF-α) agents, have been successfully used in the management of severe steroid-refractory colitis; however, their use in patients with TM has not been substantiated beyond anecdotal case reports. Their use is not recommended for the management of TM.

Frequent patient repositioning resulting in redistribution of air in the lumen of the colon has been reported to be successful in decompressing colonic distension in patients with TM. The true value of this technique has not been confirmed by randomized trial;

however, the intervention is fairly simple and should be attempted. Medical therapy is reported to be successful in 50% to 75% of patients with TM.

Management of Patients Without Inflammatory Bowel Disease

Management of patients with other diseases follows the same medical principle of aggressive supportive therapy and bowel rest. In addition, depending on the cause, other interventions may also be appropriate.

Clostridium Difficile Colitis

Withdrawal of the offending antibiotics and initiation of oral vancomycin, 500 mg four times daily, taken with intravenous metronidazole, 500 mg three times daily, are effective in the majority of patients. Patients with severe ileus may have the vancomycin delivered through an enema preparation or by colonoscopic spraying of the mucosa. It has been suggested that earlier surgical intervention may be lifesaving. Patients who survived had lower white blood cell counts and less preoperative multisystem organ failure, were less likely to be taking pressors preoperatively, and were more likely to be operated on sooner than patients who did not survive.

In another study, leukocyte counts greater than 50,000/mm^3 and lactate at concentrations greater than 5 mmol/L were found to predict mortality. Both of these reports suggest that earlier intervention saves lives. Most patients need an aggressive medical management trial with close observation; however, in the presence of any deterioration, delaying surgical intervention may result in higher rates of morbidity and mortality.

The surgical management of patients with TM secondary to *C. difficile* colitis is similar to that in patients with IBD.

Surgical Therapy

Free perforation, massive hemorrhage, and progression of colonic dilation are absolute indications for surgery. Failure to improve within 48 hours is a relative indication. Some authorities suggest continuing medical therapy for up to 7 days in the absence of any signs of deterioration, but proponents of early surgical intervention highlight the high mortality rate once colonic perforation occurs (40% vs 9%). Goligher and colleagues' (1970) popular dictum to "save the patient, not the colon" was based on a study that reduced the rate of perforation from 32.5% to 11.6%, and mortality rate from 20% to 7%, by means of early surgery. The investigators concluded that surgery should be performed shortly after diagnosis. D'Amico and colleagues (2005) confirmed this finding; they suggested that lower mortality rates (13%) can be achieved by surgical intervention at the time of diagnosis with no trial of medical therapy. However, as mentioned previously, medical management can be effective in 50% to 75% of patients and should be instituted without delay. Patients should be observed closely for signs of deterioration, but the length of medical management should be limited to 7 days, provided that the patient is stable clinically or improving.

Subtotal colectomy and end ileostomy is the treatment of choice, once surgery is deemed necessary. Because of the amount of dilation in the colon, laparoscopy should be avoided in patients with TM.

Upon admission of a patient with TM, the enterostomal therapist should be consulted as soon as possible for marking the site of an end ileostomy; a generous midline incision is used to gain access to the abdominal cavity. Mechanical bowel preparation should be avoided.

Once the abdomen is entered, the bowel should be handled with care; the bowel is fragile, and the likelihood of intraoperative perforation is high. The hepatic flexure and splenic flexure should be mobilized and the colonic mesentery divided close to the bowel wall to avoid damage to retroperitoneal structures, including the ureters and nerves. The colon mesentery can be divided with Kelly clamps and ties; alternatively, a hemostatic coagulation device can be employed. The rectum should be divided as low as possible to avoid a rectal stump blowout, and the staple line should be marked with long, permanent sutures for future identification. A large mushroom catheter is left in the rectum, taped to the inside of the thigh to prevent dislodgment, for continued drainage of the rectal stump.

The patient is transported postoperatively back to the intensive care unit, where fluid resuscitation and further support are provided (e.g., ventilatory support, antibiotics, pressure support as needed). The nasogastric tube may be removed and enteric feeds initiated upon resumption of gastric motility. The rectal tube should remain in place for a minimum of 5 days or until the patient is ready to be discharged; perioperative antibiotics should be discontinued within 24 hours, unless a perforation is encountered. Intravenous steroids should be weaned rapidly to the patient's preoperative dose over the course of a few days.

OUTCOMES

The rate of mortality as a consequence of TM has improved markedly since 1980. Jalan and colleagues reported an overall mortality rate of 45% in 1969, but studies with no deaths were being published by the end of the 1970s.

Teeuwen and colleagues (2009) reviewed the literature for colectomy in 1257 patients with colitis who were operated on in an acute setting (urgent or emergency colectomy). Since the 1970s, there has been a shift in incidence: TM has become less common (71.1% from 1975 through 1984 to 21.6% from 1995 through 2005) than severe acute colitis not responding to conservative treatment (16.5% from 1975 through 1984 to 58.1% from 1995 through 2007). Mortality rate decreased from 10.0% to 1.8%, and the review suggests that improvement in medical management of IBD may be responsible for the decreases in incidence of TM and overall mortality.

SUMMARY

TM is a severe, life-threatening emergency that can result from a variety of conditions, but it is most commonly associated with severe ulcerative colitis. Improved medical management has resulted in a decrease in its incidence due to IBD; however, increasing use of broad-spectrum antibiotics has lead to a sharp increase secondary to *C. difficile* colitis. Early recognition and multidisciplinary management are crucial if significant morbidity and mortality are to be avoided.

Crohn's Colitis

Russell Farmer, MD, and Susan Galandiuk, MD

INTRODUCTION

Originally described as inflammation of the terminal ileum, Crohn's disease (CD) has grown to describe a group of patients with myriad clinical presentations. Colitis is one of the most common of these. CD is seen primarily in the United States and Europe, with an incidence of 2 to 4 patients per 100,000, but there has been a recent increase in Crohn's colitis (CC) in Asian countries as well. Crohn's patients have a bimodal age distribution at the time of presentation (20s-30s or 50s-60s) and with a female predominance. CD is a complex disease whose etiology is still not clear. Both genetic and environmental factors play a role. Whites, especially Ashkenazi Jews, are also more likely to develop CD. Patients with a positive familial history of Crohn's are 20 times more likely to develop CD. Although high-risk variants of the NOD2/CARD 15 gene have been identified in some patients, this has not yet been found a reliable diagnostic clinical utility in practice. The best-studied environmental factor is cigarette smoking. There is increasing recognition that, like ulcerative colitis (UC), patients with CC are at increased colorectal cancer risk (CRC) due to the presence of long-standing chronic inflammation. This is true for many chronic inflammatory conditions, such as inflammatory bowel disease (IBD), Barrett's esophagitis, or hepatitis, where chronic inflammation leads to an increased risk of malignancy. This risk is further increased by the coexistence of sclerosing cholangitis, a family history of CRC, and increasing duration and extent of colonic inflammation. Pertinent clinical factors that should be foremost in the evaluation of CC patients include the anatomic location and distribution of the disease, the acuity of the disease, and the nature of the underlying disease (inflammatory, obstructing, or fistulizing). These will guide both medical and surgical treatment.

CLINICAL FEATURES

Patients with CC have an array of clinical presentations. Frequently, patients will present with vague and intermittent abdominal pain accompanied by diarrhea. Patients may also describe hematochezia; melena is rare. Given the wide differential diagnosis for these symptoms, infectious and parasitic causes should be excluded at initial evaluation. Frequently, patients will present describing symptoms associated with recurrent inflammatory colitis that they experience or recognize as a "Crohn's flare." Advanced colitis may present in the form of major lower gastrointestinal bleeding, colonic perforation, large bowel obstruction, or fulminant colitis. Pancolitis is among the most common manifestations of colonic CD, which makes differentiation from UC difficult. Direct mucosal examination using endoscopy with biopsy as initial evaluation is essential. Only one third of CC patients will display granulomas on biopsy. Frequently, computed tomographic (CT) scanning is used as an adjunct in diagnosis and can potentially elucidate overlooked areas of foregut or midgut disease, thereby establishing a diagnosis of CD versus UC. CT scanning can also indicate the presence of associated intra-abdominal abscesses. Small bowel follow-through with barium is useful in patients with established diagnoses of CD to evaluate for active small bowel disease. The clinical scenario of acuity versus chronicity will often determine the order of diagnostic testing. For example, one should seldom, if ever, plan colonoscopy in the face of an acute abdomen; a CT scan (preferably with contrast) would better suit. Conversely, endoscopy is a good starting point for a patient with chronic complaints. Approximately one quarter of patients with CD will have coexisting perianal CD. This can include anal fissures, anal strictures, and anal and rectovaginal fistula. The presence of such perianal disease simplifies diagnosis.

In order to delineate the potentially nebulous diagnosis of CD, the Working Party of the World Congress of Gastroenterology has produced successive criteria for classifications of CD. While not used as widely as traumatic or oncologic classification schema, this system established in Vienna (1994) and later updated in Montreal (2005) codified the predominant clinical forms of CD (Table 1). A portion of CC patients present with disease that is limited to isolated inflammatory episodes that can be managed medically. Conversely, some will develop significant colonic strictures or colonic perforation and fistula formation, either of which may require operation. Spontaneous sigmoid colon to terminal ileum fistula due to inflammation or obstruction is another common operative finding during operative exploration and should raise the index of suspicion for CD.

DIAGNOSIS

Patients with concomitant extracolonic CD (15%) related to IBD often simplify diagnosis. However, patients will frequently present with isolated colonic disease, making the underlying differentiation between CD and UC difficult. Use of the term *indeterminate colitis* has been employed in patients with acute colitis whose clinical and pathologic diagnoses remain indistinguishable following resection. The imperfection of pathologic examination requires synthetic reasoning by the clinician. Up to one third of patients with the pathologic diagnoses of CD or UC will be in error. Classic findings associated with CD include "skip lesions"—namely segments of intestine that appear thickened and inflamed with intervening normal segments. CC can, however, appear "UC-like" with continuous disease extending from the rectum proximally on endoscopy. External examination of the bowel shows "creeping fat"—mesenteric fat that has begun to encircle the bowel in areas of active disease. When opened, surgical specimens show a characteristic "cobble

stoning" or "bear claw" pattern with deep linear ulcers, usually along the mesenteric border of the colon (Figure 1). Macroscopically, patients with UC virtually always have some rectal disease with proximal extension, lending to a diagnosis of CD in any patient with a normal rectum and proximal colitis. Frequently, findings at operation and surgeon judgment will prove the definitive means of differential diagnosis between CD and UC.

Histology

In many patients with pancolitis, it is difficult to make an accurate diagnosis, as only one third of patients with colonic CD will display granulomas on biopsy. Other criteria, such as the presence of a transmural lymphoid aggregated in an area not deeply ulcerated, are needed to make a diagnosis of CD. Recently, "indeterminate colitis" has been adopted by pathologists for any biopsy that shows features in common with both CD and UC or for inflammation that is so profound as to preclude diagnosis.

Serology

While serology is readily available and antisaccharomyces cerevisiae IgG and IgA, anti-OmpC IgA, as well as other antibodies, have been described more frequently in patients with CD, this is not foolproof and is only one piece of supporting evidence to make a diagnosis. It is neither 100% specific nor sensitive. Similarly, genetic markers for CD do not yet have proven clinical utility.

TREATMENT

In treating the patient with CC, it is first important to differentiate which anatomic areas are affected and the type of disease (inflammatory, structuring, or fistulizing). With respect to patients with colonic CD, medical therapy will be ineffective in the presence of fibrotic strictures. The most frequently overlooked obstruction of this type that results in failure of medical therapy is the presence of an anal or lower rectal Crohn's stricture. Despite patients being on intensive medical treatment, this is often overlooked or not

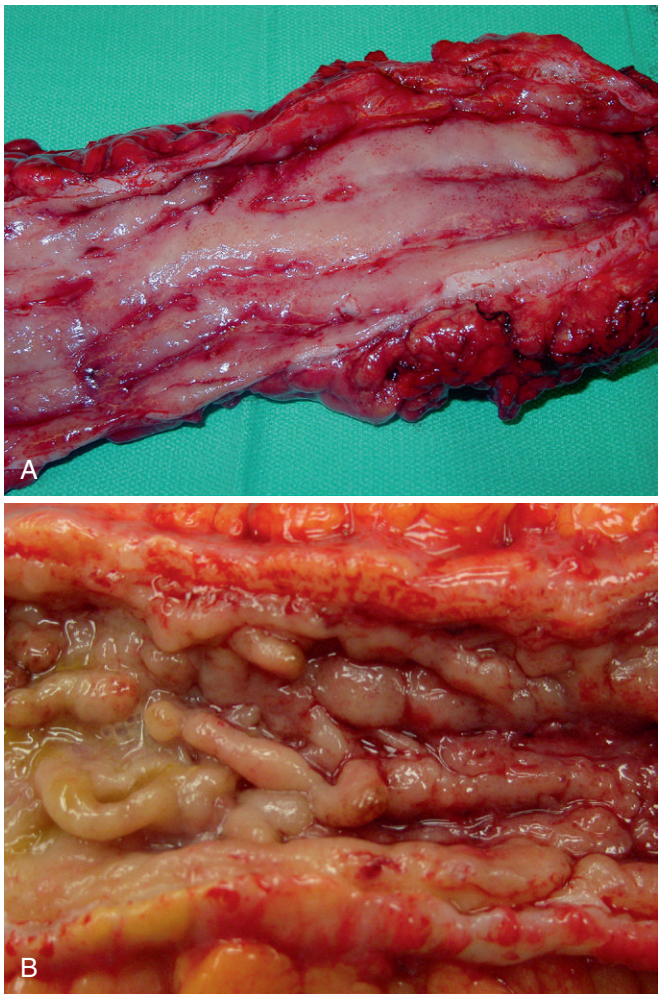

FIGURE 1 **A,** Bear claw or long linear ulcers in the colon of a patient undergoing resection for Crohn's colitis. **B,** Close-up view of colonic mucosa showing "cobblestoning" indicative of severe Crohn's with a combination of linear and transverse ulcerations. The raised areas consist of retained mucosa.

evaluated. If this is not dilated, medical therapy will not likely be effective. The same applies for more proximal colonic strictures if they pose a significant obstruction. Fibrotic strictures are less likely to respond to antiinflammatory medications and more likely to require surgical treatment.

Medical Management

The last 10 years have seen significant changes in the medical treatment of patients with CC. There are two treatment philosophies regarding medical management of CC, as there are for Crohn's treatment in general. One is the *bottom-up* strategy—that is, starting with the safest low-side-effect medications first and then gradually building up toward medications that have more side effects and are stronger (Table 2). The other is the *top-down* strategy, where one starts with more powerful agents with potentially more side effects first (see Table 2). There are pros and cons to both approaches. Advocates of the top-down approach hope to break the cycle of chronic inflammation and scar formation associated with chronic CD and limit permanent architectural damage to tissue. There are, however, cost issues to consider, such as the fact that biologic agents, a mainstay in the therapy of severe CD, are expensive and out of reach of many

TABLE 2: Organization of medical therapy for Crohn's colitis

Systemic effects	Top-down
Fewest	Other: • Antibiotics/metronidazole • Probiotics • 5-ASA and derivatives Steroids: • Intravenous prednisone • Oral prednisone • Oral budesonide Antimetabolites: • Methotrexate • Azathioprine • 6-Mercaptopurine
Most	Biologics: • Imfliximab • Adalimumab • Certulizumab pegol
Systemic effects	**Bottom-up**
Most	Biologics: • Imfliximab • Adalimumab • Certulizumab pegol Antimetabolites: • Methotrexate • Azathioprine • 6-Mercaptopurine Steroids: • Intravenous prednisone • Oral prednisone • Oral budesonide Other: • Antibiotics/metronidazole • Probiotics • 5-ASA and derivatives

patients who have no or limited insurance. In addition, many insurance carriers have requirements that patients must have tried other agents prior to proceeding to biologic therapy because of their associated expense.

The safest medications for CD are generally antiinflammatory drugs, which include sulfasalazine and the 5-ASA drugs. The 5-ASA drugs are modifications of sulfasalazine without the sulfapyridine ring. These have been modified into many different forms, which determine their site of drug release. There are many designed for colonic drug delivery, including Asacol, Dipentem, Apriso, and Lialda. Such drugs can also be administered in topical form, such as via suppository (Canasa), which delivers the drug to the rectosigmoid or in small-volume enema form (Rowasa), which delivers the drug to the rectosigmoid and left colon. If the use of these drugs alone is ineffective at inducing disease remission, steroids are frequently utilized in the form of "pulse therapy." Due to the significant side-effect profile of steroids with prolonged use with side effects such as hypertension, increased blood sugar, cataracts, aseptic hip necrosis, striae, Cushingoid appearance, and so on, the goal is to use these agents for a short time but in a fairly potent dose that rapidly deescalates. Typical regimens for severe disease would be to start a patient on 60 mg/day and then taper down by 10 mg every 2 weeks. Budesonide

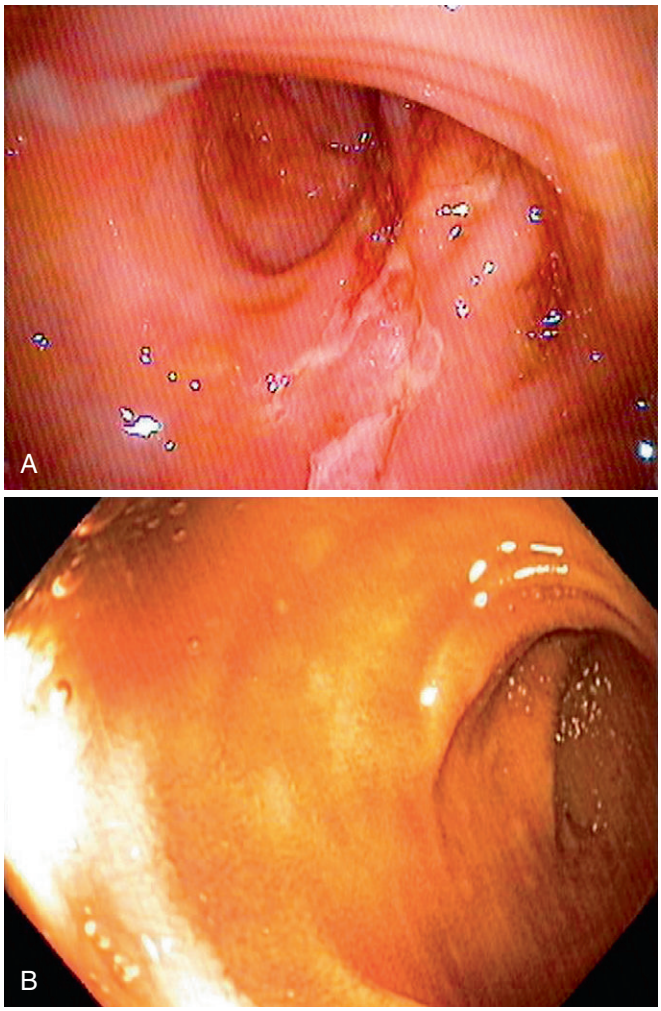

FIGURE 2 **A,** Colonoscopic view of a patient with severe Crohn's colitis before and **(B)** 1 year after beginning adalimumab therapy.

is a useful oral steroid that can be considered to be a *topical* steroid, since it is nearly completely metabolized as it passes through the enterohepatic circulation. This medication is useful for treating cases of mild to moderate colitis. Although its effect is largely topical, it does have some slight degree of systemic effect, and bone density must be monitored in patients who are on this medication long term. If oral steroids are ineffective, patients are frequently hospitalized for intravenous steroid therapy, or biologic therapy is considered. Intravenous therapy typically would consist of 100 mg of hydrocortisone intravenously every 6 to 8 hours. Clinical improvement should be seen within 48 hours.

There are currently three "biologic" agents that are FDA-approved for the treatment of CD in the United States. *Biologics*, when speaking of IBD, is the commonly used term for monoclonal antibodies directed against tumor necrosis factor alpha. These include Cimzia (Certolizumab pegol), Humira (Adalimumab), and Remicade (Infliximab). The latter is given as an intravenous infusion over 2 hours. The former two are given subcutaneously. Each of these agents requires a loading dose and then is followed by maintenance doses. Side effects of biologic agents include reactivation of tuberculosis or histoplasmosis, as well as an approximately fivefold increased risk of developing non-Hodgkin's lymphoma. In young adults who are also receiving antimetabolite therapy (azathioprine, 6-mercaptopurine), there is a greatly increased risk of fatal hepatosplenic T-cell lymphoma. The introduction of biologic therapy has done much to decrease the frequency with which patients with colonic CD require surgery (Figure 2).

For patients in whom there is a desire to maintain remission, a class of medications known as antimetabolites is frequently used. This comprises both azathioprine, as well as its metabolite 6-mercaptopurine. Both of these medications take approximately 4 months after they are started for their effect to begin, and as such they cannot be used for treatment of flares. The two main side effects with these medications are, as with biologics, an increased risk of non-Hodgkin's lymphoma, as well as an increased risk of leukopenia and pancreatitis. One can, with some reliability, predict individuals at higher risk of developing these latter two side effects by genetic testing to determine which individuals have a lower-efficiency enzyme (thiopurine methyl transferase) for metabolizing this drug. This type of genetic testing is in routine clinical practice.

Surgical Management

The indications and techniques for operation in CC are unique in scope. Determining the short- and long-term goals of surgery cannot be overemphasized prior to any operation for CD. Surgery for CD will only relieve the intestinal complications of the disease; it does not "cure" CD. The surgeon should include the patient's family, gastroenterologist, and likely psychiatrist in face-to-face preoperative consultation to determine what the desired result of surgery will be. Choice of a specific operation must be decided at an individual patient level because there are many factors that go into selection of the most appropriate operation for a given patient. This includes the condition of the anal sphincter, the coexistence of perianal disease, the presence or absence of an anal canal/lower rectal stricture, the presence or absence of small bowel CD, patient age and body habitus, their occupation, and their level of intelligence. The surgeon should pay particular attention to the duration of medical therapy, results of pathologic examinations, previous endoscopy, and previous operations, if any. A careful history of fecal continence should also be taken to avoid an exaggerated colectomy on patients likely to become incontinent. Also, the continence history may elucidate the presence of perineal CD in a patient with progressive difficulty with controlling, initiation, or terminating defecation. Performing an ileorectal anastomosis in such a patient could be devastating to quality of life and exacerbate underlying fluid and electrolyte imbalances from long-term corticosteroid treatment.

With the progression of medical therapy, the majority of patients undergoing operations for CD are now doing so following a prolonged period of treatment with either intravenous steroids or biologic agents. The vigilant surgeon would be traditionally reticent to operate on a patient who is on these medicines for fear of complications. Recent evidence shows, however, that there is little difference in outcomes in patients undergoing colectomy for CD in either the presence or absence of infliximab or steroids (Mascarenhas C, et al., 2012). Similarly, there is no difference in the complication rate for those patients receiving these medicines postoperatively (Regueiro M, et al., 2011). Furthermore, CD medical management with high-dose steroids or biologics that has "failed" is an indication for surgery. "Failed" medical treatment is considered when there is either progression of disease while taking these medicines or having no response to therapy over a 3- to 6- month period. These patients frequently present with stricture or obstruction, or any combination of the following operative indications.

STRICTURE/OBSTRUCTION

A significant majority of CD patients will present with a stricture of the small bowel, terminal ileum, or colon as the initial sign of disease. Nasogastric decompression, correction of electrolyte and fluid imbalance, and nutritional support are standard. Medical management of active CC is possible, but the surgeon must be vigilant to prevent a prolonged period of parenteral nutrition and antiinflammatory agents, which will be a potential setup for operative disaster. CT and water-soluble contrast enema are helpful in outlining the area of active CC resulting in intestinal blockage. Endoscopic dilation of colonic strictures in CD is increasingly performed, but it should be relegated to the hands of expert endoscopists because the risk of perforation is significant. This obviously also applies to stent placement. The risk of malignancy in CC strictures is real. If the affected area is not resected, biopsies should be taken to exclude cancer. Obtaining adequate endoscopic biopsies of strictures may, however, be difficult due to the fibrotic nature of these strictures.

PERFORATION, FISTULAE, AND ABSCESS

A potential first sign of CD is the development of small bowel or colonic perforation and its sequelae. Frequently, patients will present with chronic perforation that has resulted in fistula formation, development of abscess, or the presence of phlegmon. These complications are rendered more difficult to diagnose in a large subset of CD patients given the immunosuppressive nature of many maintenance medications for CD. Steroids, in particular, tend to mask inflammation and chronic leukocytosis. A CT scan is the modality of choice to determine the location of active disease. While a discrete abscess may not be seen, the presence of fatty inflammation on CT often points to the site of ongoing perforation or fistulae.

The preferred method of treatment for pericolonic abscess is bowel rest, nutritional support, parenteral antibiotics, and image-guided percutaneous drainage. An urgent operation is only needed in the case of fecal or purulent peritonitis. If not amenable to percutaneous drainage, colonic resection and abscess drainage are necessary. A classic scenario is the presence of an ileosigmoid fistula resulting from terminal ileitis, the traditional management of which has been to free the inflamed ileum from the sigmoid colon, perform an ileocolic resection, and repair the sigmoid colon primarily. Sigmoid resection may be required if there is significant fibrosis or inability to achieve a safe primary repair. A diverting stoma should be considered for patients whose disease precludes safe anastomosis; that is, there is significant associated malnutrition or pelvic inflammation to warrant concerns regarding postoperative healing.

MASSIVE LOWER GASTROINTESTINAL BLEEDING

CC patients rarely present with lower GI bleeding severe enough to require surgery. Bleeding may be in the form of melena or hematochezia, depending on the site of colonic disease. Initial therapy is medical. Endoscopic control of bleeding is difficult, considering the multifocal or pancolonic nature of CC. It is unusual for CC patients to require significant transfusion for bleeding. The administration of more than 2 units of blood over a 24-hour period, and certainly any sign of hemodynamic abnormality, should prompt surgical therapy. The evaluation of the rectum is essential and repeatable in the operating room using rigid proctoscopy. Rectal resection for severe bleeding is rarely indicated to complement total abdominal colectomy. Anastomosis is not warranted in these critically ill patients, and ileostomy should be performed.

SEVERE COLITIS/FULMINANT COLITIS/TOXIC MEGACOLON

Occasionally, patients with CC will develop progressive colonic disease to the point of systemic inflammatory response. This clinical manifestation of colonic mucosal destruction has been given several different names, but the end or final clinical presentation is the same. Patients develop fever, leukocytosis, tachycardia, and

hypoalbuminemia, which are frequently accompanied by hemodynamic instability. Ileus may be present, which may result in colonic dilation seen on plain abdominal film, leading to the moniker of "toxic megacolon." Initial care of these patients is supportive. Standard therapy of euvolemic restoration, antibiotics, gastric decompression, and urine monitoring with a Foley catheter should be supplemented with advanced hemodynamic monitoring in a critical care setting. The use of steroids as adjunctive therapy may be helpful. Operation is indicated for signs of disease progression and nonresponse to conservative treatment. Ideally, surgery should occur prior to bowel perforation. The choice of vasopressors as additional therapy is unwise because it will precipitate ongoing mucosal ischemia and only exacerbate the etiology of the disease. If a patient has progressed to the point of hypotension, colectomy is warranted.

EXTRACOLONIC MANIFESTATIONS OF CROHN'S DISEASE

Many forms of extracolonic CD exist. Commonly, patients will have disease present in the small bowel with similar presentation as in CC: stenosis and stricture, perforation with fistula formation, or perforation with abscess. These are managed largely in the same manner as CC, with the exception of those patients with recurrent small bowel Crohn's being at risk for short-gut syndrome from multiple resections. These patients are best treated with measures designed to preserve absorptive capacity and small intestinal length such as strictureplasty. Other manifestations include perineal Crohn's, cutaneous disease such as pyoderma gangrenosum, Crohn's uveitis, ankylosing spondylitis, primary sclerosing cholangitis (PSC), and growth retardation in children. Many of these improve with surgery; PSC and spondylitis are exceptions to this, however, and are often progressive. Growth retardation in children is of specific concern. Prompt surgery is needed in children with active CC because ongoing inflammation can result in epiphyseal closure and near cessation of growth.

OPERATIONS FOR CROHN'S COLITIS

The extent of surgical resection for CC is defined by the anatomic distribution of disease as well as the nature of the Crohn's inflammation. Patients undergoing surgery for CC require particular perioperative and operative considerations (Box 1). CD patients are often malnourished. Measuring serum albumin and prealbumin prior to operation serves as a means of determining nutrition status. Recognizing occult malnutrition is key, because it is a major operative risk factor. If these nutritional parameters are insufficient, increasing enteral nutrition, if possible, is desired. Patients unable to tolerate a diet may require supplemental parenteral nutrition. Midline incisions are indicated for virtually all operations for CC to preserve all four quadrants for stoma creation, if necessary. Special care must be taken in the creation of these stomas and in the abdominal incisions made because many CD patients will have these stomas for life.

BOX 1: Essential operative considerations

1. Discuss possibility of diversion (+/– temporary)
2. Mark stoma sites prior to operation*
3. Modified lithotomy position*
4. Intraoperative technique:
 a. Work from normal to abnormal tissue
 b. Frequently, fingers better than scissors for dissection of severely inflamed bowel

*Even if not anticipated to need a stoma or special positioning.

Stoma complications can lead to the need for stoma relocation, which can be made more difficult if the original operation was not planned carefully.

In the elective operative patient, antibiotic prophylaxis for the coverage of gram-negative bacteria and anaerobes is appropriate using a single dose of a second-generation cephalosporin (such as cefotetan) within 1 hour of skin incision. This dose is repeated 4 hours following incision in prolonged cases (cases >4 hours). Prevention of deep venous thrombosis and their sequelae are accomplished with a combination of serial compression devices (SCDs) and compression stockings. Perioperative heparin or low-molecular-weight heparin administration can also be used.

EMERGENT OPERATION

Emergent operation for CC is increasingly infrequent. Indications for emergent operation include perforation, abdominal or pelvic sepsis, obstruction, and major bleeding. The operation of choice for emergent treatment of CC is a subtotal colectomy with a long rectal stump. CC will result in severe mesenteric inflammation. This inflamed mesentery cannot be treated the same as that present for normal bowel. It is tempting to use measures to expedite bowel resection in this profoundly ill cohort. While energy devices are appropriate for normal bowel, in some cases of severely indurated, thickened Crohn's mesentery, they work less well. Inflamed mesentery should be divided carefully between clamps and ligated.

Care must be taken to adequately evert the ileostomy to avoid pouching complications. The rectal stump should be brought through the midline incision and tacked to the fascia in the manner of a mucous fistula. If the distal rectal stump dehisces, this is then essentially a complicated wound infection that progresses to a controlled enterocutaneous fistula rather than a pelvic abscess, which would be the case if the stump were left short and within the pelvis. Placement of a rectal drainage tube is a useful adjunct if there is high concern of "blow out" of the rectal stump or if, due to technical reasons, the distal rectosigmoid cannot be incorporated into the fascial closure. Box 1 lists essential operative considerations that are particularly useful in emergent colectomy for CD.

SEGMENTAL COLECTOMY

The use of segmental colectomy in the presence of resectable CC has become increasingly accepted as a means of surgical management. Accomplished by identifying proximal and distal areas of healthy bowel and mesentery suitable for anastomosis, segmental colectomy has become a viable alternative to total colectomy. The use of postoperative adjunctive immune modulating medicines following segmental colectomy is essential because the rate of recurrent colitis is higher than those patients undergoing total abdominal colectomy. However, in patients where preservation of colonic function (water absorption) and delay of stoma are desirable, this recurrence risk is acceptable when compared with the complications and consequences of total colectomy and proctocolectomy. Colonic strictures due to CD should generally be resected, except in the case where a right colon stricture is contiguous with a short stricture of the terminal ileum. In select cases, this can be managed with strictureplasty.

ILEORECTAL ANASTOMOSIS

Primary ileorectal anastomosis (IRA) following subtotal colectomy is a viable option for patients that do not desire an ileostomy. Rectal sparing by the disease process is a prerequisite of this choice for operation. Preoperative evaluation should focus on continence because direct ileum to rectum anastomosis will result in an increase of stool volume and number of bowel movements. This can be

severely limiting in a patient with poor resting rectal tone or a nonpliant rectum. Some surgeons have espoused the use of preoperative anorectal manometry to determine if a patient will tolerate this alternative to ileostomy. This is most often done in patients who appear to have questionable tone on digital rectal examination. In fact, if the surgeon is unsure about the ability of the patient to maintain continence after ileorectal anastomosis, manometry will be of little use, and IRA should ordinarily be avoided altogether. The ability of the rectum to stretch on insufflation of air either on rigid proctoscopy or flexible sigmoidoscopy is a good predictor of function. A rectum that does not distend well will result in poor functional results for the patient. Several issues pertaining to IRA make patient selection and preoperative consultation as essential as the operation itself. Patients with IRA will require ongoing surveillance of the rectum to assess for recurrence of CD as well as the possibility of dysplasia and cancer. Recurrence in the remaining rectum is a frequent sequela of IRA. A significant percentage (40%-50%) of patients undergoing IRA will eventually require completion proctectomy with end ileostomy.

TOTAL PROCTOCOLECTOMY WITH END ILEOSTOMY

Total proctocolectomy (TPC) with formation of an end ileostomy is the treatment of choice for several presentations of CD. For patients with pancolitis and perianal Crohn's, patients with dysplasia TPC, and those with multiply recurrent disease, TPC may be the ideal operation. It has the lowest recurrence risk of any operation performed for CD. TPC dissection is performed with the patient in modified lithotomy position so as to allow for access to both the perineum and abdominal cavity. The perineal dissection should be done in the plane between the internal and external anal sphincters. This "intersphincteric proctectomy" minimizes the size of the perineal wound and associated healing complications. The perineal wound is closed in layers with absorbable suture so as to provide coverage for eventual possible breakdown. Roughly 25% of these perineal wounds will ultimately break down and heal by secondary intention. Patients need to be aware of this.

Ileal Pouch Anal Anastomosis

Patients will often present with ileal pouches after having been initially diagnosed with UC or indeterminate colitis, only to later manifest the signs of CD. Pouch surgery is traditionally not performed in patients with CD due to the risk of fistulizing small bowel and perianal CD. In very select CC patients without perianal disease and after a very in-depth discussion of all the potential complications, ileal pouch anal anastomosis may be undertaken. This should only be done by surgeons and centers with significant experience in treating patients with IBD. Once CD is diagnosed in a patient with an ileal pouch, it is generally possible to maintain the pouch with a combination of supportive measures, including frequent examination, endoscopy, and medical therapy.

PROCTECTOMY

Completion proctectomy for CC is often performed following subtotal colectomy for recurrent disease in the rectum. The patient is placed in modified lithotomy position, and after abdominal mobilization of the rectum, the intersphincteric dissection is begun from the perineum. If cancer is present, a conventional abdominoperineal resection is performed with resection of both the internal and external sphincters. Occasionally, patients will have isolated rectal CD, or extracolonic CD, with the rectum as the only site of colonic disease. In that case, proctectomy and end-colostomy may be performed with the understanding of the potential for reoperation should the colonic disease progress.

THE ROLE OF LAPAROSCOPIC AND ROBOTIC SURGERY FOR CROHN'S COLITIS

The role of new surgical techniques for treating CC is still evolving. Clearly, the worst-case scenario is that in which a surgeon moderately skilled in minimal access surgery and with limited clinical familiarity with CD must consider which method to use. In such circumstances, we encourage the use of open or traditional skills but, most of all, organized access to a skilled gastrointestinal pathologist. Given much more ideal circumstances of technical expertise in laparoscopic and robotic surgery, one can then proceed according to the basics of Box 1 as noted above. As is true for most abdominal and alimentary tract operations, the principles are the same, although the issues of incision, pain, herniation, and so on are lessened with minimally invasive approaches. It is especially important for the general surgeon working in a remote area from specialists in gastrointestinal medicine or pathology to have a good communication path with a surgeon experienced in CD, and especially CC. That sort of channel can be arranged through a telephone call and guidance provided on a one-to-one basis in a meaningful way with patient referral as needed. The future of the surgical approach to CD will obviously become progressively less invasive over time, but familiarity with the disease and/or the techniques is essential and both are preferable.

Ischemic Colitis

Raul Coimbra, MD, PhD, FACS, and Todd W. Costantini, MD

OVERVIEW

Ischemic colitis is the most common form of intestinal ischemia and is responsible for as many as 1 in every 1000 hospital admissions. The incidence rate of colon ischemia is likely underestimated because patients with transient episodes may not seek medical attention. Ischemic colitis is predominantly a disease of the elderly, with most cases occurring in patients over age 65 years. The numerous potential causes of ischemic colitis (Box 1) result in a diverse clinical presentation that ranges from mild, self-limiting mucosal ischemia to severe transmural infarction and necrosis. Approximately 20% of patients presenting to the hospital with ischemic colitis need surgical intervention; therefore, understanding the pathophysiology of ischemic colitis and the factors associated with the progression of ischemia are necessary to provide appropriate surgical care.

ANATOMIC CONSIDERATIONS

The colon receives its arterial blood supply from the superior mesenteric artery (SMA) and the inferior mesenteric artery (IMA). The SMA gives the blood supply to the right colon via the ileocolic, right colic, and middle colic arteries. The ascending colon is supplied by the ileocolic and right colic arteries, and the transverse colon is supplied predominantly by the middle colic artery. The IMA gives rise to the left colic, sigmoid, and superior rectal arteries, which supply the distal transverse colon through the proximal rectum. The SMA and the IMA communicate through an extensive collateral circulation that limits the risk of ischemia to the colon (Figure 1).

The arch of Riolan, also referred to as the meandering mesenteric artery, is a collateral vessel that connects the proximal SMA with the proximal IMA at the base of the mesentery. This collateral vessel is variable in caliber and may serve a vital role in delivering blood to the colon in the case of either SMA or IMA stenosis or occlusion. The marginal artery of Drummond forms a continuous arterial arcade that runs along the distal mesentery near the colonic wall and serves as another collateral connection between the SMA and the IMA. Despite this collateral circulation, specific areas of the colon are more susceptible to ischemia. These watershed areas of the colon include the right colon, splenic flexure (Griffith's point), and the rectosigmoid junction (Sudek's point).

The right colon is vulnerable to ischemic insults because of low-flow states caused by hypotension resulting from hemorrhage, sepsis, or heart failure. The right colon is also at risk for ischemia from embolic events because the ileocolic artery is the terminal branch of the SMA and susceptible to embolic occlusion based on its straight take-off from the SMA. The splenic flexure is another watershed area because of its location at the distal extent of the arterial supply of the left colic (IMA) and middle colic arteries (SMA). The collateral circulation of the splenic flexure is the most inconsistent amongst individuals and accounts for its predisposition to local ischemia. In some individuals, the marginal artery of Drummond is either diminutive or absent, which limits the collateral circulation and places this segment of colon at risk for ischemic insults. The rectosigmoid junction is also considered a watershed area because it receives its arterial supply from the distal sigmoid artery branches and from the superior hemorrhoidal artery, both distal branches of the IMA. Its anatomic location, the increased incidence of significant IMA stenosis with age from atherosclerosis, and the need for IMA ligation during aortic surgery place the rectosigmoid region at risk for ischemia.

CLINICAL PRESENTATION

The signs and symptoms of ischemic colitis are often nonspecific and require a high index of suspicion to achieve prompt diagnosis. Patients presenting with ischemic colitis frequently experience sudden onset of abdominal pain that is not well localized. This may be associated with nausea and vomiting. Patients may have low-grade fever and leukocytosis. Patients often have mild hematochezia beginning within 24 hours of abdominal pain. Bleeding associated with ischemic colitis is usually minor and does not frequently require blood transfusion.

Medical history is often critical in the diagnosis of ischemic colitis, with specific focus on cardiovascular risk factors, history of hypercoagulability, embolic and thrombotic risk factors, and surgical history (specifically aortic and cardiac surgery). Other factors that have been associated with ischemic colitis include history of vasculitis, cocaine use, oral contraceptive pills, and long-distance running. For patients in whom ischemic colitis develops in the inpatient setting, factors such as heart failure, hypotensive episodes, and recent vasopressor use may favor a diagnosis of ischemic colitis.

DIAGNOSIS

On the basis of the nonspecific clinical presentation of ischemic colitis, patients often undergo an extensive imaging workup for evaluation of abdominal pain. Plain film radiographs of the abdomen may show thumb printing, colonic dilation, or mural thickening. Thumb printing, which is indicative of submucosal edema, is the most common radiographic finding in patients with ischemic colitis; however, it is nonspecific and may be the result of other etiologies causing colonic inflammation. Computed tomographic (CT) scan of the abdomen may localize the site of colitis by demonstrating segmental pericolonic fat stranding and bowel wall thickening. The presence of gas in the colonic wall (pneumatosis) suggests more severe, transmural ischemia. Abdominal free fluid may also be present on the abdominal CT scan and has been shown in one retrospective review to be predictive of the need for surgical intervention in patients with ischemic colitis.

The gold standard for the diagnosis of ischemic colitis is flexible endoscopy. Either colonoscopy or sigmoidoscopy can be used to visualize the mucosa for signs of ulceration or ischemic changes. Endoscopy is usually performed without mechanical bowel preparation to limit the occurrence of further dehydration and potential hypotension, which may exacerbate the ischemic insult. Lower insufflation pressures are advocated during endoscopy to limit the risk of colon perforation. It is also generally recommended that the colonoscope not be advanced beyond the affected area.

Findings on endoscopy that are characteristic of mild ischemic colitis include the presence of pale-appearing mucosa, mucosal edema, erythema, and petechial hemorrhages. Ulceration is also frequently noted on endoscopic examination, with a single longitudinal ulcer called the "single-stripe" sign characteristic of ischemic colitis. More severe ischemia is characterized by the dusky appearance of the tissue, submucosal hemorrhage, and hemorrhagic ulcerations, which progress to frank necrosis in advanced cases. Ischemic colitis is usually segmental in distribution with an abrupt change to normal mucosa in the nonaffected region of the colon. Histologic changes of the bowel during ischemic colitis include inflammatory cell infiltration, mucosal edema and sloughing, altered crypt morphology, and hemorrhage within the lamina propria.

There is limited role for angiography in the diagnosis of ischemic colitis because the large mesenteric vessels are generally patent in this disease process, with the ischemia present at the arteriolar level. Angiography should be performed to evaluate for acute mesenteric ischemia or acute embolic event. In the past, barium enema was commonly used to diagnose ischemic colitis; however, the utility of this technique is diminished with the improved images obtained with CT scanning. The use of magnetic resonance imaging (MRI) in the diagnosis of ischemic colitis is the subject of ongoing research in animal models and clinical studies.

The differential diagnosis for patients believed to have ischemic colitis includes acute mesenteric ischemia, infectious colitis, inflammatory bowel disease, and colon cancer. It is important to differentiate ischemic colitis from acute mesenteric ischemia, which primarily

affects the small intestine and requires urgent intervention. Patients with acute mesenteric ischemia generally present with severe acute-onset abdominal pain, which is out of proportion to their physical examination results. In contrast to patients with ischemic colitis, they generally do not have bloody diarrhea until late in their clinical course. Infectious colitis should also be considered in patients being evaluated for potential ischemic colitis. Invasive bacteria, most commonly *Escherichia coli* O157:H7, *Salmonella,* and *Shigella* should be evaluated for with stool culture studies. Patients with recent hospitalization or recent antibiotic use should be evaluated for *Clostridium difficile* colitis, which may be associated with the presence of pseudomembranes on endoscopic evaluation.

TREATMENT

The initial treatment of the patient with ischemic colitis should focus on determination of the severity of ischemia and whether any indications for urgent surgical intervention are present (Figure 2). Most patients present with mild ischemic colitis that responds to supportive, nonsurgical management. Although less common, some patients present with colonic ischemia causing transmural necrosis that requires urgent operative intervention. Therefore, prompt evaluation of patients with ischemic colitis is needed to evaluate for indications for urgent operative evaluations.

Nonsurgical Management

Nearly 80% of patients with ischemic colitis respond to conservative treatment with resolution of symptoms within a few days. Patients should initially be placed on bowel rest with aggressive fluid rehydration, as needed, if hypovolemia is believed to be a culprit in the development of colon ischemia. Nasogastric tube decompression should be considered in patients with nausea and vomiting or evidence of bowel dilation. The authors do not advocate the routine use of nasogastric tube decompression in all patients. Colon ischemia results in intestinal epithelial barrier failure, which may lead to bacterial translocation and septic complications. For that reason, empiric broad-spectrum antibiotics are recommended when ischemic colitis is suspected, despite the lack of clinical trials supporting their efficacy. Antibiotics against both anaerobic and aerobic coliform bacteria are recommended to cover the normal bacterial flora of the large intestine. Cathartics should be avoided because they may lead to colon perforation. Serial abdominal radiographs may be useful to follow changes in colonic dilation.

In critically ill patients in whom ischemic colitis develops as a complication of another illness, treatment should focus on limiting vasopressor use, if possible, to maximize mesenteric blood flow. Cardiac output should also be optimized with the consideration for use of pulmonary artery catheterization or other noninvasive hemodynamic monitoring tools to guide fluid resuscitation strategies to optimize perfusion to the ischemic colon.

Patient are at increased risk of ischemic colitis after abdominal aortic aneurysm (AAA) repair because of ligation of the IMA in open aortic surgery or coverage of the IMA takeoff during endovascular AAA repair. Patients in whom fever, leukocytosis, bloody diarrhea, abdominal pain, abdominal distention, or unexplained acidosis develops after AAA repair should be evaluated for potential colon ischemia. Supportive measure should be initiated as described previously in addition to an urgent, bedside flexible sigmoidoscopy to

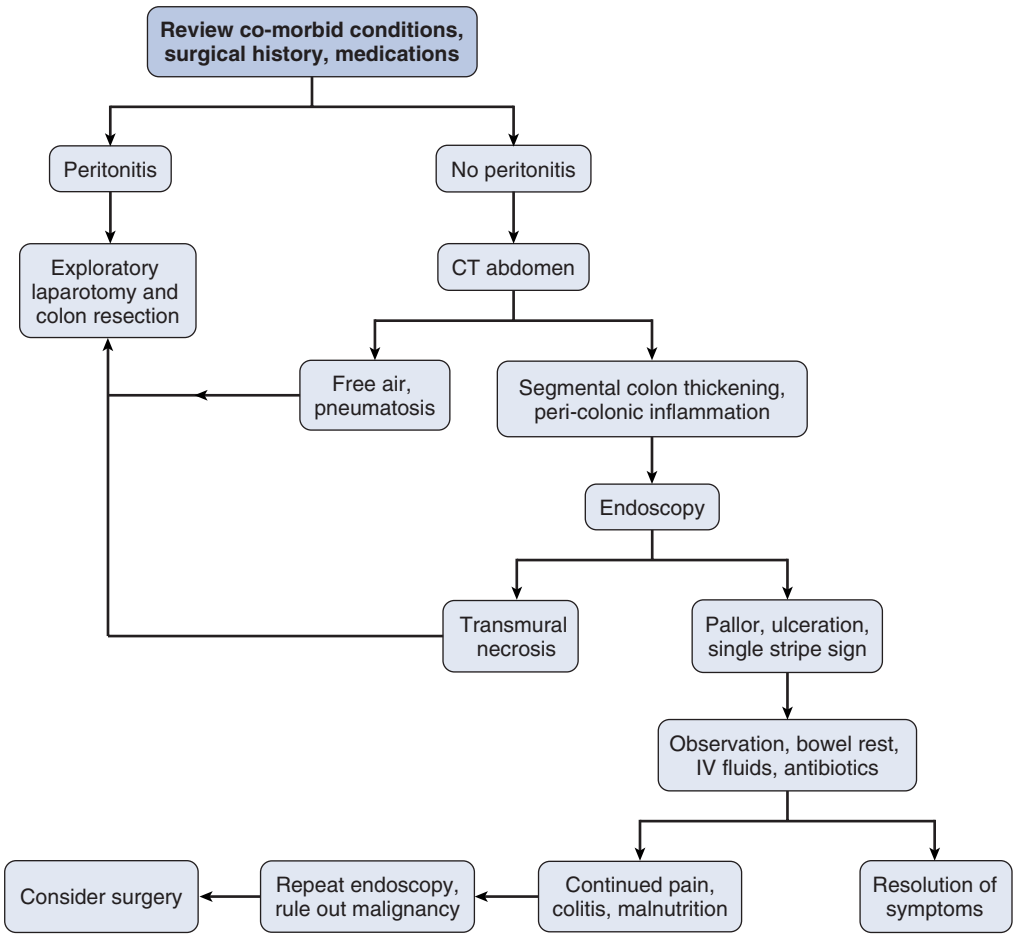

FIGURE 2 Algorithm describing the treatment of ischemic colitis. *CT,* Computed tomographic; *IV,* intravenous.

evaluate for evidence of colon ischemia. In the absence of any indication for urgent exploration, the patient should receive supportive management with consideration for repeat endoscopy to evaluate for signs of worsening ischemia.

Surgical Management

Mortality rate is greater than 50% in patients requiring acute surgical intervention for ischemic colitis. Indications for acute surgical exploration in patients with ischemic colitis include peritonitis, pneumoperitoneum, massive hemorrhage, or signs of transmural necrosis on abdominal imaging including pneumatosis or portal venous gas (Box 2). In addition, those patients with ongoing or worsening abdominal pain, increasing leukocytosis, acidosis, oliguria, or signs of sepsis during treatment with supportive measures should be considered for abdominal exploration. Right-sided colon ischemia tends to be more severe with increased likelihood of operative intervention and increased mortality compared with left-sided colon ischemia.

Surgical intervention for patient with ischemic colitis should include a thorough exploration of the abdomen through a midline incision. The entire small and large intestine should be visualized and evaluated for signs of ischemia. Segmental colon resection should be performed for segments of colon demonstrating ischemia, necrosis, or perforation. It is imperative to ensure that the resection margins are well perfused with no signs of ischemia. Confirmation of normal-appearing serosa at the margins is not adequate to confirm the presence of viable tissue because the underlying mucosa and submucosa may be ischemic despite normal-appearing overlying serosa. The resected bowel should be opened on the back table to confirm healthy, well-perfused mucosa and submucosa at the resection margins. If question exists regarding the viability of the margins, frozen section can be used to confirm the presence of normal mucosa and submucosa; however, visual inspection should be adequate to guide the need for further resection to well-perfused, viable tissue.

Ischemic colitis should be managed operatively with a segmental colon resection with diverting end ileostomy or colostomy in the urgent setting. Creation of an anastomosis is not advised because of the presence of potential tenuous blood flow to the newly created anastomosis and the presence of physiologic derangements that are likely to be present in the patient requiring emergent operation for colon ischemia. The surgeon must remember the etiology of ischemia when planning segmental resection. Because ischemic colitis usually occurs in watershed areas, an anatomic colon resection should be performed such that the remaining colon is supplied by sufficient arterial inflow. In cases of extensive or patchy involvement of the large bowel, a temporary abdominal closure with planned second-look laparotomy in 24 hours may be advisable to determine the need for further resection. In rare cases of ischemia of the entire colon or massive hemorrhage that is not localized, a subtotal colectomy and end ileostomy may be required. In contrast to mesenteric ischemia of the small intestine, interventions aimed at revascularizing the large bowel in patient with ischemic colitis are not indicated.

Patients successfully treated with nonsurgical management at the time of diagnosis of ischemic colitis may have sequelae develop in the subacute and chronic setting that may require operative intervention. Patients with ongoing colitis causing continued abdominal pain, bloody diarrhea, or recurrent sepsis lasting more than 2 weeks from the initial diagnosis should be considered for colon resection. Colonic stricture and chronic colitis may develop as a chronic consequence of ischemic colitis. Patients with chronic colitis experience intermittent bouts of abdominal pain, distention, and bloody diarrhea, which are often self limiting. Patients should undergo repeat colonoscopy with biopsy and culture to evaluate for an infectious cause of colitis. Surgical resection is rarely indicated for chronic colitis caused by ischemia; however, malnutrition or intractable symptoms may prompt the need for elective surgical resection of the affected colon.

Patients with colon stricture from ischemic colitis should undergo repeat colonoscopy and biopsy to rule out malignant disease as the cause of stricture. Once malignancy is ruled out, strictures can be observed as some resolve over time. For strictures causing ongoing symptoms, endoscopic dilation may be considered, but segmental resection with primary anastomosis is the procedure of choice in younger patients with low operative risk. Surgical resection should also be considered for those patients in whom malignant disease cannot be conclusively ruled out.

BOX 2: Indications for surgical intervention in patients with ischemic colitis

Acute
Peritonitis
Bowel perforation
Bowel necrosis
Fulminant colitis
Massive hemorrhage
Sepsis

Chronic
Intractable symptoms lasting >2 weeks
Recurrent sepsis
Chronic colitis
Ischemic stricture
Malnutrition from protein-losing colopathy

SUMMARY

Ischemic colitis represents a spectrum of disease that ranges from mild, self-limiting abdominal pain and bloody diarrhea treated with bowel rest and antibiotics to transmural necrosis with peritonitis requiring emergent colon resection. Ischemic colitis is typically a disease of the elderly but should be considered in younger patients with symptoms of colon ischemia. Although most patients present with the mild form of ischemic colitis, nearly 20% have clinical deterioration that necessitates operative intervention, which is associated with a significant increase in morbidity and mortality. Maintaining a high index of suspicion and promptly identifying patients with irreversible ischemic injury is of paramount importance in achieving prompt surgical treatment to correct the physiologic derangements caused by large bowel ischemia.

The Management of *Clostridium Difficile* Colitis

Benjamin W. Dart IV, MD, FACS, and
J. Daniel Stanley, MD, FACS, FASCRS

OVERVIEW

Clostridium difficile is a gram-positive, spore-forming anaerobic bacillus. Currently, the accepted term for colonic and, rarely, small intestinal disease caused by *C. difficile* toxins is *C. difficile* infection (CDI). Approximately 3 million CDI cases occur in the United States each year, with data to suggest that severe CDI is occurring in populations previously thought to be at low risk. The incidence and severity of CDI has increased dramatically over the last decade because of changing patterns of antibiotic use, an aging and more susceptible population, and the emergence of hypervirulent strains. For these reasons, surgical intervention for the treatment of CDI is more frequently required. The surgeon must be familiar with the medical and surgical treatment of the patient with CDI.

Multiple risk factors have been identified for the development of CDI (Box 1). Primary risk factors reflect the most commonly recognized elements of pathogenesis: a source of colonization, a change in intestinal microflora, and host debility or altered immunity. A fourth important factor in CDI pathogenesis is the degree of toxin production related to the emergence of hypervirulent strains of *C. difficile.*

Carrier state prevalence for *C. difficile* varies with age. The carrier state is common in the very young, with a prevalence rate of 25% to 80% in infants, but symptoms rarely develop. In contrast, only approximately 3% of adults are asymptomatic carriers. These individuals and patients with active disease serve as a reservoir for the spread of *C. difficile* via a fecal-oral route.

Control of transmission is difficult in the institutional setting because *C. difficile* spores can survive in the dormant state for weeks to years on inanimate objects and may be carried from patient to patient by caregivers. Colonization rates of 20% to 50% may result after hospitalization of 1 and 4 weeks, respectively.

Progression to an active infection usually requires that the protective effects of an individual's normal intestinal flora have been weakened, as with antibiotic usage. Almost all antibiotics increase the risk of development of CDI. Risk further increases with administration of multiple antibiotics or with prolonged treatment. At this time, the antibiotics most frequently associated with the development of CDI are fluoroquinolones and cephalosporins. Bowel preparation and chemotherapy may also alter the colonic microflora and result in CDI.

The postsurgical patient is particularly susceptible to CDI. In addition to having multiple established risk factors for CDI (routine perioperative antibiotic exposure, aging population, and hospitalization), surgical patient conditions are relatively immunosuppressed in the postoperative period. Not surprisingly, patients who have undergone organ transplantation and those with inflammatory bowel disease are at an increased risk for the development of CDI.

All pathogenic strains of *C. difficile* produce toxins that are responsible for the symptoms of CDI. The most important toxins are toxin A, which is primarily endotoxic, and toxin B, which is primarily cytotoxic. Recently, hypervirulent strains of *C. difficile* have emerged that are capable of producing toxins A and B in quantities sixteenfold to twentyfold higher than less virulent strains. The most often identified hypervirulent strain is known as Bi, NAP1/O27, toxinotype III, or polymerase chain reaction (PCR) ribotype 027.

CLINICAL MANIFESTATIONS

The clinical manifestations of CDI are of variable severity. The most common presentation is a mild antibiotic-associated diarrhea, which typically consists of less than 10 nonbloody stools per day, with abdominal cramping and without systemic symptoms. Classically, the colitis resulting from CDI has been synonymous with pseudomembranous colitis, but this is somewhat of a misnomer because pseudomembranes are not always present.

Surgeons must be keenly aware of worsening symptoms because progression beyond mild disease significantly increases the need for an eventual surgical intervention. Moderate to severe CDI consists of profuse diarrhea, fever, nausea, abdominal pain, leukocytosis, abdominal distention, and varying degrees of abdominal tenderness or peritoneal signs. Fulminant CDI (FCDI), which occurs in 1% to 8% of cases, is characterized by a severe systemic inflammatory response and is associated with mortality rates in the range of 30% to 90%. To further complicate the clinical presentation, as many as 37% of patients with FCDI may present without diarrhea because of an associated ileus.

DIAGNOSIS OF *CLOSTRIDIUM DIFFICILE* INFECTION

The timely diagnosis of CDI is important because evidence shows that the length of time from onset of symptoms to initiation of treatment directly correlates with mortality. Once the clinical suspicion of CDI is entertained, there are a number of options for establishing the diagnosis while assessing the severity of the disease. The most useful diagnostic tests are stool analysis, imaging studies, and occasionally, endoscopic evaluation.

Stool studies for establishing a definitive diagnosis of CDI include: 1, enzyme immunoassay for toxins A and B (ToxA/ToxB EIA); 2, PCR to identify DNA coding for the toxins; 3, stool cell cytotoxicity neutralization assay (CCNA); and 4, an enzyme immunoassay for glutamate dehydrogenase antigen (GDH; Table 1). The surgeon must be familiar with these tests given that they each have certain advantages and limitations. Other laboratory studies that are useful in evaluating and stratifying patients with CDI include white blood cell count (WBC), serum lactate, and albumin. All three have been reported as important in identifying those patients with severe and fulminant CDI. The finding of a WBC in the range of 30,000 to 60,000 may be particularly useful when considering CDI because this degree of leukocytosis is much less common in other types of bacterial infection.

Plain abdominal x-rays may reveal a megacolon, ileus, or colonic wall edema. Abdominal computed tomographic (CT) scan may be particularly sensitive in the patient with a severe or fulminant presentation, with the most common findings being localized or diffuse colonic thickening and ascites (Figure 1).

Endoscopic evaluation may be useful in the presence of colonic pseudomembranes and, in the correct clinical setting, renders an almost certain diagnosis of CDI. Colonoscopy is generally preferred over sigmoidoscopy because colitis is limited to the right colon in approximately one third of cases. It may also be used for decompression and placement of a long colonic tube for vancomycin irrigation.

MEDICAL TREATMENT

Treatment recommendations for CDI depend on the severity of disease. Asymptomatic carriers do not need medical treatment, but some general principles should be applied to both carriers and symptomatic patients. Hospital infection control practices should be implemented in patients with *C. difficile* to limit spread within the institution (Box 2). General contact precautions and hand hygiene with soap and water must be observed. Routine hand cleaning with alcohol-based products is not adequate protection against CDI because spores can be resistant to alcohol.

Patients diagnosed with CDI should have offending antibiotics discontinued if possible. If patients are severely ill with other potential sources of infection, continued administration of offending antibiotics must be weighed against the risk of prolonging the duration of CDI and increasing the chance of recurrence. Likewise, antimotility agents commonly used to treat diarrhea should be avoided because administration may result in progression to more severe disease and toxic megacolon.

Initiation of medical treatment should not be delayed for diagnostic studies in patients when the clinical suspicion for CDI is high. The duration of treatment should be for 10 to 14 days. Consideration should be given to extending the duration of this treatment in patients who need ongoing administration of other antibiotics to treat concomitant infections.

The antibiotics most commonly used to treat CDI are metronidazole and vancomycin.

Oral metronidazole (500 mg three times a day) is almost completely absorbed in the more proximal gastrointestinal (GI) tract, and the therapeutic effect is thought to be a result of both the absorbed and the residual unabsorbed component. Intravenous metronidazole (500 mg every 8 hours) provides effective concentrations within the colon and may be used if the enteral route is not available, as in the case of ileus. In mild cases, oral metronidazole is recommended as first-line therapy.

Oral vancomycin (125 to 500 mg four times a day) is recommended over metronidazole in moderate, severe, or recurrent cases. Vancomycin is not absorbed by the GI tract; therefore, high

BOX 1: Risk factors for *Clostridium difficile* infection

Primary Risk Factors
Age greater than 65 years
Antibiotic use within the previous 3 months
Hospitalization

Secondary Risk Factors
Female gender
Double occupancy rooms
Intensive care unit admission
Admission to a long-term care facility within the last year
Postpyloric tube feedings
Chemotherapy
Acid-reducing therapy with proton pump inhibitors or histamine receptor blockers
Gastrointestinal procedures
Renal disorders
Organ transplantation
Human immunodeficiency virus
Autoimmune disease
Hypoalbuminemia
Inflammatory bowel disease

Modified from Stanley JD, Burns RP: Invited commentary: Clostridium difficile and the surgeon, Am Surg *76(3):235–244, 2010.*

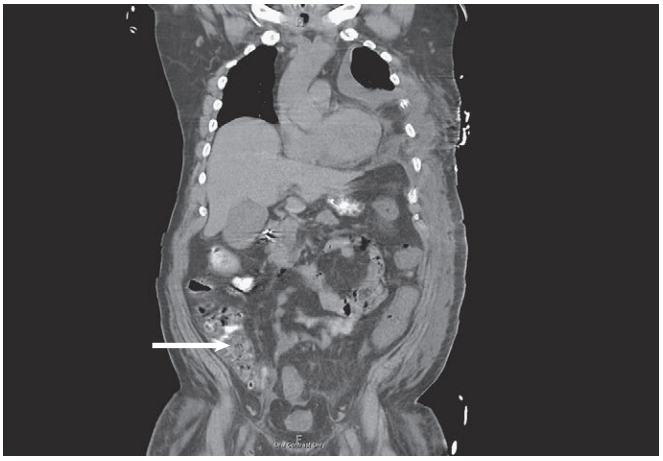

FIGURE 1 Coronal cut from a computed tomographic scan after thoracoabdominal surgery of a patient with fever and elevated white blood cell count. Note the thickened right colon with thumb printing and poor contrast filling *(arrow)*. This patient recovered after treatment with vancomycin and metronidazole.

TABLE 1: Diagnostic tests for *Clostridium difficile* infection

Test	Reported sensitivity	Reported specificity	Comments
Enzyme immunoassay for toxins A and B (ToxA/ToxB EIA)	48% to 96%	94% to 100%	Most commonly used; commercially available; 30-minute turnaround
Common antigen glutamate dehydrogenase	99% to 100%	60%	Excellent as cheap and rapid screening test; negative predictive value close to 100%; confirming test required because of low specificity
Cell cytotoxicity neutralization assay	77%; 92% to 100%	99% to 100%	Typically considered gold standard; long turnaround; requires cell culture
Polymerase chain reaction	87% to 93%	90% to 100%	Emerging as test of choice because of improved sensitivity compared with ToxA/ToxB EIA and rapid turnaround

Modified from Stanley JD, Burns RP: Invited commentary: Clostridium difficile and the surgeon, Am Surg *76(3):235–244, 2010.*

BOX 2: Infection control practices to limit the spread of *Clostridium difficile* infection

Avoidance of Inoculation
Minimize intensive care unit stay
Use private rooms
Use gloves
Hand wash with soap or chlorhexidine instead of alcohol-based solutions
Use patient-dedicated stethoscopes and instruments
Wash all nondedicated instruments between patient contacts
Follow isolation precautions

Interventions
Minimize antibiotics
- Follow guidelines for perioperative antibiotics
- Avoid broad-spectrum or multiple antibiotics
- Avoid prolonged courses of antibiotics

Avoid proton pump inhibitors and H2 blockers
Avoid unnecessary bowel preparations
Avoid antidiarrheals
Minimize gastrointestinal intubation for feeding or decompression

Institutional Measures
Consider antibiotic formulary changes in case of institutional epidemic

Modified from Stanley JD, Burns RP: Invited commentary: Clostridium difficile and the surgeon, Am Surg *76(3):235–244, 2010.*

BOX 3: Characteristics of moderate, severe, and fulminant *Clostridium difficile* infection

Moderate Colitis
Pulse, >90 bpm; SBP, >100 mm Hg; temperature, 100°F to 101.5°F; WBC, 12,000 to 15,000
Pseudomembranes on colonoscopy
Colonic thickening on CT scan
Colon, >6 cm
Oliguria responsive to volume
Normal lactate
Mild abdominal tenderness
Mild tachypnea

Severe Colitis
Moderate colitis and the following:
Pulse, >120 bpm; SBP, <100 mm Hg; WBC, >15,000
Renal failure
Respiratory distress or intubation
Albumin, <2.0
Lactate, >2.0
Mental status changes
Moderate abdominal tenderness

Fulminant Colitis
Severe colitis and any of the following:
Condition unimproved after 12 to 24 hours of treatment
Need for vasopressors
Ventilator dependence
Abrupt rise in WBC

CT, Computed tomographic; *SBP,* systolic blood pressure; *WBC,* white blood cell count.
Modified from Stanley JD, Burns RP: Invited commentary: Clostridium difficile and the surgeon, Am Surg *76(3):235–244, 2010.*

concentrations are achieved in the colon with oral administration. Intravenous vancomycin is not recommended in CDI treatment. In the patient in whom the enteral route is not an option, vancomycin enemas or irrigations through a colonic tube may be of benefit. The typical dose is 500 mg in 100 mL of normal saline solution given as a retention enema or irrigation administered every 6 hours. This may be given in addition to intravenous metronidazole.

Another antimicrobial agent, fidaxomicin, was recently approved by the U.S. Food and Drug Administration (FDA) for treatment of CDI. It is a macrocyclic antibiotic with a narrow therapeutic spectrum. It has been found to be noninferior to vancomycin, with lower recurrence rates. Despite promising results, the widespread adoption of fidaxomicin in the treatment of initial episodes of CDI is limited because of a lack of familiarity and cost.

SURGERY

The surgeon must be involved early in the assessment and treatment of CDI. Increased survival rates have been reported for patients on a surgical service, and earlier surgical intervention may improve survival in patients with severe and fulminant CDI. Surgical intervention is necessary in approximately 20% of patients who are critically ill with CDI. The classic indications for surgery include toxic megacolon or colonic perforation and, less clearly, fulminant disease or failure of medical therapy in 48 to 72 hours with continued signs of toxicity. Toxic megacolon in CDI has been defined as a cecal diameter of greater than 12 cm or a colonic diameter of greater than 6 cm on radiographic imaging. Not uncommonly, patients with CDI with a toxic megacolon may have a conspicuous lack of diarrhea. This finding should not be misinterpreted as an improvement of the disease process. A very low threshold for operative intervention must remain when toxic megacolon exists. The presence of colonic perforation with CDI has an especially poor prognosis, and emergent surgical treatment is the only option for survival.

Standardized definitions of disease severity are not well established. Likewise, failure of medical therapy in patients with severe colitis is a subjective indication of the need for surgery. A severity classification scheme is needed to guide appropriate treatment algorithms that include early surgical intervention. Although several scoring systems have been proposed and appear promising, validated studies are needed before widespread adoption. However, several observations can be made from the collective experience regarding the characteristics of moderate, severe, and fulminant colitis (Box 3). Patients who meet these criteria need close clinical monitoring, typically in an intensive care setting. On the basis of severity of illness and response to aggressive medical management, the authors recommend consideration for surgical intervention as described in Box 4. The presence or absence of a hypervirulent strain (if serotyping is available) may impact decision making.

Once the decision has been made to pursue surgical treatment, the operation must be performed in an expeditious and aggressive manner. Removal of the entire colon with preservation of the rectum and end ileostomy should be performed. A segmental colonic resection should not be performed for CDI regardless of the perceived extent of disease.

An anastomosis is not recommended. Because of the need to perform a rapid colectomy and the critical illness of the patient, a laparoscopic colectomy is also not recommended.

In preparation for surgical intervention, invasive cardiopulmonary monitoring with arterial line placement and central venous access is recommended. Aggressive fluid resuscitation is critical. Marking of a site for a planned ileostomy by an enterostomal specialist is ideal but not always immediately possible. The patient should be placed supine on the operating table. The abdomen is prepped and draped widely. A large midline laparotomy incision should be made. The length of the incision should allow for rapid mobilization of the colon. The gross external appearance of the colon can vary from normal to markedly edematous, ischemic, or frankly necrotic. At this point, the surgeon must resist the temptation to perform a

less aggressive operation solely on the basis of the appearance of the colon itself. If the diagnosis of CDI is secure and laparotomy is performed, the surgeon should proceed with a total colectomy and end ileostomy. The distal ileum and the rectum can be quickly divided with linear staplers, and the mesentery can be ligated with a clamp and tie technique. Alternatively, bipolar or ultrasonic tissue sealing and cutting devices can be helpful to quickly divide the mesentery and maintain adequate hemostasis. The omentum can be removed from the colon or divided and resected along with colon, whichever is most expeditious. Once the colon has been removed from the abdomen, the distal ileum is brought through an opening in the rectus muscle and fascia and the stoma matured after closure of the midline wound. Rarely, the patient may remain in extremis or the retroperitoneal and bowel edema may preclude closure. In this event, a damage control philosophy may be used. Delayed maturation of the stoma or use of an open abdomen strategy may be necessary to quickly conclude the operation. Stoma reversal may be considered once the patient has recovered fully. Reversal rates are low, ranging from 20% to 35% with a median interval to closure of 234 days.

The mortality after colectomy for CDI has been reported to be 34% to 57% in most series. Likely contributors to this finding include: delays in the initial diagnosis or surgical consultation, poor patient selection, and difficulty predicting the disease course.

Recognition of unacceptably high perioperative mortality has led many surgeons to reconsider whether total colectomy is the best surgical procedure for CDI. An alternative surgical procedure for the treatment of CDI has recently been proposed. A loop ileostomy is constructed (often laparoscopically). The colon is then irrigated with warmed polyethylene glycol 3350/electrolyte solution via the ileostomy. Postoperative antegrade irrigation of vancomycin solution through the ileostomy is continued for 10 days. Early data show improved mortality and high stoma closure rates. Although intriguing, recommendation of this procedure as first-line surgical treatment is premature.

After an operation for CDI, the patient should be taken to the intensive care unit. Although some patients show almost immediate improvement in their condition after removal of the diseased colon, ongoing critical care is necessary to limit morbidity and mortality. Hemodynamic support including vasopressors and large volume fluid resuscitation may be required. Likewise, aggressive treatment of multisystem organ failure may be necessary in the postoperative period.

RECURRENT INFECTION

Recurrence is a major challenge in the treatment of CDI, with reports of rates between 6% and 47% within the first 2 weeks after completion of initial medical treatment. This risk is further increased with each subsequent recurrence. For patients with a first recurrence of CDI, repeated standard dosing regimens of metronidazole or vancomycin are reasonable. Recurrence does not indicate resistance to the initial choice of antibiotic, and therefore, the specific antibiotic chosen for treatment of recurrent disease does not seem to matter in mild cases of CDI. However, in severe cases of first recurrences, oral vancomycin alone or combination therapy to include intravenous metronidazole is recommended. Subsequent recurrences require consideration of additional treatment options, such as tapering and pulsed antibiotic strategies, donor-directed fecal transplantation, and combination or adjunctive drug regimens. Antibiotic tapering is accomplished by decreasing antibiotic dosage over 4 to 6 weeks. Because the spores of *C. difficile* are resistant to antibiotics, pulsed dosing can be added to the end of a taper to allow for residual *C. difficile* spores to germinate. Although published dose-tapering and pulsed strategies may differ slightly, it is generally believed that vancomycin should be the drug of choice in this setting because prolonged use of metronidazole can lead to peripheral neuropathy.

Donor-directed fecal transplant has also been reported to be effective in the treatment of recurrent and recalcitrant CDI. Patients are given a bowel preparation with a polyethylene glycol solution. Two hundred to 300 g of stool from a healthy donor, screened for pathogenic bacteria or transmissible disease, is suspended in 250 mL of saline solution and administered via retention enema daily for 5 days. Alternatively, colonoscopic and nasoenteric tube infusions have also been described with minimal adverse effects. Cure rates in small series are high.

Other suggested drug regimens include fidaxomicin, rifaximin, tigecycline, rifampin, cholestyramine, and monoclonal antibodies. Unfortunately, no one option has shown superiority. Consequently, treatment for recurrent CDI must be individualized based on the number of recurrences, the severity of disease, comorbidities, and available resources. The role of surgical therapy for recurrent CDI has not been established. One can only speculate that novel, less invasive, surgical techniques may spark interest in operative treatment of recurrent CDI.

CLOSTRIDIUM DIFFICILE INFECTION AND INFLAMMATORY BOWEL DISEASE

C. difficile infection is well established to be increased in patients with inflammatory bowel disease (IBD), especially ulcerative colitis (UC). These patients typically experience an increased hospital length of stay, an increased need for surgical intervention, and higher morbidity and mortality independent of the stress of surgical intervention.

Although steroids, debility, frequent use of antibiotics, and episodic hospitalization contribute to CDI in patients with IBD, to what degree other immunomodulators exacerbate the problem is unclear. A diagnostic dilemma can certainly exist because many of the symptoms of IBD can mimic CDI. Therefore, the clinician must check for CDI in patients with worsening or relapsing IBD.

Treatment of CDI in patients with IBD differs little from that in the general population with few exceptions. Oral vancomycin is recommended as first-line therapy, which may be given in combination with intravenous metronidazole in more severe cases. Minimization of corticosteroids and other immunomodulators and broad-spectrum antibiotics is important. There should be a low threshold for total colectomy with ileostomy in patients with severe, fulminant, and persistent CDI.

CONCLUSION

With the increasing incidence and severity of CDI, surgeons will be called on more frequently to manage these often challenging cases. Mitigation of risk factors, early diagnosis, and aggressive treatment must be realized to improve outcomes. A high index of suspicion in those at risk helps the surgeon identify the patient with an early, atypical, or subtle presentation. CDI must be considered in any patient with a history of recent antibiotic use, unexplained abdominal pain, abdominal distention, fever, or leukocytosis, even in the absence of diarrhea.

The mortality rate of those who need surgical intervention remains high. If mortality rates are to improve, there is current consensus, albeit in the absence of significant prospective data, that early and expeditious surgery is of likely benefit and that patients will ideally receive surgical intervention before reaching a fulminant state. It is clear that when the surgeon encounters a patient with CDI who has peritonitis, perforation, or fulminate colitis, the first consideration after resuscitation is to proceed to operative intervention. Patients with severe CDI whose conditions fail to promptly respond to nonsurgical therapy should also be strongly considered for surgical intervention even in the face of contributing comorbidities. Although total colectomy with ileostomy is the accepted procedure of choice, laparoscopic ileostomy with vancomycin lavage may emerge as a promising treatment option for severe and fulminant CDI.

LARGE BOWEL OBSTRUCTION

Joseph E. Bornstein, MD, MBA, and David L. Berger, MD

OVERVIEW

Large bowel obstruction is defined as an intestinal obstruction that begins distal to the ileocecal valve. Surgery is the definitive therapy for most causes of large bowel obstruction. Morbidity and mortality rates can be as high as 46% and 18%, respectively, but vary depending on the etiology and patient characteristics.

Large bowel obstruction may be partial or complete (no passage of stool or flatus). The etiology can be intrinsic or extrinsic to the colon and mechanical or adynamic. These causes can include neoplasms, inflammatory lesions, ischemia, hernias, volvulus, intussusception, endometriosis, pseudoobstruction, and foreign body/fecal impaction. Box 1 provides a list of common causes of large bowel obstruction. The most common mechanical cause of large bowel obstruction is colorectal carcinoma, followed by diverticulitis and volvulus. A common adynamic cause of large bowel obstruction is acute colonic pseudoobstruction (Ogilvie's syndrome). Ogilvie's syndrome is often found in association with a wide variety of medical and surgical illnesses.

Accurate diagnosis and therapeutic planning require a thoughtful collection of the history, the physical examination, and pertinent laboratory and radiologic studies. Epidemiologic factors, surgical history, and the physical examination can often suggest a specific cause. Examination for abdominal wall or inguinal hernias is a must, as is a rectal examination and fecal occult blood test. The exact treatment varies based on the location of the obstruction, the mechanism of obstruction, the viability of the bowel, and goals of care.

Immediate management should include attainment of adequate intravenous (IV) access and IV fluid hydration. Fever, tachycardia, or hypotension may indicate systemic toxicity or hypovolemia. Vital signs and urine output should be monitored for endpoints of resuscitation. A nasogastric tube should be inserted, and in most cases, antibiotics should be started and blood cultures drawn.

The goals of further evaluation are to assess the degree of physiologic derangement and identify characteristics of the obstructing lesion. Useful laboratory tests include a complete blood cell count (CBC) and chemistry panel, which can reveal evidence of inflammation, bleeding, electrolyte disorders, and dehydration. An upright chest x-ray can be obtained to look for free intraperitoneal air. Computed tomographic (CT) scan is the imaging modality of choice for patients with a clinical suspicion of obstruction. CT scans can further demonstrate carcinomatosis, liver metastases, and ascites when advanced malignant disease is present.

OBSTRUCTIONS AS A RESULT OF CANCER

Colorectal cancer is the third most common cancer in the United States, representing 9% of all cancer deaths. Furthermore, 15% of colorectal cancers present as a surgical emergency. The most common symptom of a large bowel obstruction from malignancy is abdominal distention. Additional aspects of the history to obtain include recent weight loss, change in bowel habits, change in stool consistency, recent passage of flatus, nausea, and emesis. Because of the distal focus of obstruction, nausea and vomiting are late findings, especially if the vomit is stercoraceous. Chronic symptoms may represent evidence of a process that has evolved over time, and the patient may report a prolonged history of altered bowel movements. Older patients who present with acute malignant large bowel obstruction often have not had any recent colonoscopic evaluations (Figure 1).

Partial obstruction that does not require urgent surgical intervention may initially be managed with nasogastric decompression and resuscitation. This may allow added surgical planning and staging and allow for a single-stage procedure if possible.

Surgical planning in the event of complete malignant obstruction depends on the viability of bowel, the location of obstruction, the resectability of the tumor, and the goals of care. Patients may either go straight to surgery or pursue nonsurgical, palliative options. Nonsurgical therapy has evolved for malignant obstruction since the introduction of stents in 1991. Stents have been successfully applied for palliation where surgery should be avoided. A stent can also be used as a temporizing measure to allow for preoperative bowel preparation or physiologic correction. The data on the utility of bowel preparation, however, are lacking. Table 1 shows the results of a recent meta-analysis by van Hooft and associates that compares emergency surgery with temporizing colonic stenting followed by resection for acute left-sided obstruction. As shown, no significant difference was seen in the number of adverse events or mortality when used as a bridge to surgery versus proceeding directly to surgery.

BOX 1: Common causes of large bowel obstruction

- Neoplasm
 - Colorectal origin
 - Local noncolonic origin with tissue invasion or compression
 - Metastatic
- Volvulus: cecal, sigmoid
- Inflammatory-mediated
 - Diverticulitis
 - Acute
 - Chronic: stricture
 - Crohn's disease
 - Radiation
- Hernias
 - Inguinal or abdominal wall
 - Internal
- Intussusception
- Adynamic: Ogilvie's syndrome
- Ischemic stricture
- Foreign body
- Fecal impaction

The most compelling indication for stenting in colorectal cancer is for palliation. This allows the patient to avoid a colostomy in the presence of unresectable disease or advanced cancer. Stoma creation, however, remains the gold standard. Stents should not be performed in patients who have evidence of peritonitis, perforation, or ischemia. Placement of the stent requires that a catheter can cross the obstructed point. This is successful in greater than 90% of cases by experienced operators with experience greater than 20 cases. Complications from the procedure can include colonic perforation, stent migration, and stent obstruction. The use of stents appears to be safe; however, they confer no advantage to morbidity or mortality and have a lower overall success rate at relieving obstruction, based on a recent Cochrane review. One clear advantage of stents is decreased length of hospital stay and possibly decreased overall cost.

Patients who have a resectable lesion are managed with surgery. Multiple surgical options exist, and considerable advancement has taken place to decrease patient morbidity over the last 30 years. Right-sided lesions have been a matter of little debate and are best managed with a single-stage segmental colectomy. With regard to left-sided lesions, historically, a two-stage or three-stage procedure has been performed; however, when possible, a single-stage procedure is preferable and has shown to be safe and effective. Morbidity and mortality appear equivalent when a single-stage operation is performed when compared with a staged procedure. In fact, single-stage operations appear to be equally successful on both right-sided and left-sided colonic lesions.

The extent of resection has been a matter of debate. For right-sided lesions, segmental resection is appropriate. In the case of left-sided obstruction, segmental resection should be performed unless concern exists for proximal bowel viability or additional areas of colon with lesions of concern. In that event, subtotal colectomy is appropriate. Some have advocated that subtotal colectomy is the preferred operation, arguing that synchronous tumors have been found in up to 11% of patients and that the addition of on-table lavage is onerous. Current data do not support the need to remove additional colon without cause. Concern amongst surgeons about performing primary anastomosis in unprepped bowel led to the use of intraoperative colonic lavage. On-table lavage of the colon is often time consuming and caries additional risk of spillage. Some have

TABLE 1: Colonic stenting versus emergency surgery: morbidity, mortality and stoma rates

	Colonic stenting (N = 47)	Emergency surgery (N = 51)	Absolute risk difference (95% CI)	Relative risk (95% CI)	*P* value
Mortality					
30-Day mortality	5	5	−0.01 (−0.14-0.12)	0.92 (0.28-2.98)	0.89
Overall mortality	9	9	−0.02 (−0.17-0.14)	0.92 (0.40-2.12)	0.84
Morbidity	25	23	−0.08 (−0.27-0.11)	0.85 (0.57-1.27)	0.43
Stoma Rates					
Directly after initial intervention	24	38	0.23 (0.04-0.40)	1.46 (1.06-2.01)	0.016
At latest follow-up	27	34	0.09 (−0.10-0.27)	1.16 (0.85-1.59)	0.35

CI, Confidence interval.

From van Hooft JE, Bemelman WA, Breumelhof R, et al: Colonic stenting versus emergency surgery for acute left-sided malignant colonic obstruction: a multicentre randomised trial, Lancet Oncol *12(4):344-352, 2011.*

omitted this step and use manual decompression with equivalent outcomes. Furthermore, if the patient is in extremis, on-table lavage is not recommended.

After primary anastomosis, some surgeons perform a protective loop ileostomy to decrease the chance of leak at the anastomosis; however, the need for an additional procedure is not without added morbidity and removes some of the benefit of a single-stage operation.

When patients are ill, it may be necessary to perform resection and diversion or even simply divert alone as an initial operation followed by colonic resection at an additional procedure. Principles of damage control hold true in this circumstance and should guide operative planning in the unstable condition.

OBSTRUCTIONS AS A RESULT OF INFLAMMATION

Obstructions from inflammation may be secondary to an active process (acute diverticulitis) or chronic inflammation and fibrosis. The management of inflammatory mediated strictures continues to evolve. Patients with strictures from diverticulitis, Crohn's disease, or radiation colitis or at points of prior anastomoses have been treated both operatively and nonoperatively with colonic stents. Patients with chronic strictures often present with signs and symptoms consistent with a partial obstruction or constipation.

In the case of acute diverticulitis, patients may undergo an attempt at nonoperative management in the absence of hemodynamic instability and purulent or feculent peritonitis. A history of episodes of diverticulitis is highly suggestive of the diagnosis. A CBC may reveal leukocytosis. CT scan shows a transition point in the colon in the area of diverticulitis. A nasogastric tube should be placed, and IV antibiotics started. If the obstruction fails to improve, or the patient's condition begins to deteriorate, a Hartmann's procedure may be necessary. Malignancy must always be a concern, and ideally, colonoscopic biopsies should be taken at a later date if the patient is managed nonoperatively.

When an operation is required, there can be significant inflammation around the sigmoid colon. Surgery can be hazardous because difficult dissection may increase the risk of iatrogenic injury to adjacent structures, such as the ureter. Temporary loop colostomy may be necessary under these circumstances.

Chronic colonic strictures may be sequelae of prior episodes of diverticulitis, pelvic radiation, or prior bowel anastomoses. Generally, these patients present with chronic constipation and partial obstructive symptoms. Under most circumstances, patients should undergo evaluation to rule out malignancy and subsequently undergo an elective resection. Alternatively, the use of colonic stents for benign colorectal obstructions is increasing. At this time, limited data exist on its long-term efficacy and morbidity; and most studies have a small sample size. The most common benign indications for stenting are anastomotic stricture and diverticular stricture. Patients may benefit from preoperative optimization, and the stent may be used as a bridge to surgery to allow time for inflammation to resolve or physiology to improve. Alternatively, some moderately long-term results have been obtained on select patients who either are unsuitable candidates for operative resection or have refused surgery. Keranen and colleagues reported a success rate of 75% (16 of 21 cases) in clinical relief of obstruction. Unfortunately, 43% of patients experienced a complication. A significant number of the complications were from delayed perforation presenting greater than 4 weeks after stent placement. Complication rates for colonic stenting in benign disease appear higher than their malignant counterpart. The effectiveness in diverticular strictures also appears somewhat limited. Seventy percent of patients in this trial treated for diverticular stricture ultimately underwent surgical therapy. Stenting may play a role as a temporizing solution for elective repair. However, stenting should not be viewed as a definitive or long term solution for patients with benign disease.

OBSTRUCTIONS AS A RESULT OF COLONIC VOLVULUS

Acute colonic volvulus is the third most common cause of mechanical bowel obstruction after cancer and diverticulitis. Volvulus generally involves the cecum or sigmoid colon when the colon twists around its mesenteric blood supply. Sigmoid volvulus is the most common and tends to occur in elderly patients with chronic constipation. In contrast, cecal volvulus generally occurs in younger individuals.

The clinical presentation includes rapid onset of abdominal distention, pain, nausea, and vomiting. Patients may present with significant bowel ischemia that leads to perforation and peritonitis. Plain x-rays are potentially sufficient to make the diagnosis. An abdominal x-ray can show classic findings, such as a "bent inner tube" or "coffee bean sign," which are consistent with sigmoid volvulus. Cecal volvulus shows a twisted cecum in the left upper quadrant of the plain abdominal x-ray. When the diagnosis is in doubt, a CT scan may be obtained and often shows a characteristic "whirl sign," in which the mesentery twists around the vascular supply (Figure 2).

In the absence of peritonitis or perforation, sigmoid volvulus should initially be treated with colonoscopic detorsion and decompression. A rectal tube is subsequently placed for continued rectal decompression. Historically, bowel preparation was performed preoperatively, but it may not be necessary as described for other elective colonic resections. In the event of a successful detorsion, a single-stage resection and primary anastomosis is performed during the same admission. Failure to perform a definitive operation results in a high recurrence rate. In one study, up to 86% of patients treated with decompression alone recurred, which in some cases required emergency surgery. The mortality rate of nonoperative management was significantly higher than for patients treated operatively for all American Society of Anesthesiologists (ASA) classes, suggesting that nonoperative management is inferior.

In the setting of peritonitis, blood per rectum, free intraperitoneal air, signs of sepsis, or failure of endoscopic decompression, the patient should be taken to the operating room for emergency resection. Resection with colostomy may be necessary with peritoneal contamination, ischemic-appearing bowel, or hemodynamic instability. Otherwise, the patient may undergo primary resection and anastomosis. A study comparing patients with uncomplicated sigmoid volvulus who underwent Hartmann's procedure alone, Hartmann's plus colostomy closure, and primary anastomosis of uncomplicated sigmoid volvulus showed no significant difference in morbidity or mortality across the three surgical groups. A 5% rate of stoma complications was observed in addition to the added burden and cost of a second procedure.

The purpose of resection after successful detorsion is therefore to prevent recurrence and more complicated presentation necessitating emergency surgery. Some reports of percutaneous-endoscopic sigmoidopexy have been performed, but long-term studies and large series are lacking at this time.

Unlike sigmoid volvulus, surgery is the immediate definitive therapy for cecal volvulus. The multiple surgical options include resection, detorsion alone, or detorsion with cecopexy. Table 2 details the results of a retrospective review of a large series of patients with cecal volvulus. Simple surgical detorsion with or without cecopexy has been performed with some success but result in a high rate of recurrence. Given improvements in perioperative care since this review, the morbidity of right colectomy with primary ileocolic anastmosis is significantly lessened and offers the best chance of definitive cure from recurrence.

FIGURE 2 Sigmoid volvulus. *(Courtesy of Harisinghani Mukesh, MD, MGH Radiology.)*

OBSTRUCTIONS AS A RESULT OF INTUSSUSCEPTION

The workup and initial treatment for intussusception is similar to that of other causes of large bowel obstruction. Patients with colonic intussusception present more commonly with melena or guaiac-positive stool and less so with abdominal pain, nausea, and vomiting relative to the small bowel counterpart. In a small proportion of patients, a palpable abdominal mass is evident. CT scan is the most useful diagnostic test, but up to one fourth of cases are diagnosed in the operating room. CT scan often shows a target-shaped area of colon that represents the intussusceptum in the center surrounded by the intussuscipiens (Figure 3).

Unlike the pediatric equivalent, a significant portion of intussusceptions in adults are caused by a malignant focus. Colonic intussusceptions have been found to be malignant in up to 43% of cases. Surgical resection along lymphatic drainage without reduction is the preferred treatment. Right-sided lesions can be repaired with primary anastomosis, whereas left-sided lesions historically have been repaired in two stages with a Hartmann's procedure and subsequent colostomy takedown. A single operation is feasible for left-sided lesions given the outcomes in similar large bowel obstruction cases in the absence of contamination.

TABLE 2: Morbidity and mortality after operation for cecal volvulus

Operation	Percent	Abdominal complications (%)	Wound complications (%)	Mortality (%)	Recurrence (%)
Cecopexy	32	8	7	10	13
Detorsion	25	9	6	13	12
Resection	25	16	13	22	–
Cecostomy	16	25	27	32	14

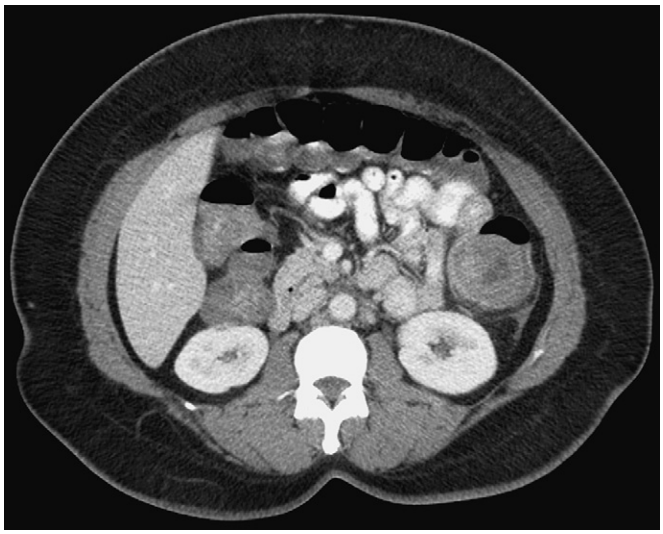

FIGURE 3 Descending colonic intussusceptions.

OBSTRUCTIONS AS A RESULT OF HERNIA

Abdominal wall and inguinal hernias should be sought out on the clinical examination. If an incarcerated hernia is the cause of large bowel obstruction, the patient should be taken to the operating room for reduction, assessment of bowel viability, and possible resection. For an incarcerated inguinal hernia, if the bowel appears viable before surgery, a groin incision may be performed in standard fashion. With signs of perforation or ischemia, a midline laparotomy should be performed in anticipation of resection. Avoidance of nonbiologic materials is required when bowel is resected. Internal hernias have been reported in the literature and are diagnosed largely with cross-sectional imaging or at the time of surgery.

OBSTRUCTIONS AS A RESULT OF OGILVIE'S SYNDROME (PSEUDOOBSTRUCTION)

Patients with colonic pseudoobstruction often have a variety of preceding medical conditions, and occurs with increased frequency in the elderly population. The exact mechanism of visceral dilation in pseudoobstruction is not clear. Massive dilation of the large bowel can result in ischemia and perforation, which is an urgent indication for operative intervention. After resuscitative measures have been taken, and potentially offending agents (narcotics, anticholinergics) have been stopped, IV neostigmine has been used with moderate success. Side effects of neostigmine must be carefully observed, including nausea, vomiting, bradycardia, bronchospasm, and hypotension. Atropine should be available, and the patient should be placed on telemetry during administration. Colonoscopic decompression can be performed with significant risk in the unprepped bowel. If these options fail to resolve the obstruction, the patient should undergo definitive operation. Endoscopic stoma placement in either the left or right colon has been performed, but the risks are high. Operative intervention can include a venting stoma if the bowel is viable. Otherwise, segmental or subtotal colectomy may be necessary. If medical therapy is successful, some data suggest that administration of polyethylene glycol helps maintain remission and prevent early recurrence.

CONCLUSION

The principles and treatment of large bowel obstruction have evolved over the last 20 years. Appropriate resuscitation should begin in the emergency department. The specific intervention is dependent on the cause and location of the obstruction in addition to the viability of the bowel. In most cases, when resection is necessary, a single-stage operation is preferable and can be performed safely without added morbidity. In cases of advanced cancer, a loop colostomy may be necessary. In some palliative and benign circumstances, the use of colonic stents is evolving and should be considered where available.

COLONIC STENTING

Patrick I. Okolo III, MD, MPH, FASGE, and Joanna K. Law, MD, MA (Ed)

INTRODUCTION

Colonic obstruction, whether of neoplastic or nonneoplastic origin, can result in significant morbidity, including hypovolemic or septic shock, acute renal or multiorgan failure, perforation, and peritonitis. Between 10% and 30% of patients with colorectal cancer present with impending or complete obstruction, which is traditionally treated with emergency surgery, which itself is associated with significant rates of perioperative and postoperative morbidity and mortality. Predictors of death include older age, a higher grade obstruction according to the American Society of Anesthesiologist (ASA), metastatic or locally advanced disease, and emergency surgery for obstruction.

In an otherwise healthy patient presenting with acute obstruction, surgical management typically involves colonic resection and primary anastomosis with or without a diverting stoma. In the patient with comorbid conditions, decompression of the obstruction with a diverting colostomy is often the first of a multistaged approach that, when possible, will subsequently include colonic resection and

reconnection. With the advent of self-expandable metal stents (SEMS), a minimally invasive alternative to emergency surgery became available to relieve colorectal obstruction. Colorectal stenting has become an effective, nonoperative, immediate means of colonic decompression that, in turn, may allow for patients to proceed to a more elective bowel resection.

At present, there are two major indications for colonic stenting in patients with colorectal cancer: (1) palliation of advanced disease that is otherwise nonoperative and (2) decompression in patients as a "bridge" to surgical resection. In the latter indication, surgical intervention in a patient at high risk can be avoided, and the patient's medical condition can be optimized before either a laparoscopic or open procedure for definitive management.

Although the role of SEMS is very well accepted in the palliative situation, the use of SEMS as a bridge in patients with acute colonic obstruction has been controversial because of the associated costs and possible complications associated with SEMS. However, several studies have demonstrated a cost savings in patients who undergo stenting as a bridge to surgery. Other observed benefits of stenting as a bridge to surgery are (1) the opportunity for patients to undergo a full bowel evaluation to rule out a synchronous lesion either endoscopically or radiologically and (2) enabling some patients to receive systemic chemotherapy and thereby downgrade liver metastases.

Colonic stenting, however, is not without risk. In a multicenter study from the Netherlands, patients with incurable left-sided colorectal cancer were randomly assigned to either a surgical or nonsurgical treatment condition in which the latter was colonic stenting. However, this study closed early because of a high number of serious adverse events in the patients in the nonsurgical condition, with six perforations, of which at least two were directly attributable to the stent. Other complications of colonic stenting include stent migration and occlusion, which may result in recurrent obstruction.

Over the years, as endoscopists have gained experience with colonic stent placement in the malignant setting, its use and indications have expanded to nonneoplastic causes of colonic obstruction, including benign strictures, such as those in diverticulitis, and disturbance of luminal integrity by fistulizing diseases such as inflammatory bowel disease (Box 1). In an institution with endoscopic, radiologic, and surgical support, the use of SEMS for colonic obstruction can be performed safely and with good outcomes for the appropriate indications.

TECHNIQUE

Enteral stents are generally self-expandable, preconstrained tubular meshwork devices usually made of nitinol, and they may be uncovered or covered. In the Unites States, most commercially available stents are uncovered stents. Endoscopic insertion of stents in colorectal obstruction is best accomplished with stents that can be placed "through the scope" (TTS). The most commonly used stents in the United States are available in 60-mm, 90-mm, and 120-mm lengths, with internal diameters of 20 and 22 mm. The TTS stent can be inserted via the accessory channel of a therapeutic endoscope, thus enabling precise placement under endoscopic visualization (Figure 1).

Another delivery mechanism that is too large to enable passage through the working channel of the therapeutic endoscope is one in which the stent is delivered alongside the endoscope or under fluoroscopic visualization. These stents are often made from nitinol and are available in lengths of 57, 87, and 117 mm, with internal diameters in the range of 18 to 25 mm. The advantages of these stents are limited in comparison with the TTS stents, and the decision to use these stents should be driven by the clinical circumstances along with the input of an expert endoscopist.

Preprocedure imaging is very helpful but not an absolute requirement in certain situations in which the clinical acuity may not allow for safe and extensive imaging. When appropriate, a water-soluble contrast enema study or abdominal/pelvic computed tomographic scan with rectal contrast medium should be performed to demonstrate the length, course, and mural complexity of the obstruction and thus facilitate in preprocedural planning (Figure 2). These studies may be particularly useful in ruling out synchronous sites of obstruction proximal to an identified colorectal stricture and may indicate the need for additional or different intervention.

Patient Preparation

Rectal enemas can be used in patients with complete obstruction to clear the field of view. In patients with incomplete obstruction, an

oral electrolyte solution can be used, especially if the lesion is proximal to the splenic flexure. Low-volume polyethylene glycol solutions are favored in this setting. It is prudent to administer antibiotics prophylactically to minimize the entry of procedure-associated bacteremia. When available, carbon dioxide insufflation (rather than air) should be used for these procedures because it reduces the consequences of barotrauma.

FIGURE 2 Computed tomographic study with water-soluble contrast enema, demonstrating a 4-cm length of narrowing in the distal rectosigmoid colon.

Endoscopic Delivery

A therapeutic endoscope is often used for these procedures and advanced to the point at which the most distal aspect of the lesion is visualized. It is often not necessary or prudent to traverse the lesion with the endoscope. A guidewire is then advanced through the endoscope and traverses the lesion under fluoroscopic or endoscopic visualization, or both. The caliber, length, and course of the obstruction can then be demonstrated with the aid of contrast medium. This step allows the endoscopist to choose the appropriate stent. If the intent is to place a TTS stent, the stent is then passed through the accessory channel of the endoscope over the guidewire; the surgeon must take time to traverse the lesion appropriately. If the intent is to place a stent nonendoscopically, the endoscope is removed, and the guidewire is left in place. The stent is then placed over the guidewire under fluoroscopic or endoscopic guidance (the endoscope is reinserted and passed alongside the guidewire to allow visualization). The stent is then deployed carefully with the intent of positioning the fully deployed stent ideally 2 cm above and below the stricture. The "waist" (narrowest, not fully expanded portion) of the stent should optimally be in the middle of the stent/stent assembly (Figure 3). It may be necessary to use multiple, overlapping stents to achieve this technical goal.

Proximal Lesions and Stent Delivery

The use of colonic stents for the treatment of proximal lesions is less well described, as many patients with these lesions proceed to surgery, and because of concerns about the safety of SEMS in the right side of the colon. In one series of 82 patients, Yao and associates (2011)

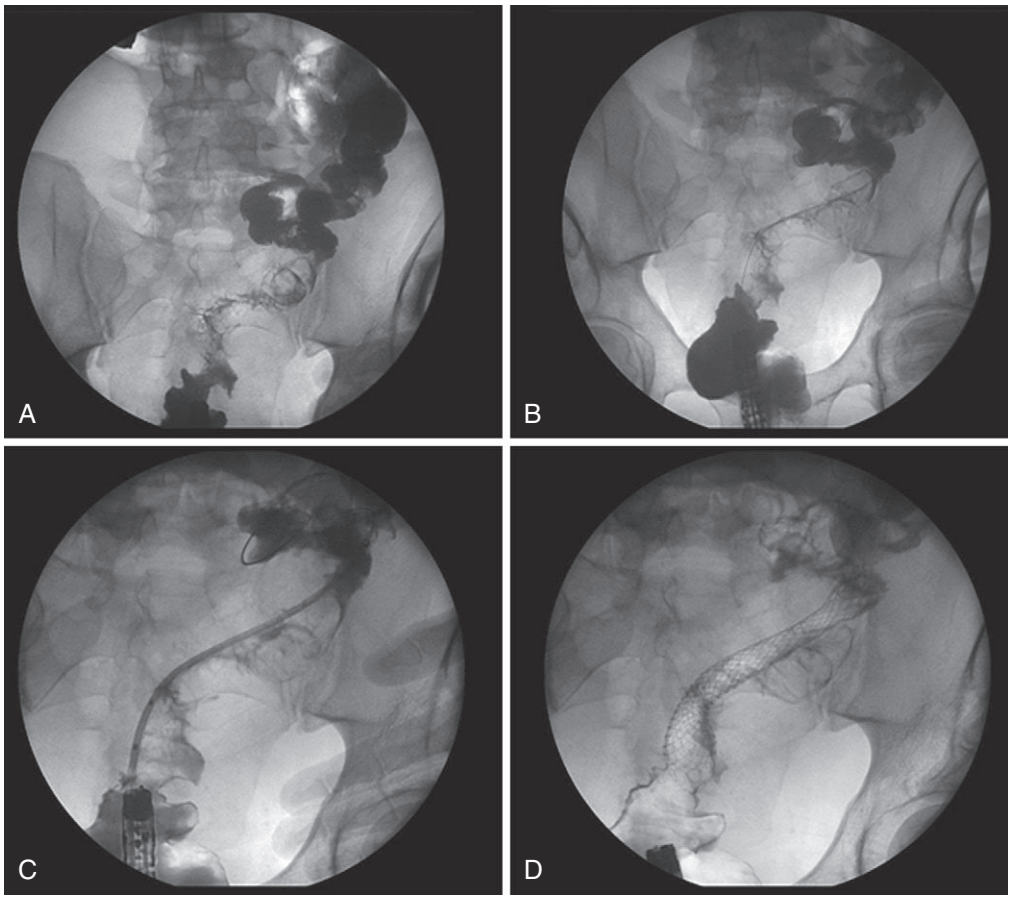

FIGURE 3 **A,** A contrast enema study performed with endoscopic and fluoroscopic visualization. **B,** Advancement of the guidewire traversing the stricture. **C,** "Through the scope" (TTS) stent bridging the stricture. **D,** Deployment of the stent across the stricture; contrast medium is observed flowing from the proximal colon.

described improved immediate outcomes among patients who underwent stent placement for obstructing lesions in the ascending colon, hepatic flexure, and transverse colon. Many patients in this series proceeded to surgical resection after stent decompression, which demonstrates the possibility of a sequential approach to colonic obstruction proximal to the left side of the colon.

Postplacement Care

The prevention of stent impaction by inspissated stool is the major thrust of care after the placement of a colonic stent. Patients should be instructed to avoid high-fiber foods. Polyethylene glycol powder may be used to titrate to a clinical response and is a useful agent in the management of patients to prevent impaction.

COMPLICATIONS

Stent-related perforation and migration are the two most worrisome common complications associated with stenting and are reported at rates of 2% to 5% and 4% to 9%, respectively. Abdominal pain after stent placement is often transient; bleeding occurs infrequently and is usually self-limited unless related to the primary tumor.

Perforations can occur immediately during or after the procedure but can be a delayed occurrence, especially when a large-caliber stent with high radial force is used. Perforations are more likely to occur in the sigmoid colon, where angulation and redundancy make stent deployment technically challenging. Experienced endoscopists are sensitive to the vulnerability of the left side of the colon to this manner of perforation and are able to mitigate these technical issues. In the systematic review by Cirocchi and colleagues (2013), perforation rates for the three included studies were in the range of those reported in previous studies, although two of the randomized controlled trials in this analysis were prematurely discontinued because of high rates of perforation. Several factors have been attributed to higher risks for perforation; patient-related factors include previous radiation therapy and certain types of chemotherapy, and procedure-related factors include predilation with a balloon before stent deployment.

According to anecdotal reports, radiation therapy appears to be a predisposition to stent-related perforation; however, the data to support this suspicion are limited. Use of the angiogenesis inhibitor bevacizumab may be associated with an increased risk of stent-related perforation. In a retrospective study, patients with stents who received bevacizumab appeared to be at higher risk for perforation (odds ratio: 20; 95% confidence interval: 5.9 to 65). Although these data are emerging, it is prudent to use stents with caution in patients receiving bevacizumab or when its use is being contemplated.

Stent migration tends to occur within the first 5 to 7 days after stent placement. Factors that promote migration include suboptimal length of stent/stent assembly, small-caliber stents, and a nonobstructing lesion. Migration may occur after oncologic or debulking therapy. In the study by Vanbiervliet and associates (2013), fully covered SEMS were used for benign strictures. The authors reported a high rate of migration (63%) but, interestingly, did not demonstrate any reduction in the efficacy rate of the stent or the recurrence rate of obstructive symptoms.

Stent failure is defined as the inability of the stent to restore luminal patency and may occur immediately after stent placement or in a delayed manner after tumor recurrence or overgrowth. Immediate stent failure may be related to mismatch between stent length and stricture length, peritoneal carcinomatosis, associated intestinal hypomotility, multifocal strictures, and early stent migration. The rate of immediate stent failure can be as high as 12% of patients in the immediate postprocedure period; the most common reason is a very tight "waist" in the stent that results in no resolution of obstructive symptoms. Pelvic computed tomographic scan with rectal contrast medium or a barium enema is essential for the evaluation of stent failure. Reintervention is often necessary to achieve luminal patency in situations in which the stent is occluded.

Stent occlusion after a period of relief may denote late recurrence of obstruction and may be caused by tumor overgrowth or by luminal compromise through the stent as a result of ingrowth. Endoscopic reintervention often involves placing another stent through the original stent or restoring luminal patency by tissue ablation (usually by argon plasma coagulation and less commonly by laser debulking).

Experienced endoscopists achieve a rate of technical success higher than 90% and a low rate of procedure-associated complications. Caution and procedural modification in patients at higher risk help minimize complications. These risk factors include:

1. The presence of multifocal obstruction
2. Extrinsic compression rather than intraluminal disease
3. Strictures longer than 10 cm
4. Use of certain chemotherapeutic agents (e.g., bevacizumab).

OUTCOMES

The bulk of experience with stents in the colon has been in the relief of left-sided colonic obstruction. Published reports have traversed all levels of evidence, including pooled/systematic analyses. From pooled analysis, these studies demonstrate technical success rates that range from 66% to 100%, with a median of 94%, and clinical success rates that range from 55% to 100%, with a median of 91% in patients undergoing colonic stenting for palliative indication. Ho and colleagues (2012) randomly assigned 39 patients with acute left-sided malignant colonic obstruction to undergo stenting, followed by elective colon resection, or to immediate emergency surgical resection. They noted no differences in mortality; however, there were significantly less stoma formations and postsurgical complications in the group who underwent stenting. The number of days spent in the intensive care unit was also significantly less in the stent recipients. Stent migration occurred in 11% of patients, and approximately 20% of patients required reintervention to reestablish luminal patency. In a systematic review of the 14 studies, Watt and associates (2007), using a survival analysis approach, found that the duration of luminal patency ranged from 68 to 288 days, with a median of 106 days. Perforations occurred in 4% of patients overall, but the rate was greater than 75% in some studies. The wide range of outcomes highlights the heterogeneity of outcomes in these studies.

SUMMARY

Successful stent placement for colonic obstruction relies upon various patient and technical factors. In patients with nonoperative malignant obstruction, more than 75% obtain successful relief of obstruction, although tumor ingrowth, stent migration, and stent-related complications may necessitate endoscopic reintervention. Stenting is favored over surgical intervention in patients presenting with incurable, malignant colonic obstruction caused by intraluminal disease with poor performance status, multiple comorbid conditions, and a colonic stricture of less than 10 cm in length. Conversely, stenting should be used with caution in patients with multifocal or long (>10 cm) strictures or extraluminal compression that results in obstruction. Concomitant or planned use of bevacizumab and possibly radiation treatment should temper the enthusiasm for stents, and full consideration should be given to alternatives so as to optimize palliative outcomes.

Stenting for acute malignant colorectal obstruction is an important option for patients with obstructing colorectal cancer, and its use for patients with nonmalignant obstruction is evolving.

Acute Colonic Pseudo-Obstruction (Ogilvie's Syndrome)

Smrita Sinha, MD, and David M. Cromwell, MD

INTRODUCTION

Acute colonic pseudo-obstruction, also known as Ogilvie's syndrome, is a disorder defined by colonic distention in the absence of mechanical obstruction. It was first reported by Sir William Heneage Ogilvie in 1948. Although the exact pathogenesis of acute colonic pseudo-obstruction is unknown, the disruption of normal colonic motility is hypothesized to result in massive distention and symptoms of obstruction. Resulting complications of ischemia or perforation can be associated with mortality rates that exceed 40%.

PRESENTATION AND DIAGNOSIS

The diagnosis of acute colonic pseudo-obstruction is based on clinical presentation combined with abdominal radiographs that confirm colonic distention. Clinical features include abdominal distention, abdominal pain (80%), and nausea or vomiting (60%). Examination reveals a tympanitic abdomen, and bowel sounds are usually present. Marked abdominal pain, fever, and leukocytosis can suggest the development of perforation or ischemia. Acute colonic pseudo-obstruction occurs almost exclusively in hospitalized patients who have a significant underlying medical or surgical comorbidity. In published reviews, most patients have had nonoperative trauma, infection, or cardiac disease. Surgical patients have most commonly undergone obstetric/gynecologic, abdominal, and orthopedic procedures. Abdominal distention occurs on average on postoperative day 4.5.

MANAGEMENT

The management of colonic pseudo-obstruction depends foremost on the patient's clinical status. Fevers, leukocytosis, and peritoneal signs can suggest colonic perforation or ischemia, and these complications should be ruled out immediately. The rate of spontaneous perforation is estimated to be 3% and is generally associated with cecum diameter greater than 12 cm and prolonged distention for more than 6 days. In the absence of suspected ischemia or perforation, initial management includes supportive care and elimination of exacerbating factors (Table 1). Supportive care includes bowel rest, maintenance intravenous fluids, and correction of electrolyte abnormalities, especially potassium, magnesium, and calcium. Underlying conditions such as cardiopulmonary derangements and infections should be treated. Nasogastric tube decompression remains a recommendation even though no published proof of its efficacy has been seen. Some practitioners also use rectal tube decompression. Medications that slow gut transit, especially opiates and those with anticholinergic side effects, should be discontinued. Frequent culprits include: antidiarrheal medications, such as loperamide; tricyclic antidepressants; antipsychotics; calcium channel blockers; and beta-blockers. Laxatives and enemas have been shown to worsen the condition and should be avoided. If air cannot be found in the rectosigmoid on abdominal radiographs, mechanical obstruction should be ruled out with a water-soluble enema. Serial abdominal examinations are recommended. Mortality doubles when the cecum diameter increases from less than 12 cm to greater than 14 cm. Upright and supine abdominal x-rays should be performed every 12 to 24 hours.

Neostigmine

Neostigmine, an acetylcholinesterase inhibitor, should be used if supportive care does not lead to improvement in 24 to 48 hours or if the patient has prolonged distention. Published success rates with neostigmine range from 60% to 100%, with clinical response within 30 minutes. The most common side effects of neostigmine are self-limited abdominal pain, nausea, and excessive salivation. Neostigmine (2 mg intravenously [IV]) should be given with atropine readily

TABLE 1: Supportive treatment for acute colonic pseudo-obstruction

available and with continuous cardiac monitoring for 30 minutes because it can cause bradyarrhythmias at a reported incidence rate of 7%. The side effects of neostigmine may be more pronounced in renal failure, so the dose should be adjusted based on creatinine clearance. Neostigmine can also exacerbate bronchoconstriction. Contraindications to its use include: suspected gut ischemia or perforation; ongoing cardiac arrhythmias; active bronchospasm; baseline heart rate of less than 60 beats per minute; systolic blood pressure of less than 90 mm Hg; serum creatinine level of more than 3 mg/dL; and pregnancy. Concomitant use of glycopyrrolate (0.4 mg IV) can mitigate the side effects of neostigmine. Pseudo-obstruction can recur after neostigmine administration. Risks for a failed response include older age, electrolyte disturbances, and use of medications that decrease gut motility. The dose of neostigmine can be repeated. The optimal interval between doses is unknown, but many practitioners repeat the dose once after 24 hours. Overall, neostigmine is an effective and safe option for colonic decompression in those patients with failed conservative management who need more urgent intervention when there are no contraindications to its use.

Very limited data suggest that erythromycin and methylnaltrexone might play a role in addition to or instead of neostigmine. Following initial response of acute pseudo-obstruction to conservative, medical, or endoscopic measures, polyethylene glycol (PEG) has been shown to be effective in preventing recurrence. In this setting, PEG can be administered orally for 7 days. Low doses appropriate for the management of constipation are recommended. The safety and tolerability of PEG make it a reasonable pharmacologic agent to help prevent recurrence of acute colonic pseudo-obstruction.

Colonoscopy

Endoscopic colonic decompression should be considered in patients who do not have improvement after 24 to 48 hours of conservative therapy, have marked cecal distention of significant duration, and have failure of or cannot tolerate initial treatment with neostigmine. Colonoscopy is contraindicated for suspicion of bowel perforation, evidence of peritonitis, or frank mucosal ischemia seen at the start of the procedure. In retrospective studies, sustained response to colonic decompression ranged from 36% to 88%. Colonoscopy with large diameter channels should be used to allow for optimal suctioning of stool and gas. The colon should not be prepped with enemas before the procedure to minimize the risk of perforation. The colonoscopy can be technically difficult in an unprepped colon and should be performed only by a skilled endoscopist. When reaching the cecum is not possible, advancement of the scope to the hepatic flexure may suffice. Anecdotal evidence suggests increased sustained response rates with placement of a decompression tube. The decompression tube should be placed to gravity or to low intermittent suction and flushed every 4 to 6 hours with saline solution to maintain patency. The tube should be removed after 72 hours if it has not already passed spontaneously with restoration of peristalsis. Colonoscopic perforation is reported to occur in approximately 3% of patients with colonic pseudo-obstruction compared with 0.1% to 0.2% in patients undergoing routine colonoscopies. Up to 20% of patients can need two to four colonoscopic decompressions before a sustained clinical response is achieved. Therefore, colonoscopy in patients with acute pseudo-obstruction should be performed carefully and with appropriate delineation of the risks to patients when obtaining consent.

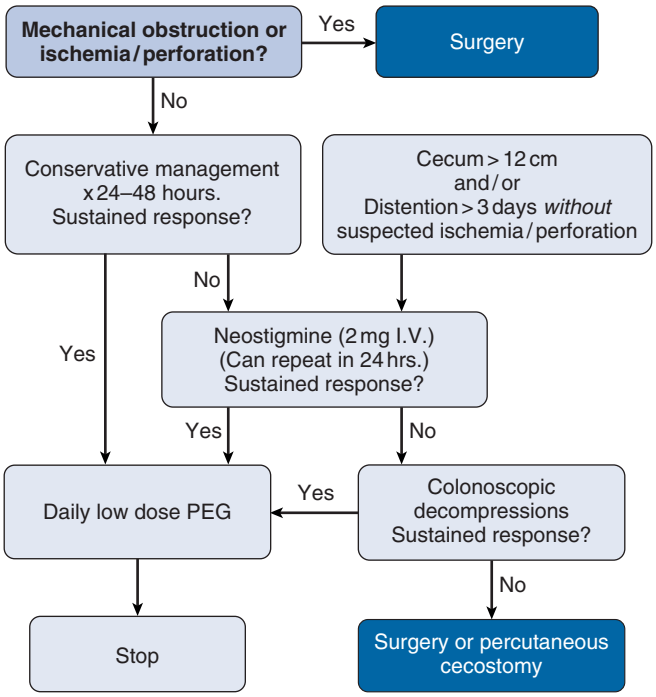

FIGURE 1 Acute colonic distension. *IV,* Intravenous; *PEG,* polyethylene glycol.

Tube Cecostomy

A percutaneous tube cecostomy can be considered in patients who do not respond to pharmacologic or endoscopic decompression, who have no evidence of ischemia or perforation, and who are poor surgical candidates. A percutaneous cecostomy can be performed with endoscopic, computed tomographic (CT) scan–guided, or laparoscopic techniques. Small case report series with these techniques report some success but cannot accurately reflect on overall safety and efficacy. Risks of the procedure include: peritonitis, wound infection, problems with tube patency, and inadequate decompression. Minimally invasive percutaneous cecostomy should be reserved for patients with failed medical and endoscopic decompression and who cannot tolerate surgery.

Surgery

Surgical intervention for the treatment of acute colonic pseudo-obstruction should only be considered when conservative, pharmacologic, and minimally invasive interventions have been unsuccessful and the patient has prolonged distention lasting more than 6 days. Overall mortality rates in patients with acute colonic pseudo-obstruction undergoing any form of surgical intervention range from 30% to 60%. For surgical tube cecostomy, the morbidity rate approaches 50% and the overall mortality rate is close to 20% to 30%. No published data exist comparing the efficacy of tube cecostomy with more invasive techniques in the management of colonic pseudo-obstruction. In the absence of colonic perforation or ischemia, the surgical procedure of choice may be placement of some form of venting stoma. Stomas have a low immediate morbidity but have been associated with recurrence of pseudo-obstruction and increased

long-term morbidity. No published studies compare different types of stoma or stomas versus resection. The high mortality and morbidity with surgical decompression or resection derive from the underlying comorbid conditions in this patient population (Figure 1).

SUMMARY

Acute colonic pseudo-obstruction is a disorder of colonic motility that results in significant colonic distention in the absence of a mechanical obstruction. It occurs almost exclusively in hospitalized patients with comorbid medical and surgical illnesses. Complications such as ischemia and perforation can result in high mortality and make the timely recognition and treatment of acute colonic pseudo-obstruction paramount. Initial management should include supportive care followed by pharmacologic and endoscopic decompression. The presence of significant colonic dilation and the duration of clinical symptoms should prompt earlier attempts at endoscopic or even percutaneous decompression. Surgical intervention should be reserved for patients who do not respond to conservative management or pharmacologic or endoscopic strategies. Surgical decompression and resection are associated with high overall morbidity and mortality.

The Management of Colonic Volvulus

Karen Deveney, MD

OVERVIEW

The term *volvulus* refers to any twisting or turning of the intestine that causes obstruction. Volvulus can occur in either the small or the large intestine. Although colonic volvulus can occur in children as a result of congenital conditions, such as malrotation or Hirschsprung's disease, or infectious disease, such as Chagas' disease, colonic volvulus is most commonly an acquired condition that occurs in adults. Characteristics of the colon that predispose to volvulus include lack of colonic fixation to the retroperitoneum, an elongated mesentery and colon, and a narrow base of origin of the mesentery. Adhesions are not a common cause of volvulus of the colon because they are in the small intestine, and most people with volvulus have not had prior abdominal operations.

Colonic volvulus is estimated to cause 10% to 15% of colonic obstructions. The sigmoid colon is the site of 60% to 80% of all cases of colonic volvulus, with 15% to 30% occurring in the cecum, 2% to 5% in the transverse colon, and about 1% in the splenic flexure. The average age of individuals with development of sigmoid volvulus is older than those with cecal volvulus, and a higher percentage of those with cecal volvulus are women; sigmoid volvulus affects men and women equally. The incidences that occur in the transverse colon or splenic flexure are too small to make accurate generalities about age and gender.

The predominant factors associated with colonic volvulus include anything that results in constipation and thereby leads to lengthening of the colon, such as advanced age, low-fiber diet, psychiatric medications, Parkinson's disease, Chagas' disease, and sedentary lifestyle. The exact pathophysiology of its development is not entirely clear, however, because colonic volvulus is far more common in non-Westernized countries, such as Africa, Asia, the Middle East, Eastern Europe, and South America, where it occurs in a younger age group and where a high-fiber diet has been suggested as a predisposing factor. Volvulus can also occur during pregnancy, which also can cause colonic lengthening.

SIGMOID VOLVULUS

Sigmoid volvulus is much more common worldwide than in North America or Western Europe. In other regions, it occurs more frequently in children than in the United States and is most often associated with congenital abnormalities, such as Hirschsprung's disease, or parasitic diseases, such as Chagas' disease *(Trypanosoma cruzii)*. In Western countries, sigmoid volvulus is predominantly a condition that affects the elderly and those taking psychiatric medications or with neurologic conditions. Because these individuals may not be able to appreciate or report their symptoms, recognition that volvulus has occurred may be delayed and the presentation may be nonspecific.

When the sigmoid colon twists, it usually obstructs the lumen completely but occludes only venous return, not arterial flow. For that reason, symptoms may be gradual and muted rather than abrupt and dramatic. Volvulus usually presents with cramping, vague lower abdominal fullness, and gradual distention of the abdomen. The volvulus may detorse spontaneously and result in explosive, large-volume bowel movements. A history of such past episodes is not uncommon. If the volvulus persists, it eventually results in nausea, anorexia, and more severe pain as the bowel becomes more distended. At that point, the individual may exhibit tachycardia and tachypnea as the elevated diaphragm restricts respiratory excursion.

When the individual comes to medical attention, volvulus has usually been present for several days. On examination, the abdomen

is distended and usually only mildly and diffusely tender. Although gangrene and perforation are not common, they can occur in individuals with a tight twist or with longstanding volvulus that has led to extreme colonic distention or venous thrombosis. The perforation may occur in the sigmoid or in the cecum, whose wall is thinner and pressures higher than in the sigmoid. The presence of peritoneal signs on examination, fever, or elevated white blood cell count (WBC) suggests ischemia or perforation.

The diagnosis of sigmoid volvulus can usually be made with abdominal x-rays, which show dilated colon occupying the majority of the abdomen and a colon configuration in the shape of a "bent inner tube" with its point in the left pelvis (Figure 1). An upright or left lateral decubitus film should also be obtained to look for free air. Although a computed tomographic (CT) scan can also be used to make the diagnosis, it is usually not necessary. Barium or water-soluble contrast enemas may also be diagnostic, showing a "bird's beak" appearance in the rectosigmoid, but are usually unnecessary and are unwise if signs of perforation are present.

When sigmoid volvulus has been diagnosed, an attempt at detorsion of the bowel is warranted if the point of torsion looks viable. Although traditionally and somewhat more successfully accomplished with rigid sigmoidoscopy with patients on their hands and knees and buttocks elevated, this position may be difficult for elderly patients to assume and maintain. Current practice most commonly uses flexible sigmoidoscopy with the patient in the left lateral position. Reduction of the volvulus with sigmoidoscopy is achieved in 70% to 80% of patients, but the volvulus recurs in more than half if definitive surgery is not performed. For this reason, a rectal tube is customarily left in place to prevent immediate recurrence and allow colonic decompression while the patient's overall condition is optimized for colonic resection as soon as it can be accomplished. Because these individuals usually are elderly and frail and may have cardiac and respiratory diseases and be on anticoagulant therapy, multidisciplinary teamwork is essential to achieve the most favorable outcome. Recurrence of the volvulus is almost unavoidable without surgery, so all but those with the most prohibitive anesthetic risk should be offered surgery. A bowel preparation and colonoscopy should ideally be performed before surgery to rule out the presence of malignancy at the site of the volvulus or elsewhere in the colon. If results of a recent colonoscopy are available and show no abnormalities, the need for a bowel preparation before surgery is controversial. Although it has been conventional practice for decades in the United States to perform bowel cleansing before elective colonic surgery, current best evidence suggests lower complications and better outcomes without a bowel preparation. The example from trauma surgery of successful anastomoses and low infection rates in primary colonic repair after penetrating colonic trauma also supports the omission of bowel preparation as safe practice.

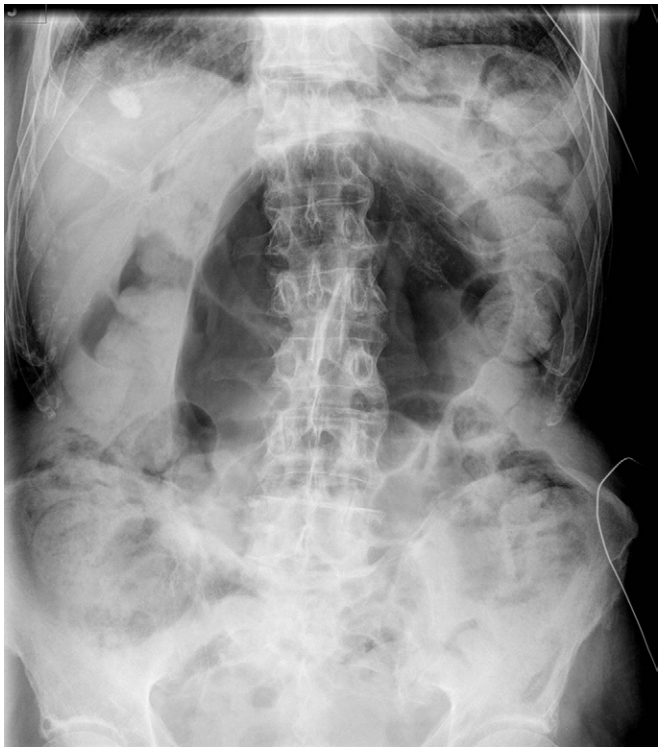

FIGURE 1 Plain abdominal film of an 88-year-old man with sigmoid volvulus, displaying the "bent inner tube" appearance. The volvulus was successfully reduced with rigid sigmoidoscopy.

If the volvulus was not able to be reduced nonoperatively or the patient's presentation suggests perforation or ischemia, emergency operation is indicated as soon as the patient is rendered normovolemic and the medical condition is optimized.

Although simple pexy of the sigmoid to the sidewall of the lateral abdomen was previously considered a surgical option, the recurrence rate (30% to 50%) is so high after this procedure that it is no longer considered a good choice. If the bowel has signs of gangrene at operation, the affected bowel should be resected without first reducing the volvulus, to avoid the release of toxins into the circulation. If gangrene is not present, the sigmoid can be resected in the usual fashion after reducing the volvulus. To minimize fecal contamination when a bowel preparation is not possible or not performed, the proximal and distal sites of resection can be identified and cleared and the mesentery resected before dividing the bowel. The distal bowel is then divided and bowel contents directed off the field into a bucket, before the proximal site is divided and the specimen passed off the field.

If the patient is hemodynamically stable and nutrition is reasonable, a primary anastomosis is generally preferable to a colostomy with Hartmann's procedure or mucous fistula. If the patient is nutritionally or immunologically compromised (e.g., renal failure, transplant, steroids, severe diabetes), a colostomy should be performed. Impaired fecal continence is another indication for a colostomy.

Series that report outcomes of sigmoid resection for volvulus show lower mortality with primary anastomosis than with colostomy and higher mortality with emergency procedures. However, these studies are all retrospective case series in which the patient's condition likely factored into the decision whether to perform a primary anastomosis or colostomy.

Occasionally, the entire colon may be massively dilated, such as in a patient with Ogilvie's syndrome (colonic pseudo-obstruction). In that case, a subtotal colectomy is indicated with ileostomy or ileoproctostomy, again depending on the patient's overall nutrition and immunocompetence.

A laparoscopic approach has been described for treatment of sigmoid volvulus and is an option if the surgeon is a very skilled laparoscopic surgeon but should probably be avoided in the emergency situation when the bowel has not been reduced because the limited working room in the abdomen makes the laparoscopic approach more difficult. In the patient whose volvulus has been reduced and colon decompressed, the same surgical options are available for a laparoscopic approach as for an open procedure. Colopexy or mesosigmoidopexy can be achieved with low mortality and morbidity and a short procedure time, but the recurrence is much higher than with resection.

An algorithm for treatment of sigmoid volvulus is presented in Figure 2.

CECAL VOLVULUS

Cecal volvulus is far less common than sigmoid volvulus, it usually occurs at a younger age (40 to 60 years) than sigmoid volvulus, and it is more frequently seen in women than in men. As in sigmoid

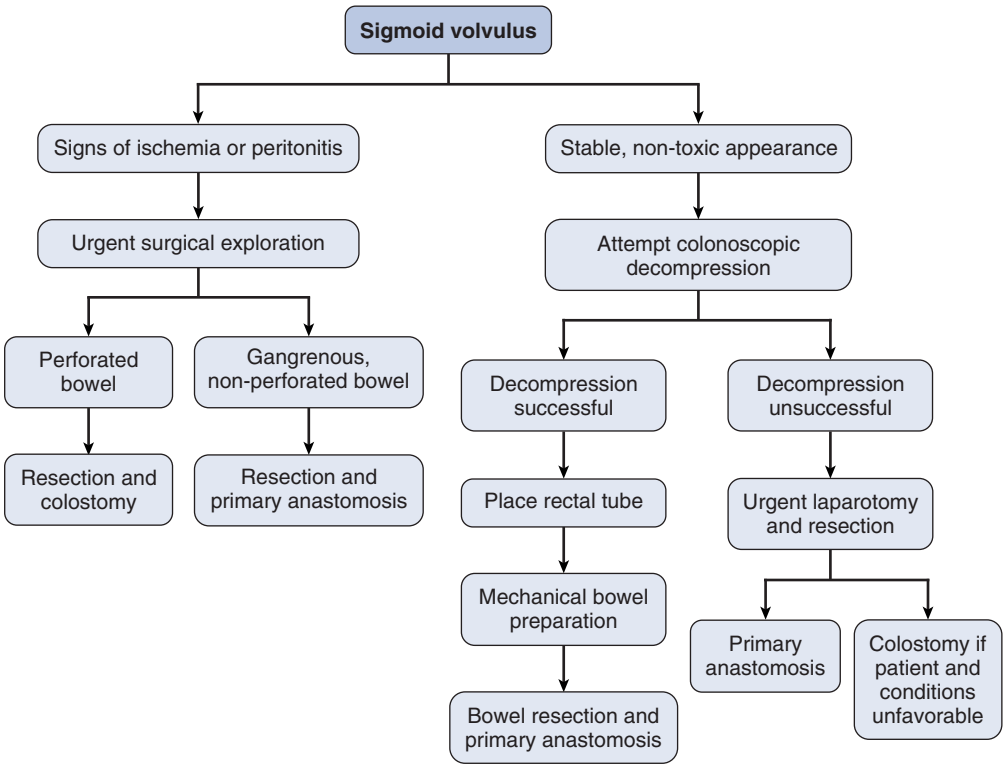

FIGURE 2 Suggested algorithm for management of sigmoid volvulus.

volvulus, the occurrence of cecal volvulus requires an elongated, mobile cecum that is not fixed to the retroperitoneum. Although it is also usually associated with constipation, cecal volvulus is less commonly associated with the elderly, nursing home patients, or those on psychiatric medications than is sigmoid volvulus.

When the entire cecum and terminal ileum rotate on a narrow mesenteric axis, a true ileocecal volvulus occurs. These individuals most commonly note sudden abdominal pain across the mid abdomen and come to medical attention sooner after the onset than patients with sigmoid volvulus. The abdomen is distended and tender; localized peritoneal signs on examination suggest ischemic bowel, and diffuse peritoneal irritation indicates perforation. Although plain abdominal films can show a dilated loop of small and large bowel extending across the abdomen to the left upper quadrant, the appearance of the gas-filled loops is often less definitive and may require CT scan for confirmation (Figure 3). Endoscopic detorsion is less likely to be successful than with sigmoid volvulus, with less than 10% success. Resolution invariably requires operative intervention, either with open or laparoscopic method. Ileocolic resection with primary anastomosis is the procedure with the highest success rate, with a mortality rate of less than 10% and equally low recurrence. If the patient is hemodynamically unstable or has perforation of the bowel with peritonitis, ileostomy may be a safer choice. As in sigmoid volvulus, gangrenous bowel should not be detorsed but resected as it lies to avoid systemic dissemination of toxic substances. Detorsion and cecopexy is an option if the length of procedure must be minimized and the bowel is totally viable, although the recurrence rate of 30% to 40% makes it a less attractive choice in any patient who is clinically stable enough to undergo resection.

A special type of cecal volvulus is cecal bascule, a condition in which the cecum folds up on itself anteriorly. The resultant obstruction may be incomplete and intermittent, making it more difficult to diagnose than a true cecal volvulus. Patients with this condition present with right midabdominal pain that may resolve and recur for several months or years. Plain abdominal films are often not definitive and difficult to interpret correctly. Cross-sectional CT images may also not reveal the abnormality, although it is more easily seen on the sagittal reconstructions. Operation is necessary for effective treatment, but the best surgical option depends on the operative findings and ranges from cecopexy to cecectomy to ileocolic resection, depending on how much of the cecum and right colon is mobile and nonfixed. Recurrence rates are 10% to 30% and depend on selecting the most appropriate procedure to resolve the hypermobile segment.

FIGURE 3 A 58-year-old woman with distal ileal and cecal volvulus. The computed tomographic scan shows a dilated cecum and distal ileum in the left upper quadrant, with an abrupt transition point as the right colon crosses the central mesentery.

TRANSVERSE COLON VOLVULUS

Volvulus of the transverse colon is seen far less frequently than sigmoid or cecal volvulus, with most reports in the literature being

case reports or a handful of cases collected over many years. Only 1% to 4% of colonic volvulus involves the transverse colon. Volvulus of the transverse colon is far more common in some geographic areas, including Scandinavia, Eastern Europe, India, and Africa. The most common anatomy of the transverse colon with its short, wide mesentery and its location between the usually fixed hepatic and splenic flexures makes it less inclined to volvulus. Factors that allow the transverse colon to twist on its axis include an abnormally long mesentery, intestinal malrotation with a narrower mesentery than normal, or lack of fixation of the flexures. Conditions that promote elongation of the colon, such as constipation or distal colonic obstruction, can also create a predisposition for the transverse colon to twist around its mesenteric axis. Most likely because of their irregular bowel patterns with subsequent lengthening of the entire colon, the mentally disabled are predisposed to volvulus of the transverse colon and the sigmoid colon.

Patients with transverse colon volvulus present in an acute or subacute fashion. Those with a sudden, more complete volvulus present with epigastric pain, abdominal distention, nausea, vomiting, and abdominal tenderness. They are tachycardic and appear very ill. The more chronic type of transverse colon volvulus, with a less complete twist or intermittent torsion, may be more gradual in onset with less severe symptoms and intermittent cramping pain. A plain abdominal film may be diagnostic, showing distension of the proximal colon and collapsed distal colon. With the almost universal availability and use in patients presenting with acute abdominal pain, CT scanning is usually the diagnostic test used in making the diagnosis. Findings on CT scan include the torsed bowel loop and the "whirl sign" of the mesenteric vessels.

The safest and most practical treatment option for transverse colon volvulus is surgical resection. Clearly, resection is mandatory if any bowel ischemia or perforation is found at exploration. The option of colopexy is less attractive in this form of volvulus because of a lack of convenient structures to which the transverse colon can be safely anchored. Whether to perform an anastomosis or proximal stoma with a mucous fistula or long Hartmann's procedure depends on the condition of the patient and the findings at surgery. The presence of perforation with peritonitis or a malnourished or hemodynamically unstable patient makes anastomosis risky and colostomy a safer option.

SPLENIC FLEXURE VOLVULUS

Splenic flexure volvulus is an extremely rare condition that occurs when the normal fixation of the splenic flexure is absent for congenital reasons or because of prior surgery that renders the splenic flexure more mobile. As with other forms of volvulus, constipation and neuropsychiatric disorders are commonly seen in these patients. The clinical presentation is similar to that of volvulus of the cecum or transverse colon. Radiographic diagnosis can be made either with plain films, showing proximal dilated colon with distally decompressed colon, or CT scan that shows the twisted splenic flexure. Treatment is surgical and can be either resection or detorsion with fixation of the splenic flexure by colopexy, depending on the surgical findings.

RECTAL PROLAPSE

Alan D. Garely, MD, FACOG, FACS,
Beth R. Krieger, MD, and Alex J. Ky, MD

Rectal prolapse is a protrusion of the walls of the rectum outside the anus. Full-thickness prolapse refers to prolapse of all layers of the bowel wall; partial prolapse involves only the mucosa. Full-thickness prolapse has a characteristic circular mucosal fold appearance, whereas partial or hemorrhoidal prolapse has radial folds. Internal rectal intussusception is when the rectum folds in on itself, but it usually does not fall outside the anus. The best method for diagnosis of prolapse is with the patient sitting on a commode bearing down to simulate a bowel movement.

ETIOLOGY AND PRESENTATION

The etiology of rectal prolapse is not entirely understood. The two most popular theories are those put forth by Moschowitz and by Broden and Snellman who, respectively, believed that prolapse was the result of a sliding hernia through a defect in the pelvic fascia or an intussusception of the rectum. A variety of anatomic defects occur with rectal prolapse. These include pelvic floor laxity, weak sphincter complex, redundant rectosigmoid, deep pouch of Douglas, pudendal neuropathy, and a lack of rectal fixation.

Most patients with rectal prolapse are women (up to 90%) over the age of 50 years with a history of vaginal childbirth. Men are typically younger, 20 to 40 years of age; the incidence rate decreases with advancing age. An increased incidence rate is also found in nursing home and psychiatric patients. Prolapse may be associated with rectal bleeding, especially after defecation, and frequently has an associated mucoid discharge. Other reported symptoms include a sensation of incomplete evacuation, tenesmus, constipation with straining, and incontinence.

EVALUATION

The evaluation of a patient with rectal prolapse should always start with a history and physical examination. During examination, the prolapse is often reduced. Patients frequently have a patulous anus and diminished resting tone and squeeze pressures on digital rectal examination. The prolapse is best reproduced by having the patient sit on a commode and bear down. Full-thickness prolapse is distinguished from mucosal prolapse by the appearance of concentric

folds. This examination may also show a concomitant cystocele or prolapse of the uterus.

Additional workup should include colonoscopy to exclude any other colonic or rectal pathology, especially in patients who are over the age of 50 years. Manometry can help assess any sphincter damage that may result from chronic prolapse. Levatorplasty at the time of surgery may improve the continence in these patients. Patients with a history of constipation should undergo colonic transit studies because this may influence their surgical options. If evidence of slow transit constipation or colonic inertia is found, a sigmoid resection or subtotal colectomy should be considered at the time of operation.

TREATMENT

Surgery is the only definitive form of treatment. Options include narrowing of the anal orifice, obliteration of the pouch of Douglas, restoration of the pelvic floor, bowel resection, suspension/fixation of the rectum to the sacrum, or any combination of these procedures. Surgery is usually divided into abdominal and perineal approaches. Traditionally, the perineal approaches have been reserved for older patients who are not appropriate surgical candidates for a more invasive abdominal operation that requires general anesthesia. Abdominal surgeries are thought to be more effective, with lower rates of recurrence. Because full-thickness rectal prolapse is relatively rare and long-term follow-up studies are limited, there is no clear gold standard surgical approach. Surgery needs to be individualized to each patient for optimization of functional outcomes.

Perineal Procedures

Perineal surgeries are typically reserved for the elderly with significant comorbidities because these surgeries can be done with local anesthesia and are usually well tolerated. Patients usually have minimal pain, earlier return of bowel function, and quicker tolerance of a regular diet and are ambulating much sooner than patients who undergo an abdominal operation. Perineal approaches include anal encirclement, Delorme's procedure, and perineal rectosigmoidectomy.

Thiersch's Procedure

Anal encirclement or the Thiersch's procedure was first described in 1891 with a silver wire. It has since been modified to use any number of products, but the basic principle involves passing a foreign material around the anus to narrow it and act as a physical barrier to prevent further prolapse. The narrowed anus should still allow passage of a 16-mm or 18-mm Hagar dilator. This procedure has largely been abandoned because of its high recurrence rates (33% to 44%) and significant morbidity. Common complications have included fecal impaction, wound infection, and erosion, all of which usually necessitate implant removal. An additional concern is that when prolapse recurs, the rectum may become incarcerated and strangulated.

Mucosal Sleeve Resection (Delorme's Procedure)

Delorme's procedure was first described in 1900 and is considered the treatment of choice for mucosal and short-segment full-thickness prolapse. A circumferential incision is made in the mucosa 1 cm above the dentate line, and the submucosa and mucosal layers are dissected off the muscularis. Injection of local anesthesia with epinephrine in the submucosa facilitates this dissection and aids in hemostasis. The stripped mucosa is excised, and a plicating stitch is then placed from the cut edge of the mucosa to the muscularis and to the mucosa just proximal to the dentate line (Figure 1).

Morbidity and mortality rates have been reported as 4% to 33% and 0 to 2.5%, respectively. Complications associated with the

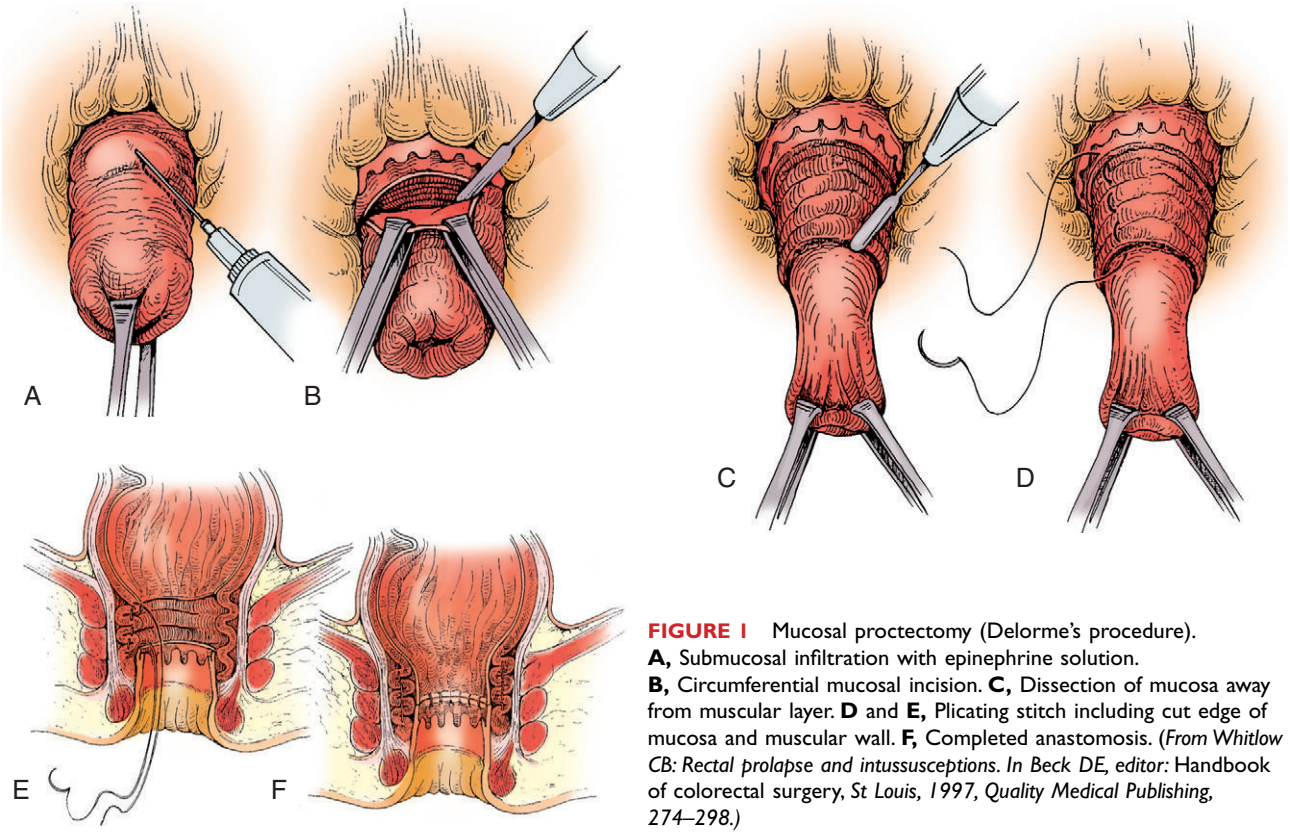

FIGURE 1 Mucosal proctectomy (Delorme's procedure). **A,** Submucosal infiltration with epinephrine solution. **B,** Circumferential mucosal incision. **C,** Dissection of mucosa away from muscular layer. **D** and **E,** Plicating stitch including cut edge of mucosa and muscular wall. **F,** Completed anastomosis. procedure include bleeding, anastomotic leak, stricture, and diarrhea. Recurrence rates have been reported to range from 6% to 26%. Up to 50% of patients reported an improvement in incontinence after the procedure and no associated constipation.

One of the largest case series was by Lieberth and colleagues who reported on 76 patients who underwent Delorme's procedure. The median age of the patients was 74 years; they were followed over an average of 36 months. There were no perioperative deaths, and the morbidity rate was 25%. The most common postoperative complication was urinary retention (12%). One patient had a myocardial infarction, and three patients had *Clostridium difficile* colitis develop. Three patients (4%) had development of suture line bleeding, two patients (3%) had an anastomotic leak, and one (1%) an anastomotic stricture. Overall recurrence rate was 14.5%, with a mean time to recurrence of 31 months (range, 1 to 60 months). No predictors of recurrence were identified.

Perineal Rectosigmoidectomy (Altemeier's Procedure)

The perineal rectosigmoidectomy was first performed by Mikulicz in 1889, but it was not until the 1970s that it became popularized by Altemeier. The rectum is prolapsed and then injected with epinephrine-containing local anesthesia. A circumferential incision is made through all layers of the rectal wall 1 to 2 cm above the dentate line. Once the full-thickness incision is complete, the redundant rectum is continually pulled out as the mesorectum is ligated and divided. For this portion of the procedure, the authors use the LigaSure device (Covidien, New Haven, Conn) for both its speed and its hemostatic properties. The anterior peritoneal reflection is opened and allows for a high ligation of the hernia sac. The rectum/sigmoid colon is pulled out through the peritoneal defect until there is no further redundancy. The rectum/colon is then divided, and the end is anastomosed to the anal ring. One modification of this procedure involves plication of the levators, which is thought to decrease recurrence and improve continence (Figures 2 and 3).

Mortality rates associated with this procedure are low (0 to 6%), and most of the morbidity (5% to 24%) stems from the patient's underlying medical problems, but there is a possibility of postoperative bleeding and anastomotic dehiscence. This is where experience comes into play; resecting too much colon and mesentery makes for an anastomosis that is under tension and poorly vascularized, thereby increasing the risk of a leak, whereas not resecting enough can lead to recurrence. Recurrence rates have been reported as 0 to 10% but are believed to increase with longer patient follow-up periods.

In an effort to report long-term data, Altomare and associates performed a retrospective review of 93 patients who had undergone Altemeier's procedure and had at least 1 year of follow-up. Fifteen percent of patients had previously had surgery for prolapse. After an average follow-up period of 41 months, 18% had recurrence of full-thickness prolapse and 6% had mucosal prolapse develop. A previous unsuccessful repair was the only predictor of recurrence (odds ratio [OR], 3.8; $P = 0.042$).

Options for recurrent prolapse after Altemeier's procedure include a repeat Altemeier's procedure or an abdominal approach. Theoretic concern exists that an abdominal resection can devascularize the distal bowel unless a coloanal anastomosis is performed. An abdominal fixation or suspension is considered a reasonable alternative.

Abdominal Procedures

Ripstein's Procedure

This technique was first described by Ripstein and Lanter in 1963. They believed that rectal prolapse was primarily the result of intussusception of the rectum that occurs with loss of the rectal attachments. This belief leads to the design of a surgical technique that affixes the rectum to the sacrum and thus prevents rectal prolapse. Initially, they used fascia lata to create a sling that they could use to fix the rectum to the sacrum, but they subsequently modified the technique and started using prosthetic mesh.

The procedure involves mobilization of the rectum down to the coccyx with dividing the lateral peritoneal attachments but preserving the lateral ligaments. While the rectum is pulled upward, a 5-cm piece of mesh is wrapped anteriorly around the rectum at the level of the peritoneal reflection and then sutured bilaterally to the presacral fascia approximately 5 cm below the sacral promontory. The sling should allow the passage of one to two fingers between the rectum and fascia because too tight of a wrap can cause obstruction.

Studies have shown that this procedure is best suited for the patient without preexisting constipation. Up to 50% of patients had improvement of incontinence; persistence of constipation occurred in 57%, and new onset constipation developed in 10%. Recurrence and mortality rates after this procedure are relatively low, 0 to 8% and 0 to 1.6%, respectively.

Unfortunately, Ripstein's procedure does have a significant morbidity associated with it; it is not used that frequently anymore. Complication rates are reported from 17% to 33% and are largely related to the placement of the sling. The most common problem was constipation and fecal impaction, but presacral hemorrhage, stricture, small bowel obstruction, impotence, and fistula formation were also notable. One of the more catastrophic complications

associated with placement of a mesh is the development of infection or erosion into the bladder. Modifying the procedure to a posterior wrap or substitution of polyvinyl alcohol sponge for the mesh have reduced the complication rates to 20%.

Abdominal Rectopexy and Sigmoid Resection

This technique, originally described in 1955, remains today as one of the commonly used and effective treatment options for full-thickness rectal prolapse. Frykman describes four essential steps to this procedure: (1) complete mobilization of the rectum down to the levator complex, with the lateral ligaments left intact; (2) elevation of the rectum with suture fixation to the presacral fascia just below the sacral promontory; (3) obliteration of the cul-de-sac with suturing the endopelvic fascia anteriorly to the rectum; and (4) resection of the redundant sigmoid colon with an end-to-end anastomosis. The procedure remains essentially the same today, but some surgeons chose to omit the obliteration of the cul-de-sac.

A recent meta-analysis of 418 patients reported a recurrence rate of 0 to 9% and morbidity and mortality rates of 0 to 23% and 0 to 6.7%, respectively. Complications related to the procedure itself included colonic and small bowel obstructions, anastomotic leak, and presacral bleeding. Most patients reported an improvement in bowel habits after the procedure. Huber and colleagues found a reduction in constipation from 44% to 26% and in incontinence from 67% to 23%.

Abdominal Rectopexy

Rectopexy without a sigmoid resection can also be used for the treatment of rectal prolapse. Fixation of the rectum to the sacrum can be accomplished with placement of interrupted nonabsorbable sutures or with use of a mesh (Ripstein's). Recurrence rates also range from 0 to 9%, but the functional outcomes are quite different as compared with a resection rectopexy. Generally speaking, constipation is worsened in these patients and incontinence improved (Table 1).

Management of the Lateral Ligaments

The Cochrane review is a meta-analysis of 12 randomized controlled trials evaluating 380 patients. One of the outcomes assessed in this review was division versus preservation of the lateral ligaments during rectal mobilization in patients undergoing open mesh rectopexy. The three distinct trials examined a total of 64 patients. Division of the ligaments was associated with a decreased recurrence rate (0 vs 19%) but increased rates of constipation (67% vs 43%).

Laparoscopy

Laparoscopy has been used to perform both abdominal rectopexy and resection rextopexy. The rates of recurrence, morbidity, and mortality have been shown to be comparable between the open and laparoscopic techniques. However, laparoscopy is associated with shorter hospital stays and faster patient recovery. A meta-analysis of 467 patients undergoing 275 open and 192 laparoscopic procedures showed no significant difference between recurrence and improvements in constipation or incontinence (Table 2).

Robotics is the next potential step in the treatment of rectal prolapse. Theoretically, one expects to see improved outcomes, particularly in patients undergoing rectopexy, because suturing in the pelvis is more facile with the robot as compared with standard laparoscopy. Because this is a newer technology, studies are small and have short

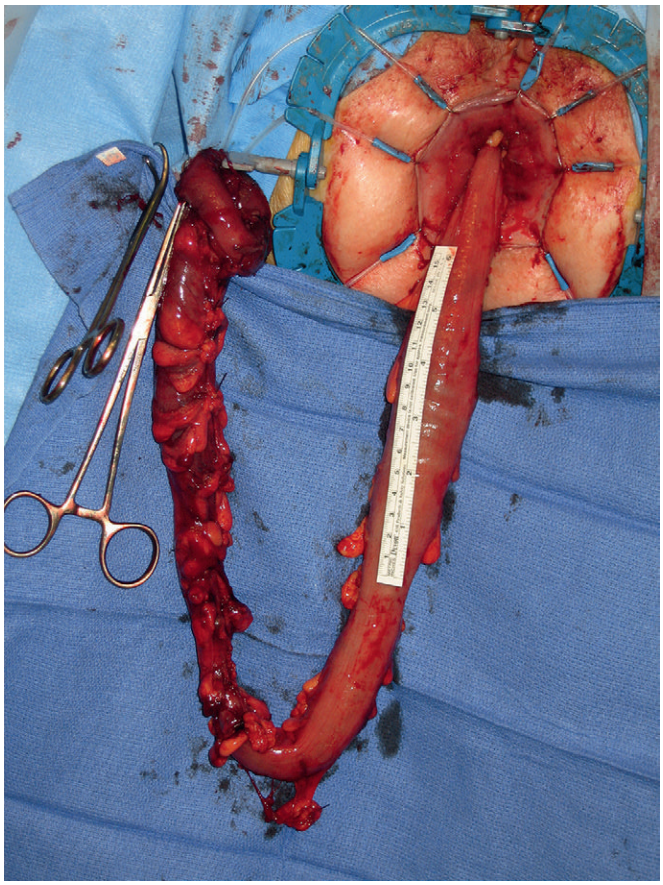

FIGURE 3 An example of how much colon can be resected from an Altemeier's procedure.

TABLE 1: Open abdominal procedures

Procedure	Mortality rates	Morbidity rates	Recurrence rates
Suture rectopexy	0	9.3%-20%	0-9%
Ripstein's procedure	0-2.8%	3.7%-33%	0-12%
Posterior mesh repair	0-1%	15%-28%	0-6%
Resection rectopexy	0-6.7%	7.1%-17.2%	0-5%

TABLE 2: Laparoscopic abdominal procedures

Procedure	Mortality rates	Morbidity rates	Recurrence rates
Suture rectopexy	0	9%-19%	0-7%
Posterior mesh repair	0	8%-14%	0-4%
Resection rectopexy	0	8%-13%	0

follow-up periods. One study of 82 patients found higher recurrence rates with laparoscopy and robotics as compared with open procedures.

Recurrent Prolapse

Because of a significant incidence rate of recurrent rectal prolapse, a discussion of the potential surgical options is important. The most important determinant of subsequent surgery is the remaining blood supply of the bowel. Patients who have previously undergone resection are at risk for development of ischemia to the segment of bowel between the two anastomoses should a second resection be attempted.

The surgeon must know the details of the patient's prior surgery. Patients who have undergone a perineal rectosigmoidectomy are candidates for a repeat perineal rectosigmoidectomy or an abdominal rectopexy without resection. Addition of a sigmoid resection could potentially cause ischemia to the remaining rectal segment. Patients who have undergone a previous abdominal rectopexy can have a redo rectopexy with or without resection or a perineal rectosigmoidectomy. Patients with prior abdominal rectopexy and resection are best treated with a redo abdominal rectopexy with or without resection; perineal rectosigmoidectomy should be avoided.

SUMMARY

Rectal prolapse can be a difficult entity to manage. A proper evaluation should be completed so that the surgeon can pick the surgical technique that will minimize morbidity and mortality, prevent recurrence, and improve the functional outcomes of the patient. Generally speaking, perineal procedures have lower rates of morbidity and mortality but higher rates of recurrence. Resection and rectopexy improve constipation, whereas rectopexy alone worsens it. Laparoscopy has similar outcomes as open procedures but reduced length of hospital stay. Patients with recurrent rectal prolapse can undergo additional surgery, but the initial surgical procedure must be taken into account. Robotics have the potential to improve patient outcomes, but larger studies with longer follow-up periods are needed to adequately assess its role in the treatment of rectal prolapse.

The Management of Solitary Rectal Ulcer Syndrome

Anjali S. Kumar, MD, MPH, Deirdre C. Kelleher, MD, and Lee E. Smith, MD

Solitary rectal ulcer syndrome (SRUS) is a relatively new term, introduced in 1964 by M.R. Madigan. The terms *solitary* and *ulcer* may be misnomers, as the condition is a physical sequela of both internal rectal prolapse and outlet obstruction constipation. The physical manifestations may not be solitary in nature, with circumferential involvement occasionally seen. Furthermore, SRUS does not always produce an ulcer, and the ulcers seen are rarely typical. Unlike the lesions seen in ulcerative proctitis, the ulcer may appear as a shallow "punched-out" gray-white lesion with a hyperemic base, caused by ischemic changes from the pressures exerted on the prolapsed tissues during defecation. Other times, a mucosal injury results from the repetitive trauma of chronic digitation or enema use to alleviate symptoms of outlet obstruction constipation. In cases of severe constipation, hard stool may cause this mucosal injury and lead to "ulcerative" damage of the rectum. In other cases, there may be no ulcer at all, but the patient specifically reports bleeding, passage of mucous, straining during defecation, and a sense of incomplete evacuation. For these patients, the only finding on inspection may be rectal erythema. Alternatively, rectal pseudopolyps may develop from repeated inflammation and healing with residual granulation.

Inflamed areas may also fill with mucin, resulting in a cystic-appearing neoplasm termed colitis cystica profunda (CCP). CCP and SRUS are related diagnoses that some clinicians consider interchangeable. SRUS and CCP are seen more commonly in women (3.2:1.0 ratio) and in individuals ranging in age from young 20s to late 60s, although SRUS has been reported in pediatric patients as young as 3 years.

CLINICAL FINDINGS

The initial symptom of SRUS is often passage of bright red blood and mucous from the rectum; rarely, massive hemorrhage can occur. Patients more frequently seek medical attention for pain, usually localized to the rectum. On interview, almost all patients report tenesmus and feelings of outlet obstruction. Some may also have incontinence to gas and liquid.

On physical examination, induration may be palpated near the lesion if it is within reach. On sigmoidoscopy, the classic finding is a shallow, well-demarcated ulcer with a red margin and yellow-gray eschar over the base, typically located 10 to 12 cm from the anus. The ulcer is most frequently located anteriorly, as a result of anterior internal intussusception. Valsalva's maneuver during defecation causes strain against a physiologically obstructed outlet and results in anterior rectal wall prolapse with a lead point near the peritoneal reflection or pouch of Douglas. The posterior rectum prolapses less frequently because its sacral attachment provides better support. However, prolapses may be seen in any location in the rectum and occasionally appear circumferential. Other examination findings include a raised ulcer margin and presence of pseudopolyps.

DIAGNOSIS

Clinical suspicion is the key to diagnosis of SRUS. Recognizing the signs and symptoms associated with the syndrome aids in ordering the correct confirmatory diagnostic tests. For visible lesions, biopsy is of the utmost importance to rule out neoplasm and inflammatory bowel disease. In a series of 14 patients with SRUS, nine patients (64%) had an initial diagnosis of rectal cancer that was subsequently corrected to the benign diagnosis after biopsy. Mistaking the benign ulcer for a carcinoma or inflammatory bowel disease (or vice versa) might lead to inappropriate therapy. Because the clinical symptoms of the syndrome can mimic other disorders, the final determination of SRUS must lie with the pathologist.

Other imaging studies are available and may aid in diagnosis of SRUS. Defecography is especially useful but is often only available at specialized centers. For this study, barium paste is introduced into the rectal vault via an enema device, and lateral video fluoroscopy images are obtained during patient defecation of the paste. The resulting film may show intussusception, nonrelaxing puborectalis muscle (resulting in abnormal angulation of the anorectal junction), incomplete or delayed rectal emptying, or a thickened rectal wall. The dynamic results of defecography are more specific than the static films from barium enema, which may only show rectal stricture, mucosal granularity, or thickened rectal folds.

Magnetic resonance (MR) defecography is a newer radiologic option for imaging internal intussusception; it adds a three-dimensional view of the anatomy. Performed at highly specialized radiographic centers, MR defecography involves insertion of a water-soluble agent (such as gel) into the rectum, followed by imaging of the patient during relaxation, straining, and postevacuation phases. In a 19-patient series, MR images were found to be comparable with those of conventional defecography, with no significant differences in detection of sphincter hypotonia, dyssynergia, or rectal prolapse during the evacuation phase. However, in a separate series, MR defecography was found to overdetect incomplete evacuation in 30% of patients. Smaller anorectal angles have also been observed, possibly as a result of the supine or left-lateral positioning of the patient, which removes the effect of gravity and alters the normal pelvic floor anatomy. Patients report difficulty mimicking defecation in this position, and many physicians believe it is less representative of the dynamic forces of defecation than conventional fluoroscopic defecography. Seated MR defecography is currently being developed and may increase the utility of this study.

In patients without defecatory dysfunction, the Valsalva's maneuver should result in pelvic floor relaxation. However, patients with SRUS frequently have nonrelaxing pelvic floor muscles. Electromyographic and dynamic manometry studies can confirm this functional abnormality. However, these tests have not been consistently useful in diagnosis or in prediction of a patient's response to therapy. Other available studies include anal and rectal ultrasound scan, which can show a hypertrophic anal sphincter or rectal wall thickening. Sometimes a shallow ulcer may also be seen with ultrasound scan, most often within the layers of the intact rectal wall. None of these supplementary tests are mandatory for diagnosis of SRUS; however, lesion biopsy is essential.

HISTOLOGIC FINDINGS

The hallmark microscopic findings of SRUS include an obliterated, fibrotic lamina propria that contains excess collagen and disorganized hypertrophy of the smooth muscle fibers from the muscularis mucosae towards the lumen. This appearance has been coined fibromuscular obliteration. Microscopic inspection of the ulcer base reveals local fibrosis and leukocytic exudates, which contribute to its characteristic gray-white color. The presence of collagen infiltration of the lamina propria distinguishes SRUS from other inflammatory, infectious and ischemic colitis. A trichrome stain can accentuate the characteristic fibrosis and collagen deposition. Lack of malignant and adenomatous features is also key to confirmation of the diagnosis of SRUS.

The distinguishing feature of CCP is the presence of mucin-filled cysts lined with columnar epithelium. CCP cysts are typically located deep to the muscularis mucosae. The overlying mucosa may be ulcerated, and the surrounding submucosa may be fibrotic, containing a mixed inflammatory infiltrate. These cysts can appear throughout the intestinal tract but are most frequently found in the colon and rectum. Given the submucosal location of these cysts, a biopsy that includes this layer is critical.

ETIOLOGY

Prolapse of the rectum leads to many of the signs and symptoms of SRUS. Ulcer formation is usually found at the tip of the prolapse. Direct pressure at the point where the prolapse abuts against the pelvic floor, especially at the level of the puborectalis muscle, can lead to blood vessel compromise and ischemia, which contributes to ulcer formation. Anismus, paradoxical contraction of the puborectalis muscle in response to the stimulus of defecation, may also manifest at this demarcation of the rectum and anus, resulting in outlet obstruction constipation. Repeated efforts to defecate against the tense sphincter mechanism contribute to the pressure and trauma on the tip of the prolapse. Because the anus distal to the dentate is quite sensate, the patient may describe a "sliding" in and out sensation with Valsalva's maneuver. This often leads patients to digitally explore the area. On palpation, patients feel the tip of the intussusception and may restore the prolapse to its normal anatomic position. Doing so alters the anorectal angle and allows stool to pass. After a sensation of incomplete evacuation, digitation finally allows some patients to complete defecation. If this becomes a daily practice, the repeated digitation may also lead to ulcer formation on the prolapsed rectum. However, this cannot explain all SRUS lesions, as a number are located beyond the reach of an inserted finger.

TREATMENT

Treatment is typically guided by the severity of symptoms. In patients with minimal symptoms, observation alone or treatment with bulk laxatives, bowel retraining, and reassurance is a reasonable initial

management. The use of topical enemas, such as steroids, 5-ASA, sucralfate, or sulfasalazine, may not heal the lesions because they are typically not true ulcers. Products to ease bowel movements are of value in reducing the efforts at defecation; bulking agents, glycerin suppositories, polyethylene glycol (PEG) solutions, or other stool softeners may help with constipation and should be tried as an initial step. Large-volume enemas may help evacuate the contents of the distal colon and rectum and alleviate the need to strain. This being said, some investigators believe that the trauma from enema tips can result in the ulcer that is frequently seen. Unfortunately, conservative therapy frequently does not result in full ulcer healing or symptom resolution. In a series of 23 patients, 16 (70%) had failed nonsurgical therapy.

In patients whose conditions are more symptomatic or unresponsive to conservative therapy, treatment must be aimed at the two features of this rare ulcer: the anismus of the pelvic floor and the intussusception. Biofeedback may be used to treat anismus by helping to promote the normal relaxation reflexes that must occur to open the anal sphincter. In a series of 11 patients, biofeedback resulted in decreased straining effort and stool frequency and improved quality-of-life measures. At least 50% healing of the ulcer was also seen in six patients (54%). Biofeedback alone often fails to treat outlet obstruction, but it may be helpful in teaching patients with incontinence to tighten the sphincter. Long-term improvements in patient quality of life are best ensured by addressing this part of the pathophysiology.

If the ulcer is caused by prolapse, the intussusception must be stopped to treat the condition definitively. Stabilizing the rectum with surgical fixation can be used for this purpose, with a reported 55% to 60% long-term improvement in symptoms. Before the introduction of laparoscopic and robotic techniques, primary fixation procedures involved suture proctopexy to the sacrum, with suture placement at the distal third of the rectum. A low short midline incision allows for good retraction of the rectum and suture placement into the lateral stalks of the rectum. Early experience with laparoscopy resulted in some failures, perhaps as a result of bleeding, operator timidity, or inability to retract the rectum adequately. In the authors' initial experience, the most frequent failures encountered after suture proctopexy for prolapse were after laparoscopic proctopexy referred from outside institutions. However, a recent series of 39 patients reported 70% success rate after laparoscopic rectopexy. As surgeons worldwide become more adept at laparoscopic rectal procedures, laparoscopic failures are expected to be rare, especially if laparoscopic visualization of the puborectalis muscle is achieved circumferentially. Enhanced visualization and articulating instrumentation of robotic surgery may also result in better outcomes with robotic-assisted approaches.

After fixation, occasionally some redundant distal mucosa or hemorrhoids may require an extended hemorrhoidectomy. This is evident 4 to 6 weeks after fixation, when the inflammation related to the initial surgery has resolved.

Surgical Management of Constipation

Supriya S. Patel, MD, and Anthony J. Senagore, MD, MS, MBA, FACS, FASCRS

Constipation is a common medical condition that accounts for millions of office visits per year and significant resource consumption. Successful management of constipation requires a clear delineation of the scope of the problem. Several definitions and classification schemes have been proposed. One of the most commonly used is the Rome III criteria, which is based on the following symptoms: straining, hard stools, sensation of incomplete evacuation, sensation of outlet obstruction, frequent need for manual evacuation maneuvers, fewer than three defections per week, and infrequent loose stools without laxative use. To fulfill the Rome III criteria, symptoms must be present for at least 12 weeks, in the 6 months before diagnosis, and irritable bowel syndrome must be excluded. Although these criteria are not entirely comprehensive, they do provide a useful basis for the initial evaluation of patients with the chief symptom of constipation.

ETIOLOGY AND WORKUP

The process of defecation involves a complex interplay between the sphincter complex, the colonic musculature, and the anorectal vault. The sphincter complex is composed of an external, striated muscle under voluntary control and an internal, smooth muscle under autonomic control. In normal situations, the sensation of stool in the anorectum results in relaxation of the pelvic floor and widening of the anorectal angle, thus facilitating stool evacuation with rectal contraction (Figure 1). A disorder in any step of this pathway can lead to impaired defecation.

The vast majority of office visits for constipation can be treated medically. Increased fiber consumption to 25 g/d coupled with increased fluid intake often improves stool frequency. Approximately 10% of patients have significant flatulence develop with psyllium-based products; their condition may be better managed with a cellulose-based fiber supplement. Constipation refractory to increased fiber and water consumption may require additional maneuvers aimed at either increasing luminal fluid content or reducing colonic transit time. Options include polyethylene glycol agents (increase fluid) and combinations of laxatives, suppositories, and prokinetic agents.

A thorough history and physical examination is critical for distinguishing between those cases that can be managed medically and

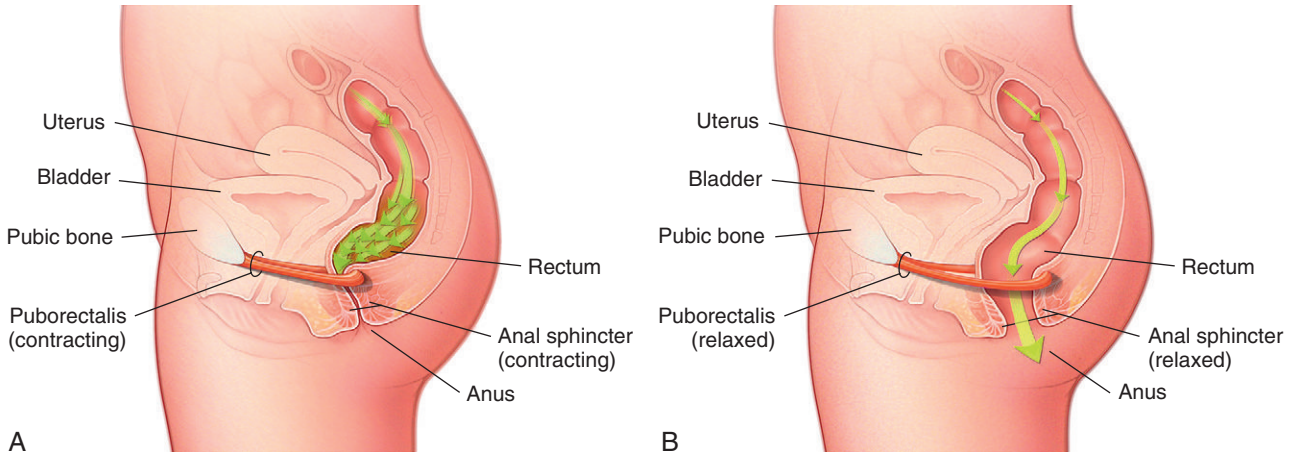

FIGURE 1 Normal anatomy of anorectal complex **(A)** at rest and **(B)** during defecation. During defecation the anorectal angle widens and the sphincter complexe relaxes, enabling evacuation of stool. *(From Bouras EP, Tangalos EG: Chronic constipation in the elderly,* Gastroenterol Clin North Am *38(3):463–480, 2009, Fig 2.)*

those that may benefit from surgical intervention (Table 1). Electrolyte abnormalities should be corrected, and comorbidities that may affect gut transit, such as diabetes and hypothyroidism, should be optimized. In addition, medications known to induce constipation, such as opioid analgesics, should be limited when possible. Physical examination should include a rectal examination to rule out a distal obstructing mass and to assess anal sphincter tone. The presence of fecal impaction or impaired perianal sensation may shed insight into the etiology of the problem. Colonoscopy or barium enema should almost always be performed before empiric therapy to exclude colonic obstruction from either malignancy or inflammatory bowel disease.

Constipation can be divided into two main categories based on the underlying pathophysiology: (1) disorders of colonic motility; and (2) disorders of defecation. In terms of motility, constipation is categorized as either normal-transit constipation or slow-transit constipation on the basis of the rate at which stool passes through the colon. Obstructed defecation syndrome (ODS) is typically used to define the various entities associated with impaired defecation.

Patients whose symptoms fail to improve with conservative measures should begin the evaluation process to exclude ODS with anorectal physiologic testing. Anorectal manometry enables detection of sphincter pressures during relaxation and straining. High sphincter pressures may indicate the presence of an anal fissure, anismus, or paradoxic puborectalis syndrome; low pressures may be suggestive of impaired sensation. Distension of the rectum normally results in relaxation of internal anal sphincter, known as the rectoanal inhibitory reflex (RAIR). The presence of this reflex effectively rules out Hirschsprung's disease. The balloon expulsion test is used for assessing ability to evacuate; normal results are indicated with the ability to evacuate a 50-mL rectal balloon in less than 2 minutes. Finally, defecography is the gold standard test for evaluation of defecatory disorders and is especially useful in the setting of suspected anatomic abnormalities. In addition to enabling visualization of perineal descent and measurement of the anorectal angle, instillation of contrast into the small bowel, vagina, and rectum facilitates the diagnosis of enteroceles, sigmoidoceles, rectoceles, and intussusceptions. An often overlooked important finding associated with ODS on defecography is internal intussusception. Classic findings associated with significant rectoceles include size of more than 3 cm and incomplete emptying, both of which are worse with an intussusception. Images can be obtained via traditional x-rays, video fluoroscopy, or magnetic resonance imaging (MRI).

A select group of patients with either ODS or slow transit constipation may benefit from surgical intervention; however, exclusion of the former is essential before colonic resection is offered. Many cases of ODS can be managed with biofeedback, which avoids the risk of surgery and improves quality of life. If a surgical option is selected, a thorough preoperative discussion is essential to define patient expectations regarding the potential outcomes because success is often relative, rather than complete, with any of the available surgical options.

TABLE 1: Preoperative workup of the patient presenting with chronic constipation

Recommended	Optional
History	Anal manometry
Physical	Cine defecography
Laboratory (hemoglobin, electrolytes, TSH, T_4, etc., if not previously obtained)	Small bowel transit study (breath hydrogen)
Anatomic study (barium enema or colonoscopy)	Gastric emptying
Transit study	Small bowel follow through
Balloon expulsion test

OBSTRUCTED DEFECATION SYNDROME

ODS is a common cause of symptomatic chronic constipation, characterized by straining and difficulty in evacuation, frequently requiring digitation of the anus or vagina to facilitate defecation. A variety of different scoring systems exists to grade the severity of symptoms; an example is shown in Table 2. The symptoms of ODS have classically been attributed to rectocele; however, better recognition of this syndrome defined by anophysiology evaluation has shown the concomitant occurrence of other abnormalities, such as intussusception, in many of these cases. ODS most frequently occurs in females and may present after an inciting event, such as childbirth or total abdominal hysterectomy. Large nonemptying rectoceles (>3 cm) are often visualized on defecography, but the degree of internal rectal intussusception may be a more important component of ODS and is frequently underappreciated. A rectocele involves a weakening of the rectovaginal septum and anterior prolapse of the rectum into the

vagina; an intussusception involves the telescoping of a proximal segment of rectum distally, often as low as the anal canal (Figure 2). Therefore, even small rectoceles with significant degrees of intussusception may be symptomatic. Initial management consists of dietary modification and biofeedback to attempt to improve coordination between anal sphincter relaxation and rectal contraction; surgical management is indicated if these measures fail and symptoms persist.

Classically, rectoceles have been repaired via transvaginal and transanal approaches, with or without mesh placement. The traditional approach to repair is the transvaginal posterior colporrhaphy. In this procedure, the posterior vaginal mucosa is incised and elevated, followed by plication of the entire length of the fibromuscular tissue of the septum and reapproximation of the vaginal mucosa. Anatomic cure is achieved in more than 80% of patients with this technique. More recently, attempts were made to refine the technique by performing site-specific repair of septal defects in hopes of reducing the incidence of dyspareunia associated with longer repairs. Similarly, the use of either biologic or polypropylene mesh has been proposed in hopes of reducing recurrence rates. There has been recent concern regarding the use of permanent mesh because of the risk of infection, pain, and erosion. Conversely, transanal rectocele repair involves the excision of redundant rectal mucosal tissue and suture reenforcement of the rectal muscularis layer as a means of repairing the defect.

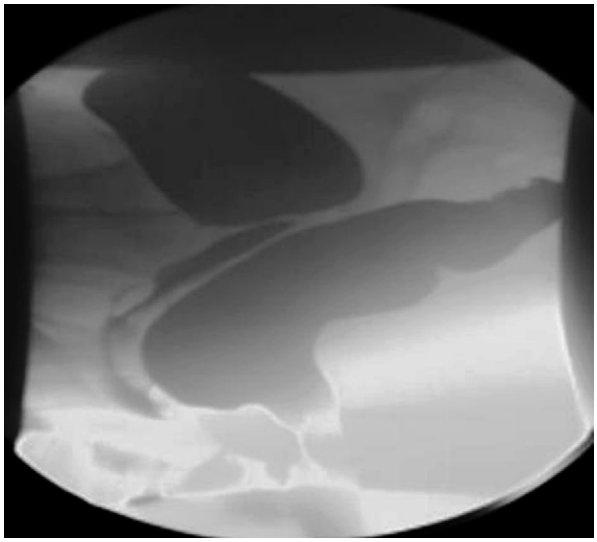

FIGURE 2 Rectocele and rectal intussusception causing impingement of the vaginal wall. *(From Hasan HM: Stapled transanal rectal resection for the surgical treatment of obstructed defecation syndrome associated with rectocele and rectal intussusception,* ISRN Surg *2012:652345, 2012, Fig 1.)*

STAPLED TRANSANAL RECTAL RESECTION

Stapled transanal rectal resection (STARR) represents a shift in thought as to the underlying mechanism of ODS, with a greater appreciation of the role of dysfunction of the rectal muscular wall. This is manifested by internal intussusception in addition to the typical presence of a rectocele. The goal of the procedure is primarily to separately resect a section of anterior and posterior rectal wall and only secondarily to impact the rectocele. This technique involves the use of two circular staplers to perform separate full-thickness, circumferential rectal resections (Figures 3 and 4). The anal canal is first dilated with lubricated dilators. The anoscope is then introduced and secured to the skin. Several nonabsorbable purse-string sutures, incorporating mucosa, submucosa, and muscularis, are placed along the anterior rectal wall, above the level of the dentate line and tip of the prolapse/intussusception. The first circular stapler is introduced and fired, with care taken not to involve the rectovaginal septum. The procedure is repeated along the posterior rectal wall; purse-string sutures are placed, and the second stapler is introduced and fired. Both staple lines are reenforced with absorbable suture as needed to ensure hemostasis.

Anatomic correction and symptomatic improvement are achieved in most patients. Upwards of 30% of patients report fecal urgency;

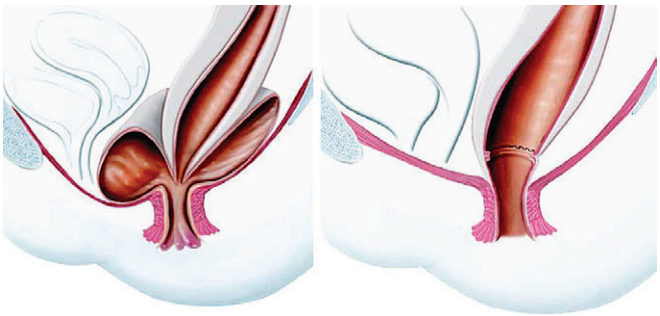

FIGURE 3 Stapled transanal rectal resection procedure. *(From Schwandner O, et al: Decision-making algorithm for the STARR procedure in obstructed defecation syndrome: position statement of the group of STARR Pioneers,* Surg Innovation *15(2):105-109, 2008, Fig 1.)*

TABLE 2: Obstructive defecation syndrome: symptom scoring

Symptoms	Never	Rarely	Sometimes	Usually	Always
Excessive straining	0	1	2	3	4
Incomplete rectal evacuation	0	1	2	3	4
Use of enemas/laxative	0	1	2	3	4
Vaginal/perineal digital pressure	0	1	2	3	4
Constipation	0	1	2	3	4

Never, 0 (never); rarely, <1/month; sometimes, <1/week, ≥1/month; usually, <1/day, ≥1/week; always, ≥1/day.

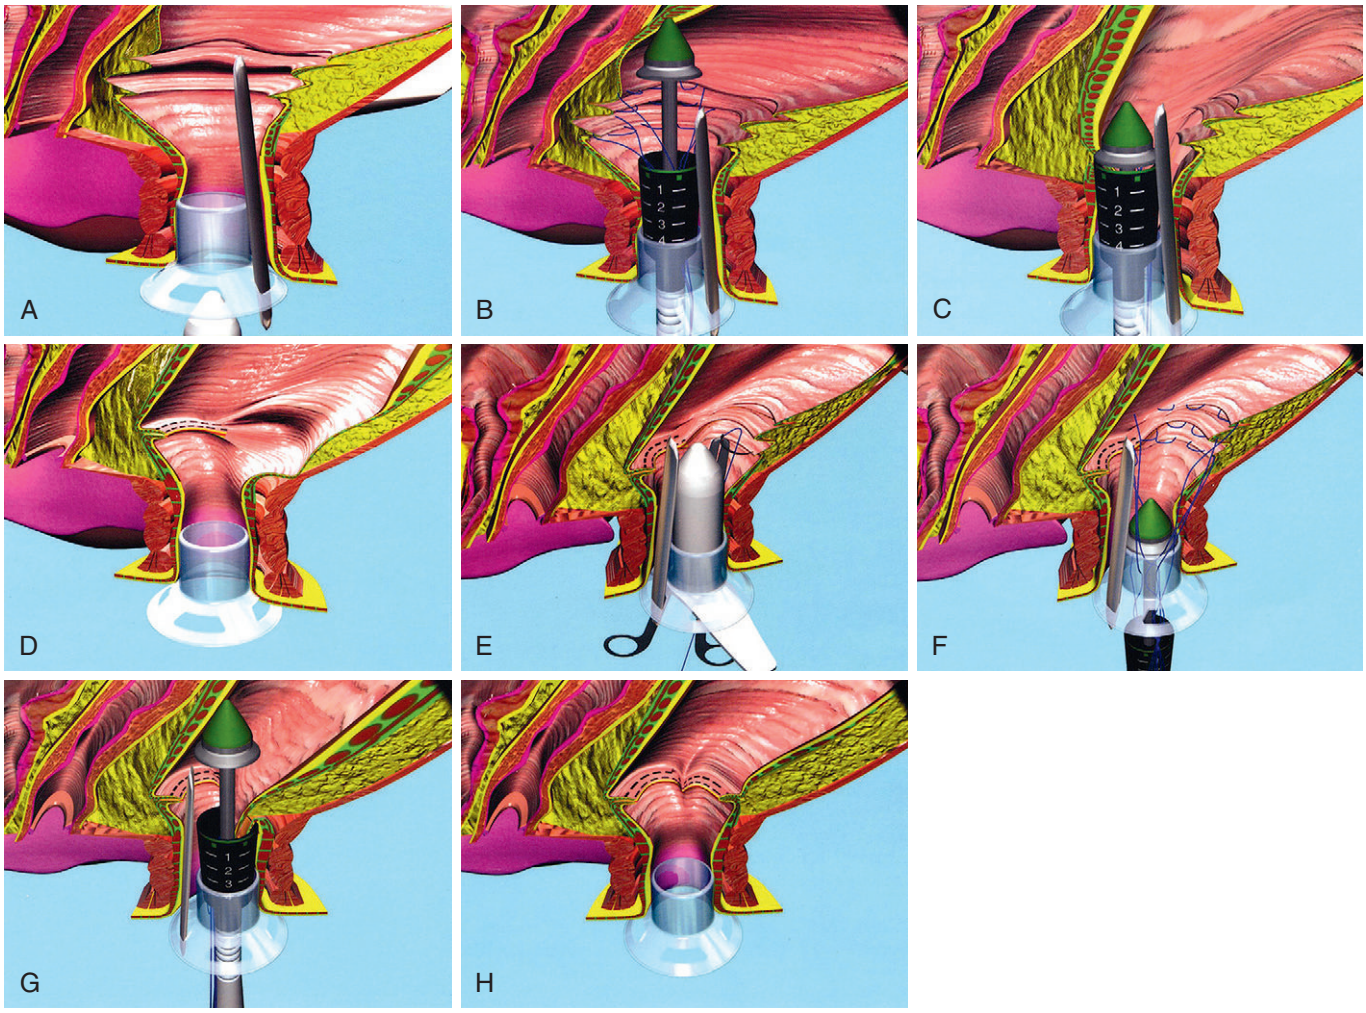

FIGURE 4 **A** to **H,** Stapled transanal rectal resection. Anal dilator is introduced, and anterior purse-string sutures are placed into the redundant rectal tissue. A retractor is placed along the posterior rectal wall to protect it during the stapling process. A circular stapler is fired. The procedure is repeated along the posterior rectal wall. *(From Pinto RA, Sands DR: Surgery and sacral nerve stimulation for constipation and fecal incontinence,* Gastrointest Endosc Clin North Am *19(1):83–116, vi–vii, 2009, Fig 7.)*

however, the symptoms typically ameliorate over several months. With appropriate procedural training, STARR is generally associated with a low morbidity rate. Nonetheless, serious complications have been reported (i.e., hemorrhage, pelvic sepsis, and rectovaginal fistula).

The stapled transanal prolapsectomy with perineal levatorplasty (STAPL) procedure is a similar technique, in which redundant tissue is excised with a circular stapler and a levator reapproximation is performed via a perineal incision. In addition to the circular stapling techniques, ODS can also be treated via application of linear stapling devices; these procedures generally involve two firings of the linear stapling devices for excision of redundant rectal tissue. Limited comparative data examining the advantages of these approaches are available.

SLOW-TRANSIT CONSTIPATION

The etiology of slow-transit constipation is unknown, but neuronal and muscular factors have both been implicated in the pathogenesis. Patients are most commonly female and frequently present with symptoms of abdominal pain, straining, and bloating. Before surgical intervention, the evaluation should include: (1) anophysiologic evaluation to exclude ODS; (2) a colonic transit study (i.e., Sitzmark's study) to confirm slow transit; and (3) either a barium enema or colonoscopy to exclude luminal disease. Upper gastrointestinal motility studies may also be indicated to rule out pangastrointestinal dysmotility. Correction of concomitant disorders of evacuation before surgery for slow-transit constipation is recommended. In addition, patients with suspected psychiatric disorders should be referred for preoperative counseling, given the high incidence rates of failure and dissatisfaction after surgery observed in this population.

The operative procedure of choice for documented slow-transit constipation is a total abdominal colectomy (TAC) with ileorectal anastomosis. This procedure can be performed open or laparoscopically. The entire colon is mobilized and resected, and the ileum is anastomosed to the rectum. Anastomoses to the distal sigmoid colon have also been performed but are associated with a higher incidence of persistent constipation and are thus generally avoided. The mean stool frequency after TAC with ileorectal anastomosis typically ranges from two to four bowel movements a day. Unfortunately, however, this procedure is associated with a high morbidity rate (especially small bowel obstruction), and greater than 40% of patients experience persistence of their symptoms or a procedure-related complication. A laparoscopic approach may reduce the technical complication rate. Common complications after surgery include diarrhea, incontinence, small bowel obstruction, and recurrent constipation.

Several alternative resection strategies for slow-transit constipation have been described (i.e., subtotal colectomy with cecorectal anastomosis, segmental colectomy). These approaches are based on the concept that minimizing the amount of colon that is resected may reduce the incidence of postoperative diarrhea. However, these limited colonic procedures typically fail to treat the constipation and often require conversion to a TAC with ileorectal anastomosis.

ANTEGRADE COLONIC ENEMAS

Antegrade colonic enemas (ACE) are a viable treatment option for the management of both fecal incontinence and constipation and avoid the risks of colectomy. The procedure involves the administration of enemas directly into the colon to facilitate the controlled evacuation of stool. The traditional Malone's procedure, first described in the 1990s, involves the use of the appendix as the conduit. Since that time, conduit constructions with terminal ileum, cecum, and colon have been described. Advances in minimally invasive surgery have made construction of these stomas possible with laparoscopic techniques. ACE is an especially attractive option in patients who wish to avoid permanent ostomy creation and has been well described in the pediatric surgery literature. Leakage around the stoma site and stomal stricturing are common complications.

SACRAL NERVE STIMULATION

Sacral nerve stimulation (SNS), a U.S. Food and Drug Administration (FDA)–approved method for treatment of fecal incontinence, is gaining increasing attention in the management of chronic constipation. The procedure involves two components. In the first part, a test stimulation is performed with placement of a stimulating electrode, connected to an external pulse generator, into the S3 foramen; peripheral nerve function is then evaluated. Patients with successful responses to the test stimulation proceed to permanent implant placement.

The exact mechanism of action by which SNS regulates bowel function is poorly understood, but it is thought to involve a modulation of neuronal signaling pathways. The subset of patients with chronic constipation who may benefit from this technique has not been clearly defined. Further investigation is required before the routine application of this technique for chronic constipation is implemented.

OSTOMY CREATION

In most cases, ostomy creation is a considered a last-resort measure for patients with refractory chronic constipation. Options include ileostomy and colostomy formation. Stoma marking before surgery is critical, given the high likelihood of the stoma being permanent. Careful construction of the stoma can help avoid common stoma-related complications.

SUMMARY

Chronic constipation is a common and debilitating medical condition with a wide variety of causes. Careful differentiation of those patients who are best managed medically from those who may benefit from surgical intervention, is of paramount importance. Disorders of motility should be distinguished from disorders of defecation because these conditions frequently require different management algorithms. To increase the likelihood of success in the surgical treatment of constipation, a multidisciplinary approach should be adopted and clear communication between the patient and treating physicians established.

RADIATION INJURY TO THE SMALL AND LARGE BOWEL

Rachit Kumar, MD, and Joseph M. Herman, MD, MS

OVERVIEW

The treatment of most malignancies in the abdomen and pelvis requires a multimodality approach. The combination of surgery, chemotherapy, and radiation has improved survival in malignancies of the genitourinary tract, gastrointestinal tract, and gynecologic systems. Specifically, not only has the use of radiation led to improvements in local control and disease-free survival in the primary setting, but it is also used frequently in the palliative setting. The small and large intestines are two of the radiation dose-limiting organs in malignancies of the abdomen and pelvis. Modern technologic advances, including three-dimensional (3D) conformal, intensity-modulated, stereotactic, and intraoperative radiation therapy, allow for higher radiation doses to the tumor or tumor bed while limiting dose to the bowel and subsequent toxicity. As such, knowledge of the radiation dose limits, timing of radiation toxicity, and management of subsequent side effects are critical for both general surgeons and surgical oncologists.

Radiation as a treatment modality has advanced significantly over the past two decades. Traditional radiation therapy uses external beam radiation from the anterior-posterior direction (AP-PA) or with additional beams applied laterally (3D or conformal radiation). However, the increased implementation of intensity-modulated radiation therapy (IMRT) has allowed for a higher dose of radiation to a tumor with decreased toxicity to surrounding tissue. IMRT uses several radiation beams (>3) from multiple angles that are modulated (shaped) and converge to conformally cover the tumor volume. Stereotactic body radiation therapy (SBRT) is a form of IMRT that increases the daily dose of radiation applied to each individual

radiation beam while decreasing the overall number of treatments (generally one to five treatments total). SBRT allows for a very high (ablative) dose of radiation to the tumor plus a small margin (<5 mm) but can result in an increased risk of damage to adjacent bowel if included in the radiation field. Intraoperative radiation therapy (IORT) can be delivered with x-ray radiation (electrons) and brachytherapy (the application of radiation sources in close approximation to the tumor). IORT allows for increased doses of radiation to the tumor bed with decreased normal tissue toxicity. Because IORT is delivered at the time of surgery, a higher dose of radiation (>10 Gy) can be delivered because the normal bowel has been removed from the treatment area. IORT is often combined with preoperative and postoperative radiation to achieve a dose that is high enough (>60 Gy) to sterilize microscopic residual disease (R1 resection). In general, IORT has been shown to be most effective when used with preoperative and neoadjuvant radiation therapy and when margins are negative (R0). However, emerging data have shown that IORT with high dose rate brachytherapy (HDR-IORT) can sometimes be effective even with R1/R2 resections.

RADIATION DOSE TOLERANCE TO THE SMALL INTESTINE AND RECTUM

A surgeon working with irradiated tissue needs to have a familiarity with the terminology used in describing radiation dose and tissue sensitivity. The small bowel is an organ arranged in a serial configuration (i.e., a relatively small volume of the small bowel receiving a high dose of radiation may lead to severe, irreversible side effects). In contrast, the large bowel and rectum are arranged in a parallel configuration; a single area of the organ may tolerate a very high dose, whereas the whole organ dose should be limited. A landmark paper from Emami and associates published in 1991 evaluated the radiation dose limits of multiple tissues. From this paper, a maximal dose limit to the small intestine was established at 45 to 50 Gy. More recent data from the QUANTEC investigators at the Radiation Therapy Oncology Group has compiled results from multiple studies to improve on Emami's initially identified dose limits. The investigators conclude that the radiation dose limit to the small intestine should be limited to no more than 195 cm^3 of small bowel receiving greater than 45 Gy (V45, or volume receiving 45 Gy or more, should be <195 cm^3). With SBRT, radiation to the small bowel should be limited to 12.5 Gy in a single fraction (V12.5<30 cm^3), or limited to 30 Gy in a 3 to 5 fraction regimen.

In contrast to the small and large bowels, the rectum has a much higher radiation dose tolerance. As noted previously, radiation toxicity to the rectum is largely based on the volume of the organ receiving a given a dose. From Emami and associates, if the rectum receives more than 60 Gy of radiation, there is only a 5% risk of long-term complications. However, if the bowel receives more than 80 Gy, there is a 50% risk of long-term complications. The risk of complications from radiation can also increase if concurrent chemotherapy is used or if the patient has conditions that may make the bowel more sensitive to radiation, such as Crohn's disease. The QUANTEC investigators refined these dose limits based on their analyses of prostate cancer radiation dose escalation studies. The risk of grade 3 or higher proctitis was determined to be less than 10% with a dose of 79.2 Gy with 1.8 to 2.0 Gy fractions. A more practical model based on dose-volume constraints is that less than 20% of the rectum should receive greater than 70 Gy (V70 <20%). Adhering to these dose limitations helps to ensure that the both the acute and the late complications of radiation are minimized.

PATHOPHYSIOLOGY OF RADIATION TO THE INTESTINAL TRACT

Radiation therapy has both short-term and long-term effects on malignant and healthy tissue. Short-term side effects typically occur from the end of the first week of therapy and may be seen up to 2 weeks after the completion of radiation. Subacute effects occur between 2 weeks and 3 months. Long-term side effects may occur from 3 months to many years after the radiation therapy is completed. The pathophysiology of these side effects occurs by significantly different mechanisms. A better understanding of these processes assists practitioners in the management of both categories of complications.

Acute radiation to the bowel results in a decline in crypt cell mitosis and mucosal cell necrosis. The combination of these effects leads to villous sloughing. Symptomatically, patients report diarrhea as a consequence of the decreased absorptive surface area. Radiation enteritis often results in nausea and vomiting and in abdominal pain. The high radiosensitivity of the small bowel may result in an ulcer. Late radiation damage to the bowel is a consequence of both submucosal/serosal fibrosis and injury to the microvascular support structure within the intestinal wall. Fibrosis may result in adhesions that lead to kinked bowel loops, potentially resulting in small bowel obstruction. Although this risk is less than 10% in most cases, it is increased in the postoperative setting and should be considered in evaluation of a patient with an emergent abdomen.

Early radiation effects in the rectum generally result in crypt abscesses, decreased mucous production, and eosinophil infiltration. As with the small intestine, this may result in tenesmus, bleeding, pain with defecation, and diarrhea, although this tends to be self limited, with resolution of symptoms shortly after the completion of therapy. Colorectal fibrosis may be seen from 6 months to many years after the completion of radiation, with an incidence similar to that of the small bowel. Damage to the serosal blood vessels is an important mediator of this effect. Radiation proctitis, as manifest by recurrent bleeding years after completion of the radiation, is typically less than 15% and is usually increased in patients with rectal manipulation after radiation.

Certain factors may predispose to radiation enteritis, including pelvic inflammatory disease and endometriosis. A history of abdominopelvic surgery, either before or after radiation, significantly increases the risk of stricture and small bowel obstruction (SBO). As expected, preexisting vascular damage from hypertension, diabetes mellitus, and cardiovascular disease is detrimental on two accounts. First, the patient likely has initial damage to the vascular support structure within the lumen of the vessels. Second, any damage that occurs has more limited repair capacity because of poor nutrient transport. A thorough history of all patients for radiation should always include an assessment for collagen vascular disease, including rheumatoid arthritis, inflammatory bowel disease, and systemic lupus erythematosus, because these conditions often cause a greater acute and delayed response to irradiation. Many of these conditions may be discovered years after the completion of radiation in the setting of delayed radiation toxicity.

The risk of a second malignancy after radiation is extremely small, typically less than 1% in the lifetime of most patients with irradiation. This is an age-dependent value, with most cases of radiation-induced malignancy requiring more than 8 years to develop. Therefore, this is an important consideration in younger patients undergoing radiation and should be discussed with the patient's treating radiation oncologist.

The Radiation Therapy Oncology Group (RTOG) has developed a scoring scale to standardize side effects reported during and after radiation therapy (Table 1).

MANAGEMENT OF RADIATION ENTERITIS

As discussed previously, acute side effects of small intestine irradiation include malabsorption, altered gut mobility, diarrhea, nausea, and vomiting. Later side effects may include mucosal ulceration, eventually developing into perforations, fistulae, bleeding, and

TABLE 1: RTOG acute and late gastrointestinal toxicity scale

	Acute toxicity	Late toxicity
Grade 1	Increased frequency or change in bowel habits not requiring medication; rectal discomfort not requiring analgesics.	Increased frequency of bowel movements or rectal discomfort not requiring medications.
Grade 2	Diarrhea requiring parasympathetic drugs; mucous discharge not necessitating sanitary pads; rectal or abdominal pain requiring analgesics.	Frequent stools requiring parasympatholytic drugs; mucous discharge not requiring pads; pain requiring analgesics.
Grade 3	Diarrhea requiring parenteral support; severe mucous or blood discharge necessitating sanitary pads; abdominal distension.	Diarrhea requiring parenteral support; severe mucus or blood requiring pads; abdominal distension on x-ray.
Grade 4	Obstruction, fistula, or perforation; gastrointestinal bleeding requiring transfusion; abdominal pain or tenesmus requiring tube decompression or bowel diversion.	Acute or subacute obstruction, fistula, or perforation requiring surgical intervention; gastrointestinal bleeding requiring transfusion; abdominal pain or tenesmus requiring tube decompression or bowel diversion.
Grade 5	Death as a consequence of radiation-induced side effects.	Death as a consequence of radiation-related side effects to the intestine.

Radiation Therapy Oncology Group *(RTOG)* early and late toxicity scale for both genitourinary and gastrointestinal toxicity.
Adapted from Cox JD, Stetz J, Pajak TF: Toxicity criteria of the Radiation Therapy Oncology Group (RTOG) and the European organization for research and treatment of cancer (EORTC), Int J Radiat Oncol Biol Phys *31(5):1341–1346, 1995.*

abscesses. The development of fibrosis may cause a stricture and SBO. Chronic malabsorption may lead to severe anemia and hypoalbuminemia. Although many of the acute side effects resolve quickly after radiation, late side effects may be severe, progressive, and irreversible.

Generally, acute radiation enteritis should be managed conservatively. This includes antidiarrheal, antispasmodic, and antiemetic medications as necessary. In patients with ongoing diarrhea despite medical management, a low residue diet should be applied. In some cases, this approach may be used for patients without antidiarrheal medications. Nonetheless, most patients respond to antidiarrheal medications rapidly. Careful observation should be made to a patient's nutritional status in the event that oral intake becomes particularly limited. In cases of severe nausea, total parenteral nutrition may be needed. Given the rapid repair capacity of the small bowel, a short radiation break often leads to functional improvements. Care is required with this approach because the risk of repopulation of the tumor with a more aggressive phenotype has been well recognized.

Small bowel obstruction after irradiation may be a consequence of stricture or adhesions leading to bowel loop entrapment. This surgical emergency should be managed as would any acute abdomen case. Initially, patients should be put on nothing by mouth (NPO) status for bowel rest and allowed to decompress. The site of stricture may be identified with enteroclysis. In certain cases, strictureplasty or dilation of the affected segment may be possible. However, this is not the preferred technique for treatment. Anastomosis with a proximal, nonirradiated segment of bowel has been performed with good results. In cases in which the viability of tissue is of concern, a temporary ileostomy is recommended. Of note, this is generally accepted as the standard of care in patients in whom a low rectal repair is required. The typical time of reversal of the ileostomy is approximately 3 to 6 months once the nutritional status has improved. Adhesiolysis may also be necessary in this patient population and, as expected, is more commonly seen in patients in the postoperative setting. In regards to the appropriate method of incisional approach, emerging data suggest improved outcome with transverse, subumbilical incisions as opposed to standard, vertical incisions. The former allows excellent exposure with fewer postoperative wound complications (Figure 1).

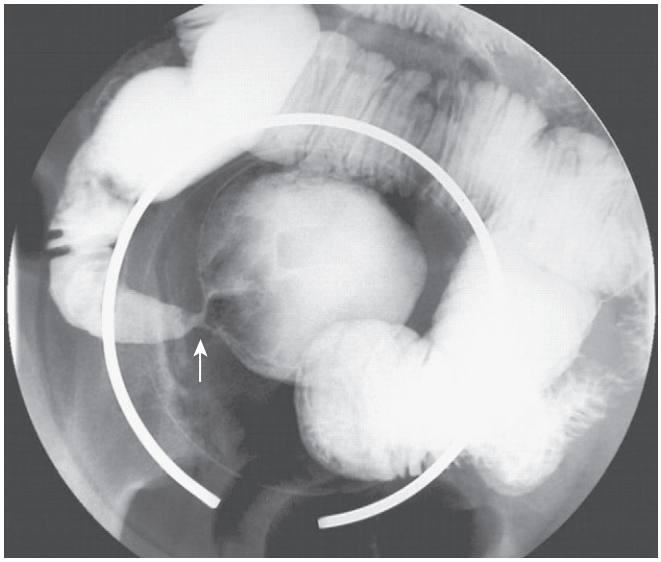

FIGURE 1 Enteroclysis shows a small bowel stricture and obstruction from a postoperative adhesion. The white arrow denotes a stricture with dilated proximal bowel on the right and normal caliber distal bowel on the left. *(From Nicolaou S, et al: Imaging of acute small-bowel obstruction,* Am J Roentgen *185(4):1036–1044, 2005, Fig 4.)*

Perforation and fistulae may be caused by radiation but are also a consequence of tumor recurrence. Therefore, the first evaluation must be whether recurrent or residual tumor is the precipitating agent of this effect. If a perforation is noted, the loop of involved segment should be resected and, as with cases of obstruction, an anastomosis between healthy loops of bowel should be performed. Again, a temporary ostomy may be indicated if there is concern regarding the viability of the anastomotic segments. Further, the surgeon should understand the vulnerability of irradiated tissue, including skin, to the risk of wound-healing complications. As noted from a review of patients for irradiation in whom surgery was

required for enteric complications, wound healing was the most commonly seen adverse event after surgery (Table 2).

Postradiation fistulae not associated with biopsy-confirmed tumor recurrence should be managed based on the involved segment of bowel and the site of drainage. A water contrast study can help identify the afferent and efferent ends of the fistula if not clinically apparent. Computed tomographic (CT) scans are highly sensitive in identifying the site of a fistula, particularly within the bladder. Fistulae involving the proximal bowel prior to the ileum are typically high output with a significant risk of malnutrition and dehydration. These cases are best managed with resection with anastomosis rather than with diversion or bypass. For lower fistulae, bypass or diversion with an ostomy is an effective way to allow for healing while preserving later continent function. Further, in cases of acute enterocutaneous fistulae, it is sometimes prudent to allow the fistula to mature before closure is attempted. Fistulae involving the bladder and vagina require similar measures as those described previously. Resection and anastomosis are preferred over bypass because of the risk of perforation, bleeding, abscess, and carcinogenesis associated with the remnant bowel. A critical part of the process of anastomosis is to ensure that a section of healthy bowel is identified. An increasingly used technique in preventing anastomotic leak or stricture is via a stapled side-to-side anastomosis. Omental or rectus flaps may occasionally be used to provide a healthy tissue barrier between the anastomosis and the affected organ (Figure 2).

Patients with massive intestinal damage after radiation may need significant surgical resection of affected segments resulting in short bowel syndrome, clinically presenting as severe diarrhea. This is best managed with fasting, total parental nutrition (TPN), and somatostatin.

MANAGEMENT OF RADIATION PROCTITIS

Acute radiation proctitis is generally manifest by tenesmus, bleeding, and diarrhea. Late-term side effects include bleeding, ulcers, strictures, and fistula. Unlike small bowel, malabsorption tends not to be a consequence of radiation to the pelvis. Instead, painless rectal bleeding is the most common long-term side effect.

Similar to radiation enteritis, acute side effects of radiation to the distal colon and rectum should be managed conservatively. The most common side effects reported by patients in the acute setting for rectal and lower genitourinary malignancies are tenesmus and diarrhea. Repeated episodes of rectal urgency are common during definitive radiation for prostate cancer, as the length of treatment for this malignancy lasts up to 8 weeks. Initial management for these symptoms includes antispasmodic medications. A low-fiber, low-residue diet also helps mitigate these symptoms and may reduce pain associated with tenesmus. Nonsteroidal anti-inflammatory medications (NSAIDs) may assist with the initial symptoms of pain associated with defecation. If pain is refractory to NSAIDs, opiates should be added to the patient's medication regimen. Opiate-induced constipation can be a secondary benefit in the patient with both diarrhea and dyschezia.

The treatment of certain long-term side effects, including strictures and fistulae, has been discussed previously. Radiation proctitis,

manifested by hematochezia, is established as the most likely complication of rectal irradiation months to years after therapy. In the setting of hematochezia after radiation, a thorough history and physical examination should be performed. Hemorrhoids are not uncommon in this population, and the patient's sexual practices should be determined. Endoscopic evaluation is the gold standard for diagnosis of radiation-induced rectal bleeding. The affected rectum has friable telangiectasia along the mucosa (see Figure 1). Many of these cases resolve spontaneously with time, and unnecessary biopsies of the affected mucosa prolong bleeding and delay healing. The treating physician should notify the performing gastroenterologist regarding a history of radiation therapy to the rectum to avoid a protracted course of hematochezia. The diagnosis of radiation proctitis can be made clinically without a mucosal biopsy (Figure 3).

Patients in whom hematochezia is continuous and progressive may consider a variety of nonsurgical treatment techniques. These include preparations of topical lidocaine, steroid-containing suppositories (prednisone), short chain fatty acid enemas, sucralfate, or steroid enemas (hydrocortisone) concurrently with metronidazole, which have been effective. No consensus regarding medical management procedure exists at this time, but the generally accepted course of therapy is to proceed with a single medication before proceeding to multimodality medication therapy.

Progressive hematochezia despite medical management should prompt consideration for minimally invasive surgical or topical procedures. These options include formalin therapy (chemical cauterization) and thermal coagulation therapy. Formalin therapy produces local chemical cauterization at the site of telangiectatic vessels and ulcers. Typical formalin solutions include 3.6% and 4% formalin, although 10% formalin has been described in the literature. Formalin is applied via either irrigation or direct application of formalin-soaked gauze. Complete response rates vary from 64% to 100%, with a duration of response lasting between 3 and 20 months. Side effects include stricture, anal ulcers, anal pain, incontinence, anal stenosis, and bleeding.

Thermal coagulation is accomplished with bipolar/heater cautery, an argon laser, or a yttrium aluminum garnet (YAG) laser. Bipolar or heater cautery is performed with a probe attached to a standard colonoscope. Multiple treatment sessions are often necessary for complete response. Cautery was found more effective than medical management in the long-term treatment of recurrent bleeding episodes. Further, this form of treatment is relatively rapid, with a response rate of 100% noted in most studies, and no major side effects reported. Both plasma argon therapy and YAG laser show high levels of response, with better response rates noted for plasma argon therapy. Side effects are noted to be potentially significant for this approach and include mucous discharge, prostatitis, rectal stricture, tenesmus, ileus, abdominal pain, rectal ulcers, and rectal strictures.

Hyperbaric oxygen therapy has also been used in subacute and chronic radiation proctitis. Increasing local tissue oxygen tension is thought to promote wound healing by stimulating collagen formation. Despite a number of studies that assessed the results of this method, the quantification of improvement remains vague. Hyperbaric oxygen therapy may require as many as 80 or more treatments for symptom relief. Potential side effects include visual trauma, aural trauma, ear drum perforation, and angina. This therapy can also potentiate tumor growth; therefore, patients with residual disease must be excluded. The benefit of this form of therapy may be limited to patients in whom multiple other therapies have been unsuccessful.

PREVENTION OF RADIATION ENTERITIS AND PROCTITIS

Modern radiation techniques use a variety of methods to help reduce normal tissue radiation dose. Some of these have been mentioned previously and include IMRT, SBRT, IORT, and brachytherapy. Despite the improvements these technologies provide, potential for significant toxicity remains because of very high dose per fraction (SBRT), proximity to healthy tissue (IORT and brachytherapy), and radiation dose inhomogeneity (IMRT/SBRT). Information needed to assist in determination of whether radiation is the cause of specific symptoms includes the radiation plan, dose, fractionation, and treatment delivery. Optimally, the patient should be presented in a multidisciplinary tumor board to determine the best course of management.

Radiation oncologists may implement a variety of methods at the time of CT simulation (also known as the "planning scan") to help reduce side effects at the time of therapy. This includes treating the patient with a rectal balloon in place, and a full bladder and empty rectum to limit the dose to the small bowel and rectum. A rectal balloon helps push the posterior wall of the rectum away from the radiation field and is often used in patients with prostate cancer, especially those treated with high radiation doses per fraction. Placement of a spacer at the time of surgery can limit the volume of bowel in the radiation field; the spacer is often used during surgery in patients undergoing cystectomy or hysterectomy if radiation therapy is expected in the adjuvant setting.

Treatment of the patient in the preoperative setting is routinely done in multiple malignancies, including rectal cancer and sarcoma. The advantage of treating patients in the neoadjuvant setting, in terms of tissue toxicity, is that the organ of interest acts as a tissue

spacer: physical space is provided by the organ against the entry of other organs, such as the bowel, as may be seen in the postoperative cases. Neoadjuvant treatment also takes advantage of reoxygenation and reassortment, which may be more effective in sterilization of the tumor. Another benefit of neoadjuvant therapy is the organ of concern is often excised, thereby preventing late side effects from occurring. However, practitioners should understand that this approach entails a higher risk of poor wound healing. A temporary diverting ileostomy should be considered if a low anastomosis is planned after chemoradiation. Optimally, a complete treatment plan, including an explanation of potential toxicity and prevention of long-term side effects, should be discussed with all practitioners at the time of the initial diagnosis and consultation.

Medicinal techniques that have been successfully used in the prevention of acute radiation enteritis include sulfasalazine and a low-residue diet. Although sulfasalazine has been shown to be effective in reducing radiation-induced diarrhea, questions remain regarding its potential radioprotective effects on the tumor. As such, many practitioners recommend a low-residue diet as prophylactic treatment of radiation enteritis.

Hereditary Polyposis Syndromes

George Apostolides, MD, FACS, FASCRS

INTRODUCTION

Within the realm of gastrointestinal pathology and disease are a number of conditions, aside from polyposis, associated with multiple colorectal polyps. This condition can occur with inflammatory polyps of inflammatory bowel disorder (IBD), intestinal lipomatosis, and neurofibromatosis. Therefore, biopsy is of the utmost importance for proper diagnosis and classification.

In this chapter, the discussion is limited to the true polyposis syndromes, which include:

1. Adenomatous types (familial adenomatous polyposis [FAP], mut y homolog [MYH] polyposis and some of its clinical variants, attenuated FAP, Turcot's syndrome); and
2. Hamartomatous types (Peutz-Jeghers syndrome [PJS], juvenile polyposis [JPS], PTEN hamartomatous polyposis syndromes).

The chapter focuses on the characteristics of the individual polyposis syndromes and their genetics, diagnosis, surgical and medical therapy, and extracolonic manifestations.

ADENOMATOUS POLYPOSIS SYNDROMES

Familial Adenomatous Polyposis

Familial adenomatous polyposis is an autosomal dominant inherited condition caused by a mutation of the APC gene. FAP frequency is 1/10,000 (Table 1). Cardinal elements to meet the criteria for this disease are either greater than 100 adenomas or fewer than 100 with a positive family history. The polyps usually develop in adolescence, with the onset of cancer around 40 years of age. Approximately 25% of patients do not have a family history of FAP. Bleeding is the most common symptom (80%), followed by diarrhea (70%), abdominal pain, and mucous discharge. Mount Sinai Hospital, New York, reported a 27% incidence rate of colorectal cancer at the time of presentation in a series of 115 patients (Table 2).

Congenital hypertrophy of retinal pigment epithelium (CHRPE) is a patchy fundus discoloration. The presence of four or more on examination is a specific phenotypic marker present in two thirds of families with FAP.

Attenuated Familial Adenomatous Polyposis

Unlike classical FAP, attenuated FAP is characterized by patients with fewer than 100 adenomas that develop at a later age (34 to 44 years). Similar to patients with classic FAP, these patients are also at high risk of colorectal cancer. They may exhibit extracolonic manifestations and carry a germ line APC mutation. Cancer onset occurs at a later age than with classic FAP (mean age, 56 years). The polyps are mostly proximal to the splenic flexure, and their numbers vary

TABLE 1: Hereditary colorectal polyposis syndromes

Polyposis syndromes	Phenotypic expression	Genotype
Familial adenomatous polyposis	Attenuated: <100 synchronous adenomas Mild: <1000 synchronous adenomas Severe: >1000 synchronous adenomas	Dominant inheritance of germ-line mutation in APC
Mut y homolog–associated polyposis	Attenuated/mild polyposis	Recessive inheritance: biallelic mutations of yMUTYH
Hyperplastic polyposis	>30 hyperplastic polyps, any size or location >10 hyperplastic polyps, proximal to sigmoid Any number of hyperplastic polyps with a family history of hyperplastic polyposis	Unknown
Hamartomatous polyps	Two of the following criteria:	
Peutz-Jeghers syndrome	Mucocutaneous pigmentation Gastrointestinal Peutz-Jeghers polyps Family history of Peutz-Jeghers polyposis	Dominant inheritance of germ-line mutation in STK11
Juvenile polyposis coli	>4 juvenile polyps in the colorectum Any number of juvenile polyps and a family history of juvenile polyposis	Dominant inheritance of germ-line mutation in SMAD4 or BMPR1
PTEN tumor-hamaroma syndromes		
Cowden's syndrome Bannayan-Riley-Ruvalcaba syndrome Proteus syndrome	International Cowden's consortium criteria	Dominant inheritance of a germ-line mutation in PTEN

TABLE 2: The extracolonic features of familial adenomatous polyposis

Most frequent	Upper GI adenomas	95%
	Osteomas, mainly jaw	80%
	CHRPE	75%
	Epidermoid cysts	50%
	Fundic gland polyps	40%
Less frequent	Unerupted and supernumerary teeth	17%
	Desmoids	15%
	Upper GI cancers	5%
	Adrenocortical adenomas	5%
Rare	Papillary thyroid carcinoma	<1%
	Biliary tract carcinoma	<1%
	Hepatoblastoma	<1%
	Medulloblastoma	<1%

CHRPE, Congenital hypertrophy of retinal pigment epithelium; *GI,* gastrointestinal.

significantly between family members. The genotype can be one of three groups: germ-line APC mutation, biallelic MYH mutations (30% of patients when APC is normal), and germ-line DNA mismatch repair (MMR) gene mutations. With regards to extracolonic findings, fundic glands and duodenal adenomas are frequent, but CHRPE are not found in this group. Desmoid disease is rare in 5′ mutations but frequent in 3′ mutations.

A full colonoscopy and genetic testing of APC/MYH mutations should be done in patients with 10 or more colonic adenomas, especially with a positive family history of colorectal adenomas or cancers. A full search for extracolonic features of FAP, including upper gastrointestinal (GI) endoscopy, testing of polyps or tumor for microsatellite instability (MSI), and MMR immunochemistry (IHC), may be helpful to exclude Lynch's syndrome. If the polyps are few and endoscopically controllable, then yearly endoscopy is reasonable. If the adenoma burden is uncontrollable, then colectomy with ileorectal anastomosis (IRA) should be performed.

Mut Y Homolog–Associated Polyposis

Mut y homolog–associated polyposis (MAP) is the autosomal recessive form of FAP caused by a mutation in the MYH gene, not the APC gene. Most affected individuals have fewer than 100 adenomas, but some may have several hundred and thus present as a true FAP case. Most polyps are predominantly right sided. Colonic microadenomas, duodenal adenomas, desmoid tumors, and fundic gland polyps can all be present. MAP can mimic many of the other hereditary forms of colorectal cancer, from sporadic cancer to FAP, and from Lynch's syndrome to hyperplastic polyposis (HPP). Because of its uniquely autosomal recessive inheritance, MAP has major implications for genetic counseling. MAP should be suspected and testing for MYH should be done with the following criteria: no APC mutation is found, the mode of inheritance is not clearly autosomal dominant, or the number of polyps is low.

The genetic mechanism of MAP is a biallelic mutation in MYH. Its protein product functions in the base excision repair pathway to correct base-pair mismatches that result from oxidative damage. Those biallelic carriers have an 80% cumulative lifetime chance of development of colorectal cancer by age 70 years. The locations of the pathogenic human muty homolog (hMUTYH) mutations vary with ethnicity. The most common mutations involve Y179C (associated with a more severe phenotype) and G396D.

The presence of 10 or more synchronous adenomas, or the presence of serrated polyps with multiple adenomas, warrants a genetic counseling and testing referral. Once MAP is confirmed, colonoscopy

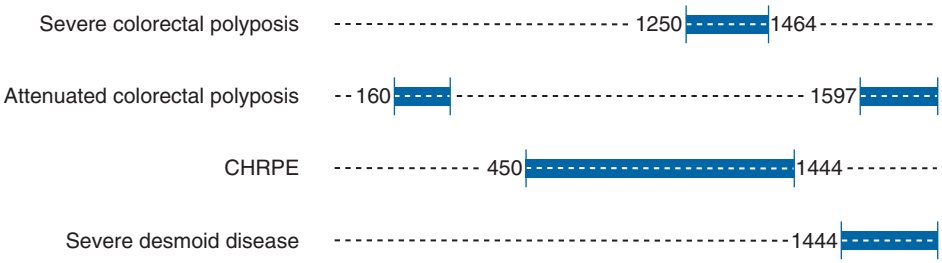

FIGURE 1 Schematic representation of the APC gene showing genotype-phenotype correlations. The *shaded areas* indicate regions of the codon where mutations are mostly found. *CHRPE,* Congenital hypertrophy of retinal pigment epithelium.

and esophagogastroduodenoscopy (EGD) are done, starting between the ages of 25 and 30 years. In rare cases with limited colonic adenomas, endoscopy can control disease and surgery can be avoided. More often than not, surgery is necessary with colectomy and IRA.

Turcot's Syndrome

Turcot's syndrome is the association of colorectal adenomatous polyposis and central nervous system tumors. In two thirds of the families, an APC gene mutation is present and the predominant tumor is a cerebellar medulloblastoma. In the other third of cases, variants of hereditary nonpolyposis colon cancer (HNPCC) are associated with glioblastoma.

GENETICS

The APC gene is a large gene situated on chromosome 5q21. In FAP and most sporadic colorectal cancers (CRC), a mutation of the APC gene is one of the earliest events. It is a key gene in colorectal carcinogenesis and is mutated in a majority of sporadic colorectal cancers. Most mutations are between codons 168 and 1640 (exon 15), with a particular concentration in two hotspot codons 1061 and 1309. More than 820 germ-line APC mutations have been found to cause FAP, and all result in a truncated APC protein product that then fails to act as a tumor suppressor in the *wnt* signaling pathway.

Although the APC protein is expressed in all organs, the messenger RNA is found in particularly high levels in normal colonic mucosa. The 300-kd APC protein is found in the cell cytoplasm and interacts with several other proteins, including β-catenin and the cytoskeleton. It plays a role in the *wnt* signaling pathway, which is involved in the normal development of three-dimensional structures and is abnormally activated in some malignant diseases. APC binds and downregulates cytoplasmic β-catenin, thereby preventing its translocation to the nucleus. In contrast, abnormal APC fails to do this, so that β-catenin is free to enter the nucleus and form a complex that results in a specific transcription of cell cycle, simulating DNA sequences and ultimately cell proliferation.

Genotype-Phenotype Correlation in Familial Adenomatous Polyposis

Several genotype-phenotype correlations have been observed in FAP. Evidence is found of significant correlation between the position of the germ-line APC mutation (genotype) and the various aspects of the phenotype (Figure 1).

SURGICAL THERAPY

Once the molecular genetic diagnosis of FAP is confirmed, and irrespective of whether the patient is symptomatic, prophylactic surgery is recommended. Full colonoscopy is mandatory to evaluate the number and distribution of the polyps. Biopsies are taken to detect any cancer or dysplasia, especially in the rectal and anal mucosa. Close collaboration between the surgeon, gastroenterologist, geneticist, and the patient is needed. Many factors need to be considered in deciding the optimal management and subsequent surgical procedure.

Although the prevention of cancer remains a crucial priority in the management of patients with hereditary colorectal cancer, one should also aim to maintain a good quality of life. This is especially true in the young asymptomatic patient diagnosed with screening. Considering that surgery does not cure FAP, the timing and choice of surgery should be the one with the least impact on social, academic and vocational activities.

Timing of Surgery

Patients with severe polyposis (>1000 colonic or >20 rectal polyps) or symptomatic patients should have surgery as soon as possible. Asymptomatic patients with mild disease (100 to 1000 adenomas, <1 cm size, without severe dysplasia) can have surgery delayed until the patient reaches appropriate physical and intellectual maturity. Another important reason for surgical delay is the concern for the development of desmoid disease, especially in women with a family history of desmoid disease, extracolonic manifestations of Gardner's syndrome, and a 3′ APC mutation. In these cases, annual colonoscopy is advised for monitoring of the polyps. Most patients with classic polyposis have surgery between the ages of 16 and 20 years, well before cancer typically develops.

Choice of Operative Procedure

The most common surgical therapy for FAP includes: (1) total proctocolectomy (TPC) and end ileostomy or Kock's pouch (done in select centers); (2) total abdominal colectomy (TAC) and IRA; and (3) TPC and ileal pouch–anal anastomosis (IPAA), stapled or hand sewn, with or without mucosectomy. Any of these surgeries can be done with equal efficacy and safety, through the conventional open or laparoscopic approach, depending on the expertise of the surgeon (Table 3).

Total Abdominal Colectomy and Ileorectal Anastomosis

Total abdominal colectomy with IRA is a reasonable and safe option in young patients, particularly children and teenagers without 1309 mutation or severe polyposis, especially with fewer than five to 10 rectal polyps. Any polyp of more than 5 mm should be removed, and polyps with high-grade dysplasia are a relative indication for completion proctectomy. The main disadvantage of this surgical technique for FAP is that follow-up studies have shown a 12% to 29% risk of cancer developing in the rectal stump within 20 to 25 years, despite close follow-up observation. Patients with IRA should undergo yearly endoscopic surveillance of the rectum. If severe dysplasia or uncontrolled polyposis develops, completion proctectomy, with or without ileoanal pouch formation, is recommended.

TABLE 3: Indications for prophylactic surgery for patients with familial adenomatous polyposis

Factor	TAC and IRA (leave 15 cm rectum)	TPC and IPAA	PC with Ileostomy (or kock's pouch in select centers)
Indications for surgery	<20 rectal polyps APC	Most of patients with FAP Rectal polyp carpeting Resectable rectal cancer Desmoids in family history	Older patients after IRA Poor sphincter tone Low rectal cancer nonresectable oncologically
Age at surgery	Within 2 years of phenotypic expression and molecular diagnosis	Within 2 years of phenotypic expression and molecular diagnosis	At CRC diagnosis
Mortality rate	Very low	Very low	Very low
Morbidity rate	Low (15%-20%)	High (15%-50%)	Very low
Functional outcome Early Late Follow-up	 Good Good Rectal endoscopy 1×/y	 Average Good Pouch endoscopy 1×/3 y	 Good Good Same as for sporadic CRC Pouch endoscopy 1×/3 y
Disadvantages	Risk of rectal cancer	Complex surgery, often needs stoma, bowel function unpredictable, risk of damage to pelvic nerves and decreased fecundity in women, risk of ATZ adenomas and cancer	Permanent stoma

ATZ, Anal transition zone; *CRC,* colorectal cancers; *FAP,* familial adenomatous polyposis; *IPAA,* ileal pouch–anal anastomosis; *IRA,* ileorectal anastomosis; *PC,* proctocolectomy; *TAC,* total abdominal colectomy; *TPC,* total proctocolectomy.

Patients are at higher risk of development of rectal stump cancer when the polyposis is more severe, with a mutation in exon 15 G, and in codon 1309. The advantage of this approach is the avoidance of risk of damage to erection, ejaculation, and bladder function in men that occurs in about 1% of patients and to fertility in women. This procedure removes the entire colon and leaves about 15 cm of rectum to which the ileum is anastomosed. One should avoid entering the presacral plane to facilitate future pelvic dissection when the prospects of a completion proctectomy and a restorative IPAA become more appropriate.

Restorative Proctocolectomy With Ileal Pouch–Anal Anastomosis, Stapled or With Mucosectomy

This option is favored in cases with severe polyposis or severe rectal disease or in patients predisposed to duodenal or desmoid disease. IPAA is thought to alter bile salt absorption via the enterohepatic circulation with secondary decreased bile acid production and less duodenal exposure to intestinal carcinogens. Reports by Blasco and associates indicate a lower incidence rate of duodenal adenomas after IPAA than after IRA.

In this operation, the colon and rectum down to the level of the dentate line are removed, thereby theoretically eliminating the risk of colorectal cancer. The dissection plane must be close to the rectal wall to avoid injury to the pelvic nerves. If the lower rectum is spared from heavy polyp burden, then a stapled anastomosis is adequate as the bowel function is better than with mucosectomy or hand-sewn anastomosis. When the lower rectum is carpeted with adenomas to the dentate line, then a mucosectomy and hand-sewn anastomosis is recommended. This method does minimize the risk of cancer in the anal transitional zone. The endoanal mucosal stripping can be done either in the prone (the author's preferred method) or lithotomy position. Division of the rectal mucosal dissection is easier in three quadrants through a vertical incision from the dentate line extending proximally about 6 to 8 cm. The dissection is performed with electrocautery, after an infiltration of the submucosa with a diluted solution of 1:100000 epinephrine mixed in normal saline solution; then each mucosal strip is removed separately. The Lone Star retractor (Lone Star Medical, Strafford, Tex) greatly facilitates the exposure during this dissection. Another method is to perform a circular sleeve resection. In both methods, removal of all of the mucosa is imperative. Nevertheless, controversy still remains as to whether a mucosectomy should be done in the absence of dysplasia in the transition zone because it results in more complications and poorer function.

In the case of cancer of the upper or middle rectum, an oncologic dissection can be done with the IPAA by incorporating a total mesorectal dissection. Then, the abdominal colectomy is performed, laparoscopically or open, with a Pfannestiel's or lower vertical midline incision for construction of the ileal pouch and a diverting loop ileostomy. The ileostomy can then be closed 3 months later. A J pouch (most common type, 15-cm to 25-cm limbs) or S-shaped pouch can be constructed with either stapled or hand-sewn anastomosis with similar functional results. In select patients, the obese patient, or tall slender men, there can be difficulties with mesenteric reach. Various maneuvers can be done to lengthen the reach of the pouch. Complete mobilization of the mesentery to the level of the duodenum and near the pancreatic head, transection of the ileum close to the colon, transverse scoring of the peritoneum over the superior mesenteric artery (SMA), and occasionally selective division of mesenteric arcade may be needed for lengthening. In practical terms, the author has found the following simple maneuver to be a good indication of whether the pouch will reach the dentate line. When the apex of the pouch reaches approximately 6 cm beyond the symphysis pubis, then the pouch most likely will reach its target. It may be helpful to anchor the pouch to the pelvic sidewall to prevent twisting or torsion and subsequent ischemia.

Early postoperative complications of this procedure are: pouch leaks in 5% to 7%, small bowel obstruction in 20% to 25%, and

pouchitis in 5% (much less than the 20% to 25% seen in ulcerative colitis), for an overall complication rate of 15% to 50%. This is the operation of choice for most patients with FAP. Short-term results are inferior to IRA as far as stool frequency, urgency, day and nighttime continence, and need for antidiarrheal medications. In the long term, after 2 years, the results are comparable with IRA.

Ileoanal pouches should also be followed endoscopically because of a high rate of adenoma formation in pouches, with reported rates as high as 50% and even reported cases of cancer formation. Adenomas in the anal transition zone occur twice as commonly with stapled anastomosis compared with the hand-sewn IPAA. These adenomas can be excised individually or the entire anal transitional zone (ATZ) can be stripped. If stripping is to be performed because of the extent of the polyposis, it should be performed in two stages to avoid stenosis. Dysplasia in the ATZ occurs twice as often in the stapled anastomosis (18.5% vs 7.2%) with the mucosectomy method. Needless to say, redo pelvic procedures in patients with FAP are technically demanding as the tissue planes are nonexistent and scarring can be severe. Ureteral stents should be placed before surgery. Recommendations are to refer this kind of secondary revisional surgery to experienced surgeons.

Proctocolectomy With Permanent Terminal Ileostomy (or Kock's Pouch)

Proctocolectomy with permanent terminal ileostomy is rarely indicated except in cases of advanced rectal cancer requiring subsequent pelvic radiation or low rectal cancer, older patients, and poor sphincter function or preclusion of IPAA. It is a simple operation with low morbidity and reoperation rates. It does, however, mean creation of a permanent stoma. The creation of a Kock's pouch to achieve full continence is performed in select centers, but there is a significant complication rate. The most common complication is valve slippage (10% to 20%), which necessitates reoperation and small bowel obstruction (6% to 15%). Although patient satisfaction is high, morbidity and reoperation rates are also high.

Other facts may also dictate the surgical procedure that should be done. These involve the patient's comorbidities, ability to withstand potential complications, baseline sexual and bladder function, and patient's priorities and preferences.

MEDICAL THERAPY

Adenoma Chemoprevention

Both nonsteroidal antiinflammatory drug (NSAID) sulindac and cox-2 inhibitor celecoxib were found to be effective in reducing the number and size of adenomas in the retained rectum. Chemoprevention, however, is not an alternative to prophylactic surgery because no reduction in the rate of cancer was shown. In fact, cases are seen of rectal cancer in patients on sulindac despite reduction in the number and size of polyps.

The circumstances in which the use of chemoprevention is indicated are: unfeasible completion proctectomy because of desmoid disease, delayed surgery, a very high family risk of desmoid disease, or treatment of pouch polyposis.

EXTRACOLONIC DISEASE

Upper Gastrointestinal Polyposis

Upper GI polyposis is a major extracolonic finding in patients with FAP. Fundic gland polyps are seen in the stomach in 80% to 90% of patients with FAP. They are made up of areas of cystic hyperplasia. Usually the condition is benign, but recent reports show a 40% rate of low-grade dysplasia and a 3% rate of high-grade dysplasia. The best clinical practice is to biopsy representative fundie gland polyps (FGPs) during regular surveillance.

Gastric adenomas occur in 10% of patients, usually in the antrum. The incidence rate of gastric cancer in FAP in Japan is seven times that in the West; for Koreans, it is three times the rate.

More than 95% of individuals with FAP have duodenal adenomas. These occur about 15 years later than colonic polyps. Duodenal cancers, although rare (5%), are the second most common cause of death in FAP. Average age at diagnosis is 50 years.

The adenomas are mostly found in the area of the ampulla of Vater. In fact, up to 50% of normal-appearing ampullas are dysplastic on biopsy. Adenomas and even cancer can also occur in the small bowel.

Duodenal surveillance is essential in properly managing FAP. Duodenal adenomas are flat, white mucosal patches. They are completely different from in appearance from colonic adenomas. The Spigelman staging system allows for an objective assessment of the severity of duodenal polyposis in FAP (Table 4).

In Spigelman's original cohort of patients at 10-year follow-up, there was a 2% risk of cancer in stages II or III compared with a 36% risk of invasive duodenal carcinoma in stage IV. Regular endoscopic surveillance of the stomach and duodenum is therefore recommended. The use of forward-viewing and side-viewing scopes starts at age 25 years. The interval of recommended surveillance is outlined in Table 5.

The management of severe duodenal polyposis is difficult, and once invasive carcinoma develops, outcome is poor. Endoscopic mucosal resection is an attractive option but is made difficult by the plaque-like morphology of the polyps and their proximity to the ampulla, as even a simple biopsy of the ampulla can result in acute pancreatitis and repeated diathermy can result in scarring and stricturing. Duodenectomy and open polypectomy carry a 100% recurrence rate at 1 year.

Chemoprevention with sulindac can result in small polyp regression but has no effect on large ones. A randomized trial of cox-2 inhibitor has shown a significant improvement for those with mild to moderate disease.

Duodenectomy is a last resort option. Pancreas-preserving duodenectomy for Spigelman stage IV provides satisfactory control with reasonable low morbidity. If cancer is suspected, a Whipple's procedure is the best choice, although associated with a high rate of complications.

TABLE 4: Polyp scoring system in Spigelman staging for duodenal adenomas

Points	Number of polyps	Size of polyps (mm)	Histology	Dysplasia
1	1-4	1-4	Tubular	Mild
2	5-20	5-10	Tubulovillous	Moderate
3	>20	>10	Villous	Severe

TABLE 5: Derivation of Spigelman stage from scores

Total points	Spigelman stage	Suggested interval to next duodenoscopy (years)
0	0	5
1-4	I	3-5
5-6	II	3
7-8	III	1
9-12	IV	Duodenectomy; if not, rescope in 6 months

TABLE 6: Intra-abdominal desmoid tumor staging

Stage	Description
I	Size <10 cm, not growing, asymptomatic
II	Size <10 cm, mildly symptomatic, slow growing (<50% growth in 6 months)
III	Size 10-20 cm, moderate symptoms (bowel or ureteric obstruction), slow growing
IV	Size >20 cm, severe symptoms (abscess, fistula, hemorrhage) or rapid growth (>50% growth in 6 months)

Desmoid Disease

A desmoid tumor is by far the most troublesome and disabling consequence of FAP. It is a locally invasive, nonmetastasizing clonal proliferation of myofibroblasts. Although rare in the general population, the tumors are found in up to 30% of FAP cases. It is the third most common cause of death in patients with FAP overall (11%), after metastatic colorectal (58%) and duodenal cancer. Desmoids can vary from white sheet-like plaques to large rapidly growing tumors. Intra-abdominal desmoids tend to pucker and distort adjacent tissues, causing obstruction in tubular organs. Peak incidence is around 30 years of age, or 2 to 3 years after surgery. In patients with FAP, desmoids typically occur within the abdomen (50% of cases), especially in the small bowel, and in the abdominal wall in about 45%. Trauma (as in surgery) and estrogens are causative factors. There is also some degree of genotype-phenotype correlation as desmoids have been reported more frequently in patients with 3′ germline APC mutations. Many patients with desmoids also have mutations in the 5′ half of the APC gene. Surgeons should be alert to recent publications mentioning a "desmoid risk factor" score, with the important elements being: female gender, presence of extracolonic manifestations (as in Gardner's syndrome), and, most predictive, a family history of desmoids.

Computed tomographic (CT) scan and magnetic resonance imaging (MRI) are the most useful tools for investigation and follow-up, allowing for visualization and measurements and demonstrating the relationship of the desmoid tumor to other key structures such as ureter and bowel.

The treatment is controversial, often empirical and difficult. The natural history is variable, with about 10% resolving spontaneously, 10% growing rapidly and relentlessly, and the rest showing variable cycles of resolution and growth or remaining stable. Abdominal wall and extraabdominal desmoids are best treated with surgery. Even if recurrences are common (20% to 50%), complications are few.

A staging system for intra-abdominal desmoid tumors has been proposed by Church and Bomann and colleagues and is shown in Table 6.

Intra-abdominal desmoids are much harder to treat. Because most desmoids involve the root of the mesentery, complete resection is often impossible. Even after residual free (R0) resections, recurrence rates are around 50%. Any foolhardy attempt at resection of a desmoid tumor affecting the root of the small bowel mesentery is associated with high mortality from hemorrhage or high morbidity from extensive loss of small bowel. Ureteric obstruction is best treated with stents, and in rare instances, renal autotransplantation has proven effective. Often nonresective surgery is effective to treat the complications, such as careful lysis of adhesions, bypass procedures in the face of bowel obstruction, and occasionally diversion by means of stoma creation.

Clinical Scenarios

If one finds an unexpected desmoid at time of the first surgery, then it is best to do a proctocolectomy and pouch if possible. If the pouch does not reach, then an IRA is the next best choice for mild polyp load, with a proctocolectomy with end ileostomy reserved for severe polyposis.

If a desmoid is found at a completion proctectomy after a previous IRA, the rectum must be removed because it may well be impossible to do a restorative proctectomy.

The third scenario is with a need for prophylactic surgery in a patient with a strong family history of desmoids. Surgery in this case should be delayed as long as it is possible and safe. Yearly colonoscopy and treatment with sulindac are reasonable options for patients in their 20s. Otherwise, IRA or a proctocolectomy and pouch are both adequate options.

Conflicting reports exist regarding the value of radiotherapy. Its use for intra-abdominal desmoids is limited because of the risk of radiation enteritis. Medical treatment may involve NSAIDs, such as sulindac; antiestrogens, such as tamoxifen, raloxifene or toremifene; and cytotoxic chemotherapy in aggressive nonresectable disease, such as doxorubicin, dacarbazine or a combination of vinblastine and methotrexate.

The following algorithm for management of intra-abdominal desmoids may provide useful suggestions in their management (Figure 2).

HAMARTOMATOUS POLYPOSIS TYPES

Peutz-Jeghers Syndrome

Peutz-Jeghers syndrome is an autosomal dominant inherited cancer syndrome with an incidence rate of 1/200,000. It is caused by mutation of LKB1 (or STK11) on chromosome 19. This LKB1 mutation is found in 60% to 70% of cases. A significant number of cases occur de novo. They are hamartomas with a characteristic branching morphology containing smooth muscle in the submucosa.

The presence of two of three of the following characteristics defines this disease: perioral, buccal, or genital melanin pigmentation; gastrointestinal hamartomatous polyposis (PJS); and a family history of PJS. Pigmentation appears in childhood and fades in the late 20s. The polyps occur mostly in the small intestine (78%), stomach (38%), colon (42%), and rectum (28%).

Clinical concerns in PJS are many. Anemia from chronic blood loss and small bowel obstruction are the most common clinical issues. The risk of malignancy increases with age. In one series, by age 57 years, approximately half of patients had died of cancer. The

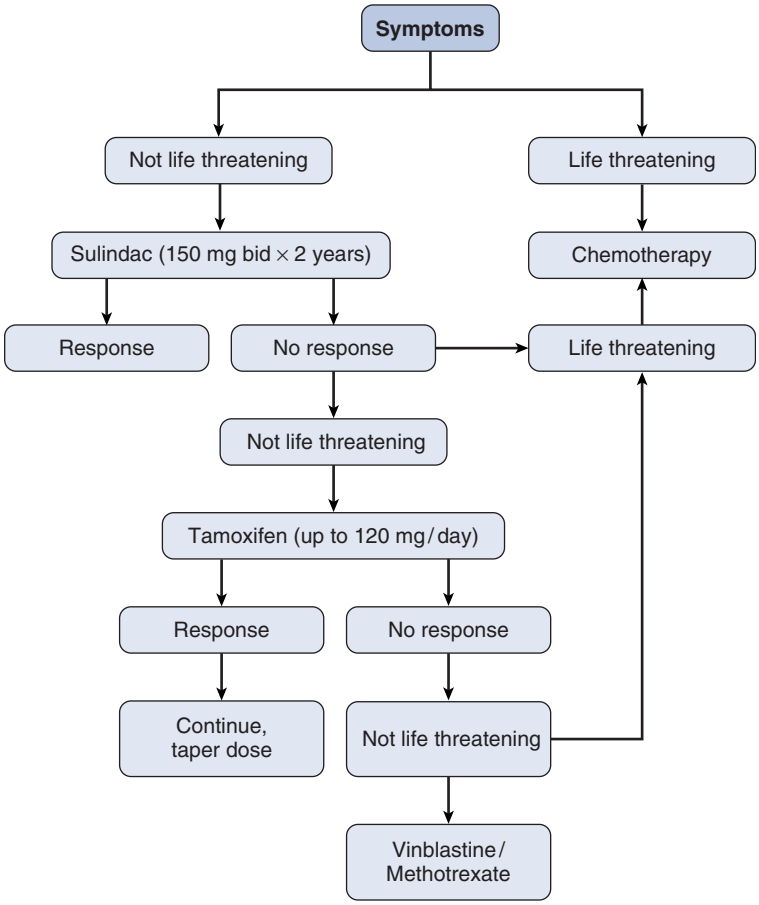

FIGURE 2 Algorithm for management of intra-abdominal desmoids.

cause of death in half of those cases was gastrointestinal related. In a lifetime, 90% of patients have cancer develop: colorectal, 20%; gastric, 5%; breast, pancreas, 30%; ovarian sex cord tumors, pulmonary, and cervical malignancies.

Medical and surgical management of PJS can be complex. Emergency laparotomy may be necessary for intussusception or bleeding. The best technique is the "clean sweep" technique where at the time of laparotomy, endoscopy per anus to the small bowel and per oral into the jejunum are performed. The scope is then withdrawn in a darkened room, and all polyps marked with sutures for later removal through enterotomies with suture ligation at the stalk of the polyps. With this technique, the entire small bowel is cleared of polyps, minimizing the need for future reexploration. Capsule endoscopy is useful for surveillance of asymptomatic patients. Colonic polyps are controlled endoscopically.

Surveillance depends on the number, size, histology, and location of the polyps. An EGD, capsule endoscopy, and colonoscopy should follow a normal examination 2 to 3 years later. Hemoglobin should be checked annually. Any polyps over 1.5 cm should be removed. Extra intestinal surveillance should be done according to national standards for breast and cervical screening and physical examination for testicular tumors in prepubertal boys. Clinicians should be aware of the high cancer risk and maintain a low index of suspicion.

Juvenile Polyposis

Juvenile polyps (JPS) are hamartomas that lack smooth muscle. Juvenile polyposis is defined as the presence of five or more juvenile polyps in the colon, or any number of juvenile polyps associated with a family history of JPS or multiple juvenile polyps in the upper and lower GI tract. The colon is affected 100% of the time, and the stomach and small bowel up to 50%. Most affected patients have between 50 and 200 polyps. It is a rare condition, occurring in 1/100,000. Associated morphologic abnormalities (macrocephaly, cleft lip/palate, congenital heart disease, genitourinary malformations, malrotations) are present in 10% to 20% of patients. Disease presents with rectal bleeding, anemia, and polyp prolapse at around 9 years of age. Adenomatous dysplasia in those hamartomatous polyps can develop in up to 50% of cases, with possibility of progression into adenocarcinoma.

This condition is different from a solitary juvenile polyp, which is the most common colorectal lesion in children (2%) and carries no malignant potential.

Genetic studies have shown JPS to be heterogeneous, as three separate germ-line mutations have been identified. The first mutation is present in SMAD4, a tumor suppressor gene on chromosome 18q21, and occurs in about 40% of patients with JPS in the United States but in only 3% to 28% in Europe. Mutations in a second gene, BMPRIA on 10q22, have been found in 15% of cases. Lastly, mutations in PTEN have been reported in JPS. Mutations in SMAD4 carry a high risk of hereditary hemorrhagic telangiectasia (HHT), manifesting as multiple vascular anomalies in the brain, lungs, mediastinum, and bowel.

In JPS, the cumulative colorectal cancer risk is about 30% to 50%, and upper GI cancer is at about 10% to 20%. Management of first-degree relatives should include a colonoscopy by age 12 years; if the patient is asymptomatic, then 5 years thereafter is appropriate if colonoscopy was normal. Upper GI endoscopy is advised by age 25 years. When the polyp load is minimal, the condition can be controlled endoscopically. When the polyp load is too large, or if the patient is symptomatic with diarrhea, bleeding, or abdominal

cramps, a colectomy and IRA or a restorative proctocolectomy may be advisable.

PTEN Tumor Hamartoma Syndromes

PTEN tumor hamartoma syndromes are three very rare dominant inherited conditions involving hamartomatous colorectal polyps and craniofacial, skeletal, and dermatologic phenotypic features. The three syndromes are: Cowden's syndrome, Bannayan-Riley-Ruvalcaba syndrome, and serrated polyposis (SPP). All share common germ-line mutations of PTEN, which is an important tumor suppressor gene.

Cowden's Syndrome

Cowden's syndrome consists of macrocephaly, trichilemmomas (pathognomonic), and benign or malignant tumors of the thyroid, breast, uterus, and skin. Hamartomas occur in the mouth and give a nodular appearance to the buccal mucosa. The colon is affected with various polyps (hamartomas, lipomas, fibromas, neurofibromas adenomas). The colorectal cancer risk in Cowden's syndrome is not yet well defined. Colonoscopy should be done by age 30 years and every 3 years if findings are minimal.

Bannayan-Riley-Ruvalcaba Syndrome

This syndrome involves colorectal hamartomas (50%), characteristic pigmented penile macules, macrocephaly, mental retardation (50%), lipomatosis, and hemangiomas. It is caused by mutations of the same gene. No evidence of increased colorectal cancer risk.

Serrated Polyposis

Initially thought to carry no premalignant potential, the polyps in SPP are now known to be potential premalignant precursors to cancer pathways. These polyps are called serrated because the overcrowded hyperplastic glands are thrown into a saw-toothed or serrated pattern. When patients have multiple lesions, they are at high risk of colorectal cancer, with reported rates up to 50%.

The World Health Organization definition of serrated polyposis is:

- At least 30 serrated polyps, any size and location.
- More than 10 serrated polyps proximal to the splenic flexure, of which two are larger than 10 mm.
- Any number of serrated polyps with a family history of SPP.

No germ-line mutation has been identified yet, and the pattern of inheritance is not clear. The treatment is either endoscopic or surgical. These polyps can be easily missed on colonoscopy; therefore, yearly colonoscopy is advisable to prevent cancer. When the polyp load is too large and not controlled with endoscopy, then colectomy and IRA is advised.

CONCLUSION

The ultimate concern in polyposis syndromes is the potential for malignant transformation and development of colorectal cancers. Each particular syndrome is associated with a certain risk for this outcome. The essence of proper management is to balance the elimination of cancer risk with maintenance and preservation of quality of life. This principle allows for the selection of the most appropriate surgical intervention and proper timing. Understanding the genetic basis of the polyposis syndrome, diagnosis, and surveillance assist in selecting the surgical therapy. A multidisciplinary approach involving genetic counselor, pediatrician, gastroenterologist, and surgeon is crucial to maximizing appropriate medical care.

Colon Cancer

Elizabeth Hechenbleikner, MD, and
Elizabeth Wick, MD, FACS

BACKGROUND AND EPIDEMIOLOGY

Colorectal cancer arises from the epithelial lining of the colon or rectum, with roughly 75% of cases occurring in the colon and 25% in the rectum. Colon cancer is one of the most commonly diagnosed cancers and a leading cause of cancer death in the United States. There is considerable geographic variation in colon cancer incidence, both within the United States and across the world, with increased incidence associated with developed and developing countries. Differences in diet, physical activity, and access to healthcare services are some of the proposed reasons for this regional variation. Most colon cancers are sporadic adenocarcinomas diagnosed in adults over the age of 50 years. In the United States, over the past decade, a consistent decline has been seen in colon cancer incidence rate in adults greater than 50 years old; however, in adults under the age of 50 years, the incidence rate has been rising nearly every year since 1992. Colon cancer mortality has also been decreasing in the United States, but disproportionately fewer white patients die from colon cancer as compared with African American patients, regardless of cancer stage. Because screening colonoscopy is not recommended until 50 years of age for individuals at average risk, colon cancers in younger patients generally present later, when symptoms such as abdominal pain or bloating develop. Timely screening colonoscopy is paramount for the early detection and potentially curative treatment for premalignant (adenomatous) and malignant lesions.

SCREENING RECOMMENDATIONS

Colonoscopy is considered the gold standard among colon cancer screening techniques because it is highly sensitive and allows for biopsy of abnormal areas and polyp removal. Overall screening colonoscopy rates are improving but continue to fall short of recommended levels in the United States, with cost and fear of the procedure and bowel preparation the major barriers to widespread adoption. Key goals during colonoscopy are to visualize the entire colon, including adequate cecal inspection, and to identify and remove all polyps. Two common screening tests that are less expensive than colonoscopy are the fecal occult blood test (FOBT) and flexible sigmoidoscopy. FOBT is less sensitive than colonoscopy, and sigmoidoscopy only visualizes the lower one third of the colon; however, decreased colon cancer mortality has been associated with regular use of FOBT and one-time screening sigmoidoscopy in select patients. Another test that has been available since the 1990s is computed tomographic colonography (CTC) or virtual colonoscopy. CTC, which still requires a bowel preparation, has been shown in some settings to be as effective as colonoscopy for detection of tumors 1 cm in size or larger.

Screening recommendations are based on one's lifetime risk of development of colon cancer. Most individuals have no identifiable risk factors and are considered average risk, with a 5% to 6% lifetime risk of colon cancer. In patients at average risk who are 50 years of age or older, the 2008 joint guidelines from the American Cancer Society, the U.S. Multi-Society Task Force on Colorectal Cancer, and the American College of Radiology recommend: (1) annual FOBT; (2) flexible sigmoidoscopy every 5 years; (3) flexible sigmoidoscopy every 5 years with annual FOBT; (4) colonoscopy every 10 years; or (5) double-contrast barium enema every 5 years. In the 2008 joint guidelines, CTC was endorsed as a suitable screening option for those who decline or cannot tolerate colonoscopy, but the timing of repeat examinations is still uncertain. Moreover, a positive finding on FOBT, sigmoidoscopy, double-contrast barium enema, or CTC mandates follow-up colonoscopy.

About 25% of the population is at increased or moderate risk of development of colon cancer because of a personal or family history of colon cancer or adenomatous polyps. In this group, timing of colonoscopy screening examinations varies based on the individual's clinical situation. For example, patients with three to 10 adenomas or one adenoma larger than 1 cm or with high-grade dysplasia should have all lesions removed at initial colonoscopy, with a repeat examination within 3 years. In individuals with first-degree relatives with colon cancer diagnosed before the age of 60 years, colonoscopy should begin either at age 40 years or 10 years before the youngest diagnosed family member, with follow-up colonoscopy every 5 years.

Approximately 6% to 8% of the population is at high risk of development of colon cancer because of a hereditary syndrome like familial adenomatous polyposis (FAP) or hereditary nonpolyposis colon cancer (HNPCC) or a chronic medical condition like inflammatory bowel disease (IBD). Patients with suspected hereditary colon cancer should undergo genetic testing and counseling. Individuals with known or suspected FAP should undergo yearly flexible sigmoidoscopy or colonoscopy starting in childhood (age 10 to 12 years) until prophylactic or therapeutic total colectomy or proctocolectomy is deemed appropriate. Patients with HNPCC should have screening colonoscopies every 1 to 2 years starting in early adulthood (age 20 to 25 years) or 10 years before the youngest immediate family member with colon cancer. Patients with IBD should undergo screening colonoscopies with biopsies for dysplasia every 1 to 2 years after 8 years of pancolitis or 12 to 15 years of left-sided colitis.

PRESENTATION, DIAGNOSIS, AND WORKUP

Early colon cancer typically has no symptoms but may be discovered with a positive FOBT and subsequent colonoscopy. As the primary lesion enlarges, a change in bowel habits may be seen, such as decreasing stool caliber or rectal bleeding. Patients with late or advanced colon cancer often present with fatigue, weight loss, iron-deficiency anemia, or abdominal pain. Presenting symptoms may differ in patients with early or advanced colon cancer based on the location of the tumor. Right-sided tumors have a tendency to present with anemia; left-sided lesions are more likely to cause abdominal pain, obstruction, or rectal bleeding. Interestingly, various studies since the 1980s have reported an increasing percentage of right-sided colon cancers, perhaps in part because of increased colonoscopy utilization and different tumor biology and environmental factors that are currently under investigation.

When a patient is diagnosed with colon cancer, a thorough evaluation is required to establish the proper treatment. Medical comorbidities should be identified as should pertinent family history to rule out hereditary cancer syndromes. Complete colonoscopy with biopsies must be performed to confirm and tattoo the primary lesion along with any synchronous lesions. When a sporadic colon cancer is diagnosed, there is a 6% to 8% chance of having a synchronous lesion. Computerized tomographic (CT) scan of the abdomen and pelvis is done to evaluate the presence of metastases and adjacent organ invasion from the primary tumor. Chest x-rays should also be performed, and abnormal findings usually require chest CT scanning. Approximately 20% of patients in the United States present with metastatic disease, with the liver, lung, and peritoneum as the most common sites. Currently, the National Comprehensive Cancer Network (NCCN) does not recommend positron emission

tomography with CT scan for the initial staging of a primary colon cancer intended for surgical resection. Regarding laboratory data, a baseline serum carcinoembryonic antigen (CEA) level should be measured before treatment, particularly surgical resection. After surgical resection, CEA levels that do not normalize or subsequently become elevated indicate inadequate tumor resection, recurrence, or progression of disease and require further evaluation. Serum electrolytes, liver function tests, and a complete blood count are part of a standard workup, along with a proper nutrition assessment, and should be optimized before surgery whenever possible.

SURGICAL RESECTION AND STAGING

Surgical resection is the foundation of curative treatment for localized colon cancer and select patients with limited metastatic disease. Approximately 75% of patients are candidates for potentially curative surgical resection at the time of diagnosis. Ten percent to 25% of patients with isolated liver metastases are operative candidates. The goal of surgery is to achieve an appropriate oncologic resection, ideally an R0 resection, while minimizing complications like infection, hemorrhage, and sexual or urinary dysfunction. The abdomen should be thoroughly explored and any extracolonic tumor spread to the liver, omentum, hemidiaphragm, abdominal wall, or pelvis identified, along with careful palpation of the entire large bowel. The involved colonic segment should be completely removed with a 2-cm to 5-cm margin and en bloc resection of any local structures or organs invaded by the primary tumor. The major vascular pedicle and lymphatic drainage basins of the involved colonic segment should be removed in a curative resection. Per NCCN guidelines, a minimum of 12 lymph nodes are required for accurate assessment of nodal involvement. Bowel continuity should be restored when possible with a well-vascularized, tension-free anastomosis.

Selection of the appropriate surgical procedure is based on the location of the primary tumor and the presence of synchronous lesions or a hereditary cancer syndrome. The vascular supply to the involved colonic segment dictates the extent of resection. Removal of the appropriate vascular supply should ensure adequate lymphadenectomy. A right colectomy is performed for cancers of the cecum, ascending colon, and hepatic flexure. In this procedure, the ileocolic artery is ligated, as is the right colic artery if present, and the terminal ileum is transected roughly 10 to 15 cm proximal to the ileocecal valve (Figure 1). The transverse colon is divided proximal to the right branch of the middle colic artery (MCA), which can be ligated if necessary. An extended right or, in some instances, transverse colectomy can be performed for tumors in the mid transverse colon. For an extended right colectomy, the ileocolic and MCA are ligated at their origin; for a transverse colectomy, only the MCA is ligated. In this case, an anastomosis is created between either the ileum (extended right colectomy) or the ascending (transverse colectomy) and distal transverse colon. A transverse colectomy requires mobilization of both the hepatic and the splenic flexure to allow for adequate reach and a tension-free anastomosis. Splenic flexure tumors can be treated with either a subtotal colectomy or, if adequate mobility is present, a left colectomy. Descending colon cancers and select proximal sigmoid colon cancers are managed with a left colectomy with a descending to sigmoid or rectal anastomosis. With a left colectomy, the inferior mesenteric artery (IMA) should be ligated high near the aorta to allow for a tension-free anastomosis. The inferior mesenteric vein can be ligated just below the duodenum if additional mobility is needed. Sigmoid cancers are treated with a sigmoid colectomy and high ligation of the IMA (see Figure 1).The splenic flexure should be mobilized for left colon resections to ensure creation of a tension-free anastomosis. In the case of patients with synchronous colon cancers or a hereditary cancer syndrome, a total abdominal colectomy with ileorectal anastomosis may be warranted.

The most important prognostic factor after surgical resection is the pathologic stage. The tumor node metastasis (TNM) classification system developed and maintained by the American Joint Committee on Cancer (AJCC) and the Union for International Cancer Control (UICC) is the most universally used staging system for colon and rectal malignant diseases. Table 1 includes the most updated TNM staging for colorectal cancer. Colon cancer is localized to the bowel wall in stage I and II, regionally spread in stage III (i.e., lymph node involvement), and distantly spread or metastatic in stage IV. The 5-year survival rate decreases with stage progression: (1) stage I, 70% to 95%; (2) stage II, 54% to 65%; (3) stage III, 39% to 60%; and (4) stage IV, 0 to 16%. The risk of regional lymph node spread correlates with bowel wall penetration by the primary tumor (T status). Primary tumors limited to the submucosa have a 10% risk of regional spread, whereas those penetrating to the subserosa have a 45% risk. Extent of nodal metastases (N status) is the most important determinant for long-term survival and treatment planning. Inadequate lymphadenectomy is a poor prognostic indicator in localized and regionally spread colon cancers. Lymph node retrieval can be difficult but is facilitated by high ligation of vasculature. Too few lymph nodes can lead to understaging and thus inappropriate adjuvant treatment. Moreover, accurate histologic assessment of lymph nodes can vary markedly based on the pathologist's technique and skill.

OPEN VERSUS LAPAROSCOPIC COLECTOMY

Open colectomies are typically performed through a midline incision with the patient supine for right colon resections and in modified lithotomy position for left colon resections. The right or left colon is mobilized off the retroperitoneum via a lateral-to-medial approach. This approach begins in an avascular plane known as the white line of Toldt (the lateral reflection of parietal peritoneum). Peritoneal attachments at the hepatic or splenic flexure are taken with electrocautery, clipping, or suture ligation with care to avoid undue traction, which can cause avulsion injuries. The transverse colon is mobilized as far as required for an adequate oncologic resection and to facilitate bowel anastomosis, and a portion of the omentum near the tumor is removed with the specimen. The vascular supply is divided and ligated at the base of the mesentery based on tumor location as previously described. A hand-sewn or stapled bowel anastomosis is performed per surgeon preference with no significant difference in complications or outcomes. For transverse colectomy, the greater omentum is removed with the specimen.

Laparoscopic colectomy offers many advantages over traditional open surgery. Postoperative pain and length of hospital stay are significantly reduced, but oncologic outcomes remain similar for localized colon cancer. Correct patient positioning is an integral part of successful laparoscopic colectomy. The patient is secured supine for right colectomies and in the modified lithotomy position with minimal hip flexion and legs in padded stirrups for left colectomies. The patient must be secured to the bed with a strap to prevent the patient from slipping because the bed is frequently repositioned to facilitate laparoscopic dissection. For right colectomy via a lateral-to-medial approach, four basic ports can be placed as follows: an umbilical camera port and three working ports in the left upper quadrant, left lower quadrant, and suprapubic midline (Figure 2, *A*). Similarly for left colectomy, a four-trocar technique can be set up as follows: an umbilical camera port and three working ports in the right upper quadrant, right lower quadrant, and suprapubic midline (Figure 2, *B*). Additional ports can be placed to optimize exposure based on surgeon preference.

Passive exposure of the colon is achieved with steep Trendelburg's positioning and rotating the table away from the anatomic location of the tumor. The small bowel and omentum are moved into the upper abdomen. The colon can be mobilized via a lateral-to-medial or medial-to-lateral approach. In the latter, the main vascular pedicles are divided first followed by complete mobilization and transection of the involved colonic segment. The colon can then exteriorized

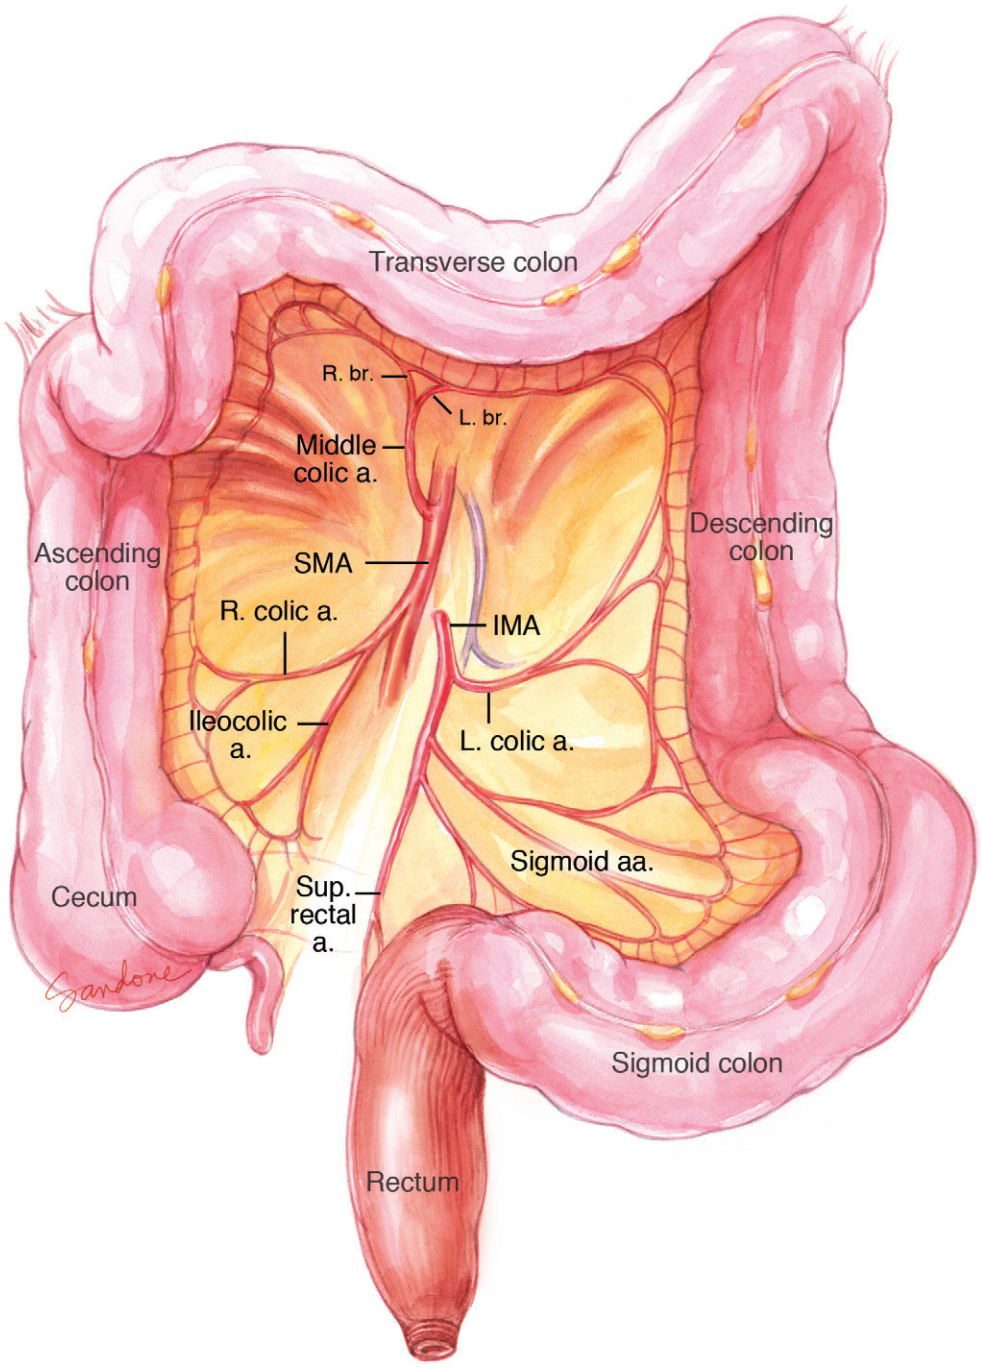

FIGURE 1 Different segments of the colon with the corresponding vascular supply. *a.,* Artery; *aa.,* arteries; *IMA,* inferior mesenteric artery; *L.,* left; *R.,* right; *R. br.,* right branch of middle colic artery; *L. br.,* left branch of middle colic artery; *SMA,* superior mesenteric artery; *Sup. through either an enlarged trocar incision or a separate incision followed by extracorporeal anastomosis. Hand-assist ports can also be used for bulky tumors or difficult patient anatomy. Hallmark anatomic complications include injury to the ureters (right and left colectomy), duodenum (right colectomy), and spleen (left colectomy). When recognized during surgery, all injuries should be repaired immediately with conversion to an open procedure as necessary. Roughly 30% of ureteral injuries involve the distal ureter, and most can be repaired with ureteroneocystostomy and stent placement. Iatrogenic splenic injury is uncommon and usually involves a capsular tear from excessive traction. Splenic salvage should be attempted with packing, topical hemostatic agents, or suture repair. If bleeding persists and is uncontrollable, splenectomy is required.

CHALLENGING AND COMPLICATED CASES

The location of the primary tumor predisposes patients to specific complications like malignant duodenocolic fistula in the setting of transverse colon cancers. If the cancer is localized, surgical management includes a right hemicolectomy and pancreaticoduodenectomy

TABLE 1: Tumor node metastasis (TNM) staging system for colorectal cancer

Note: *cTNM* is the clinical classification, and *pTNM* is the pathologic classification. The *y* prefix is used for those cancers that are classified after neoadjuvant pretreatment (e.g., ypTNM). Patients who have a complete pathologic response are ypT0N0cM0 that may be similar to stage group 0 or 1. The *r* prefix is to be used for those cancers that have recurred after a disease-free interval (rTNM).

*Dukes *B* is a composite of better (T3 N0 M0) and worse (T4 N0 M0) prognostic groups, as is Dukes *C* (and TN1 M0 and any T N2 M0). MAC is the modified Astler-Coller classification.

Primary tumor (T): *T0,* no evidence of primary tumor; *Tis,* carcinoma in situ: intraepithelial or invasion of lamina propria; *T1,* tumor invades submucosa; *T2,* tumor invades muscularis propria; *T3,* tumor invades through muscular propria into pericolorectal tissues; *T4a,* tumor penetrates to the surface of the visceral peritoneum; *T4b,* tumor directly invades or is adherent to other organs or structures.

Regional lymph nodes (N): *N0,* no regional lymph node metastasis; *N1,* metastasis in one to three regional lymph nodes; *Nla,* metastasis in one regional lymph node; *Nlb,* metastasis in two to three regional lymph nodes; *Nlc,* tumor deposit(s) in the subserosa, mesentery, or nonperitonealized pericolic or perirectal tissues without regional nodal metastasis; *N2,* metastasis in four or more regional lymph nodes; *N2a,* metastasis in four to six regional lymph nodes; *N2b,* metastasis in seven or more regional lymph nodes.

Distant metastasis (M): *M0,* no distant metastasis; *M1,* distant metastasis; *M1a,* metastasis confined to one organ or site (e.g., liver, lung, ovary, nonregional node); *M1b,* metastasis in more than one organ/site or the peritoneum.

American Joint Committee on Cancer: AJCC cancer staging manual, *ed 7, New York, 2010, Springer.*

or segmental duodenectomy (en bloc). Ascending colon cancers invading the right kidney require right hemicolectomy with en bloc partial or total nephrectomy. Malignant colovesical fistulae can occur in the setting of sigmoid colon cancers. Surgical management in this setting is often a sigmoid colectomy or Hartmann's procedure (rectosigmoid colon resection with rectal stump closure and end colostomy) with en bloc partial cystectomy, but total pelvic exenteration may be required for extensive tumors or those involving the prostate. Advanced colon cancers can also involve the ovaries. Oophorectomy is recommended during colon cancer resection if the ovaries look grossly abnormal, are invaded by the primary tumor, or have known metastases. Ovarian metastases develop in less than 15% of women with colon cancer, and prognosis is generally poor. Routine prophylactic oophorectomy is not recommended unless there are pertinent risk factors, such as a history of HNPCC or a breast cancer susceptibility (BRCA) gene mutation.

Although most colon cancer resections are elective, some patients present emergently if there is acute obstruction or perforation. Emergent surgery in this setting is associated with high morbidity and mortality. Surgical management is based on the location of the obstructing lesion. One-stage right hemicolectomy with primary anastomosis is the preferred approach for right-sided lesions. Left-sided colonic obstructions can be challenging to manage, and the optimal approach is somewhat controversial. The historically advocated three-stage approach is as follows: defunctioning colostomy (first stage), primary resection of colon tumor (second stage), and colostomy closure (third stage). Given the morbidity associated with three operations, this approach is now typically reserved for cases where neoadjuvant treatment is needed to facilitate an R0 resection. More recently, a Hartmann's procedure was the operation of choice for patients presenting with colorectal cancer (CRC) and acute obstruction, but now, surgeons favor resection with primary anastomosis with or without a diverting loop ileostomy for patients with hemodynamically stable conditions and acute presentations. Sometimes an on-table, intraoperative colonic lavage can be done to facilitate primary anastomosis in the patient with obstruction. When patients with left-sided colon cancers present with obstruction, the entire colon can be very dilated and the cecum, the area of the colon with the thinnest wall, can even perforate. In this case, a subtotal colectomy may be indicated. Colonic stents have been available since the 1990s and can be used when appropriately skilled endoscopists are available, usually for left-sided cancers. Stents are used for palliation in unresectable cases or as a temporizing measure to allow for proper staging workup so that a definitive treatment plan can be determined.

The role of surgery in metastatic colon cancer continues to evolve. Patients with liver-only metastasis should be offered surgical resection when feasible because this offers the greatest likelihood of cure. Five-year survival rates after surgical resection range from 24% to 58%, with median survival times averaging approximately 35 to 40 months. Resectability is defined as the ability to remove all macroscopic tumor tissue (R0 resection) while maintaining adequate inflow, outflow, and remnant liver parenchyma. High-quality cross-sectional CT imaging with three-dimensional volume rendering is routinely used to determine tumor resectability. When hepatic resection is not feasible, other nonextirpative treatment options include radiofrequency ablation (RFA), hepatic artery infusion (HAI) chemotherapy, transarterial chemoembolization (TACE), and transarterial brachytherapy. The integration of chemotherapy with liver surgery for the treatment of stage IV colon cancer has increased the complexity of patient treatment. Patients with initially resectable liver metastases may be given chemotherapy in the neoadjuvant or adjuvant setting with the goal of improving curability and survival by eliminating occult micrometastatic disease. Patients with initially unresectable liver disease are sometimes given neoadjuvant chemotherapy to convert metastases to resectable lesions. The timing of liver resection in patients with metastases is a controversial issue. A one-stage approach with combined colon and hepatic resection is a reasonable option for patients with low-volume liver metastases who can tolerate simultaneous procedures. Complications with the primary tumor such as perforation or bleeding take priority and delay liver resection until further workup is completed. Bilobar liver metastases or questionably resectable lesions should be managed

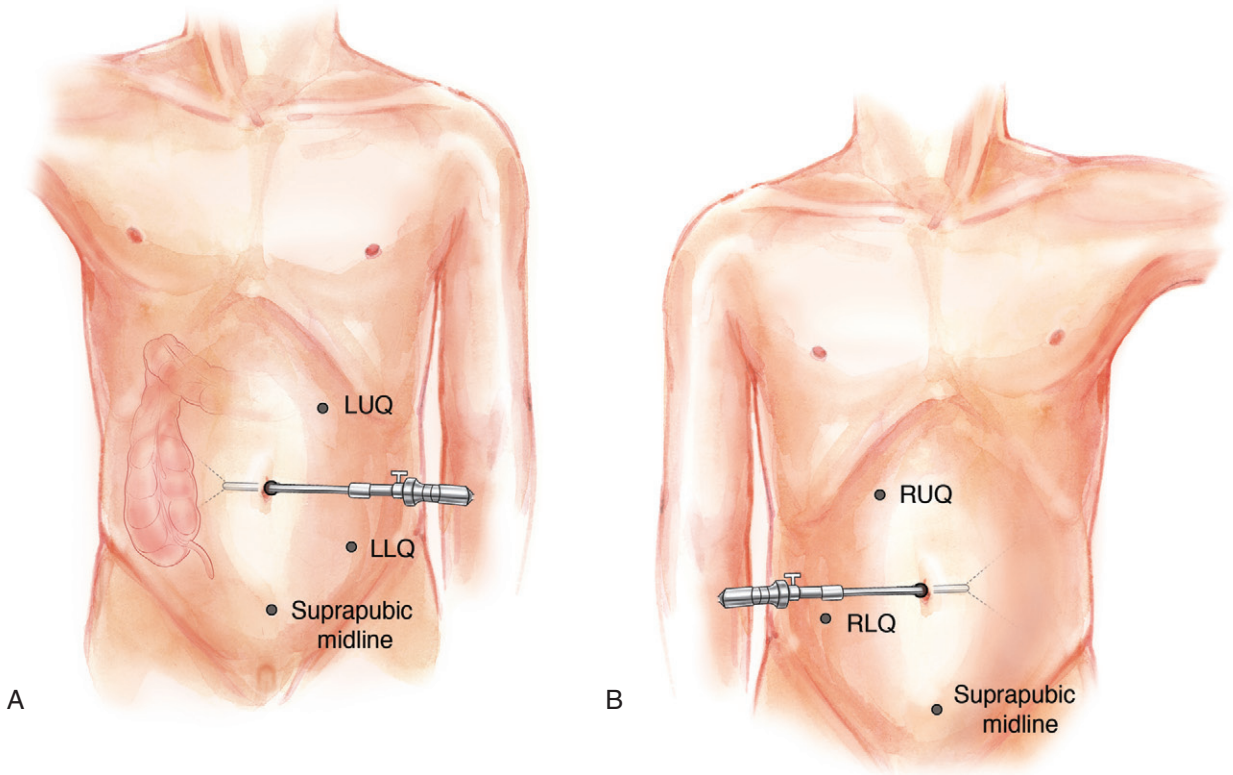

FIGURE 2 Laparoscopic port placement sites for right colectomy **(A)** and left colectomy **(B)**. *LLQ,* Left lower quadrant; *LUQ,* left upper quadrant; *RLQ,* right lower quadrant; *RUQ,* right upper quadrant. *(Illustration used with permission from Cameron JL, Sandone C:* Atlas of gastrointestinal surgery, *ed 2, vol II, 2012, Shelton, CT, PMPH-USA.)*

with delayed hepatic resection after primary tumor resection and chemotherapy.

ADJUVANT TREATMENT

Multiple options exist for systemic chemotherapy after complete resection of primary colon cancer. In contrast, postoperative radiation therapy is rarely indicated because of the risk of toxicity to the small intestine. Radiation therapy is sometimes used to irradiate the tumor bed in cases where the primary lesion invades local structures and there is an incomplete resection. Since the 1960s, 5-fluorouracil (5-FU) with leucovorin (LV) has been the cornerstone of first-line therapy for stage III colon cancer in the adjuvant setting and has been shown to decrease recurrence rates by 40%. Oxaliplatin combined with 5-FU and LV (FOLFOX) has shown even further benefit and is now standard of care for stage III disease. NCCN guidelines currently recommend 6 months of adjuvant chemotherapy. Certain stage II colon cancers are considered high risk for recurrence because of poor prognostic features like perforation, poor tumor differentiation, or histologic evidence of lymphovascular invasion. Postoperative chemotherapy should be considered in this subset of patients with stage II disease.

Increasing knowledge about the genetic diversity of colon cancers has facilitated the use of targeted adjuvant therapies in select patients. KRAS (v-Ki-ras2 Kirsten rat sarcoma viral homolog) gene molecular testing opened the era for targeted treatments. Only wild-type KRAS tumors respond to anti–epidermal growth factor receptor (EGFR) monoclonal antibodies like cetuximab. Up to 50% of colon cancers harbor a KRAS mutation, which indicates that roughly 50% of patients may benefit from this therapy. For KRAS wild-type tumors, further testing should establish BRAF (v-raf murine sarcoma viral homolog B1) gene mutation status because some data suggest that anti-EGFR agents have limited efficacy in patients with BRAF mutation.

SURVEILLANCE AND FOLLOW-UP

Intensive surveillance is important in the first 2 to 3 years after primary colon cancer resection because most patients have recurrence during this time. The goal is to identify patients with metachronous cancers or recurrent disease early so that appropriate treatment is given. Follow-up colonoscopy is recommended within 1 year of resection. If results are normal, repeat colonoscopies are generally done at 3-year intervals. Any abnormal findings mandate modification to the colonoscopy interval based on appropriate screening guidelines. A history and physical examination with a serum CEA test should be done every 4 months for the first 2 to 3 years, every 6 months for 2 years, and annually thereafter. Per NCCN guidelines, annual CT scan of the chest, abdomen, and pelvis should be considered for the first 3 years in individuals at high risk, such as patients with stage III disease or stage II disease with poor prognostic features.

The Management of Rectal Cancer

Robert E. Roses, MD, and
Miguel A. Rodriguez-Bigas, MD, FACS, FASCRS

INTRODUCTION

Colorectal cancer is the third most common malignancy and cause of cancer death in American men and women. Cancers of the rectum specifically account for approximately one third of these cases. Confinement of the rectum within the bony pelvis and proximity of more distal tumors to the anal sphincter complex make surgical therapy for rectal cancer particularly challenging. Over the last two centuries, a range of surgical approaches, including transperineal, transanal, posterior, and transabdominal, have been applied with variable success. The description of total mesorectal excision (TME) in the early 1980s as well as the emergence of more effective systemic therapies and demonstration of the advantages of preoperative radiotherapy have made a significant impact on the management of rectal cancer over the past two decades. Contemporary treatment paradigms for rectal cancer emphasize TME, sphincter preservation, and multimodality therapy. Defining the role of local excision and the identification of those patients who can forgo radiation or systemic therapy are focuses of ongoing investigations.

DIAGNOSIS

Goals of the initial assessment of the patient with a suspected rectal cancer include confirmation of the diagnosis, accurate pretreatment staging, and an evaluation of comorbidity and baseline bowel function. A complete history should establish baseline bowel function, comorbidities, and physical disability, and should elicit signs and symptoms of advanced disease (e.g., obstructive symptoms, pelvic pain, urinary symptoms, weight loss). A personal or family history of cancer should be sought as well and may alert the clinician to the possibility of a familial colorectal cancer syndrome.

The physical examination is invaluable in localizing the tumor and may alert the clinician to the presence of more advanced disease or unrecognized comorbidity. Low tumors may be appreciable on digital rectal examination (DRE), and fixation of the tumor to the sphincter complex or involvement of adjacent structures (e.g., the vagina or prostate) can often be identified. DRE also allows an assessment of sphincter tone and function. Both rigid and flexible endoscopy are valuable adjuncts to physical examination and can establish the precise location of the tumor and the degree to which the rectal lumen is obscured by the mass.

A complete blood count, basic chemistries, liver function tests, carcinoembryonic antigen (CEA) level, and staging computed tomographic (CT) scan of the chest, abdomen, and pelvis are routinely obtained. Both endorectal ultrasound (ERUS) and orthogonal axial high-resolution T2-weighted magnetic resonance imaging (MRI) can be used to assess pretreatment T and N status. Both modalities have a reported accuracy of up to 90% for both T and N staging, with N staging being slightly less accurate than T staging. MRI allows for an evaluation of involvement of the mesorectal fascia (circumferential margin) and adjacent organs. Figures 1 and 2 illustrate lymphadenopathy in and outside the mesorectum, respectively. The choice of EUS or MRI depends on institution-specific expertise and availability. Positron emission tomography (PET)/CT scan is not used for staging primary rectal cancer. A complete colonoscopy, when feasible, should be performed before the initiation of treatment to exclude the presence of additional colorectal pathology. If complete colonoscopy is not possible (e.g., obstructing tumor), CT colonography can be considered.

TREATMENT APPROACH BY STAGE

Staging based upon a clinical assessment and preoperative imaging forms the basis for the initial treatment strategy (Figure 3). Definitive pathologic staging is only possible after surgical resection. Currently, the TNM classification is preferred (Table 1).

Localized Disease

Radical surgery is the mainstay in the treatment of early-stage (stage I) rectal cancer. The role of local excision continues to evolve. In general, tumors smaller than 4 cm, occupying less than 40% of the circumference of the lumen, and without evidence of lymphadenopathy are amenable to local excision (Box 1). In our experience, transanal excision should only be attempted when the proximal extent of the tumor is palpable on DRE. It also bears emphasis that tumors involving the sphincter complex are no more appropriately removed via a transanal approach than they are with sphincter-sparing proctectomy. Transanal endoscopic microsurgery (TEM) is broadening the indications for local excision, because this approach allows for safer excision of higher lesions and, perhaps, more consistent negative margin excision. Even when strict selection criteria for local excision are utilized, there is a significant local recurrence rate (upwards of 10% for T1 tumors in most series with long-term follow-up). In the Cancer and Leukemia Group B (CALGB) 8984 prospective registration study, at a median follow-up of 7.1 years, rates of local recurrence and distant metastasis after local excision alone for T1 tumors were 8% and 5%, respectively. The 10-year overall survival and disease-free survival rates were 84% with 75%, respectively.

Importantly, local excision does not allow an adequate surgical assessment of lymph node status. Pathologic features associated with a higher rate of nodal positivity include poor differentiation, lymphovascular invasion, and mucin production. These findings should prompt consideration of complete surgical extirpation of the rectum and mesorectum. Additionally, the depth of invasion of the

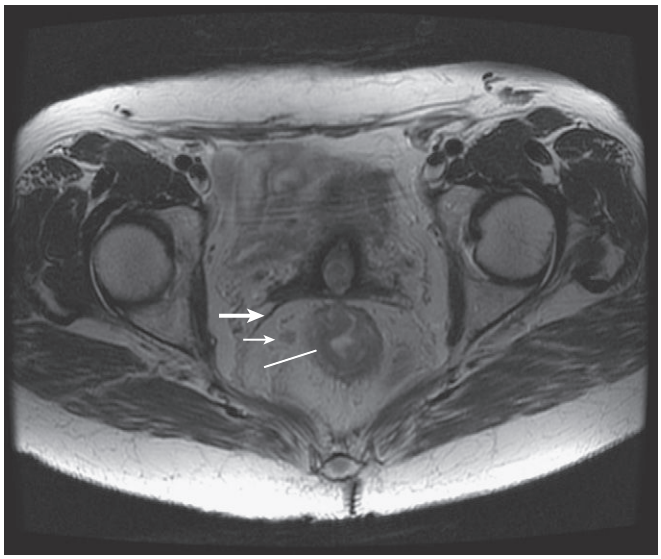

FIGURE 1 Primary rectal tumor with mesorectal lymphadenopathy. *Line,* primary rectal tumor; *large arrow,* mesorectal fascia; *small arrow,* mesorectal lymph node.

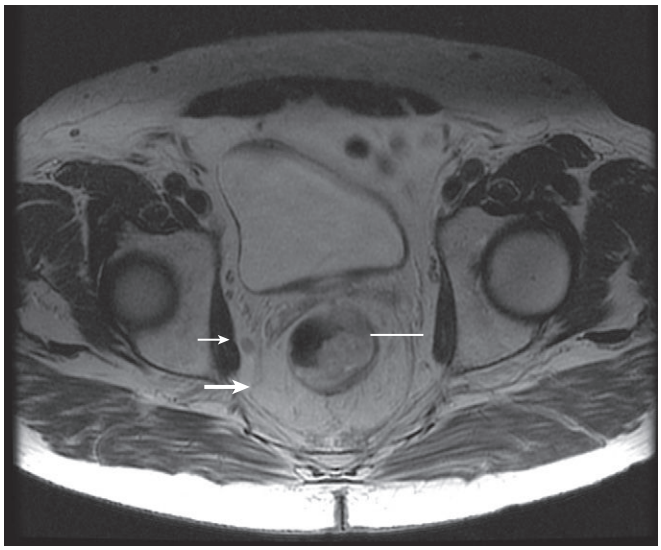

FIGURE 2 MRI with lymphadenopathy outside the mesorectum. *Line,* primary rectal tumor; *large arrow,* mesorectal fascia; *small arrow,* lymph node outside mesorectal fascia.

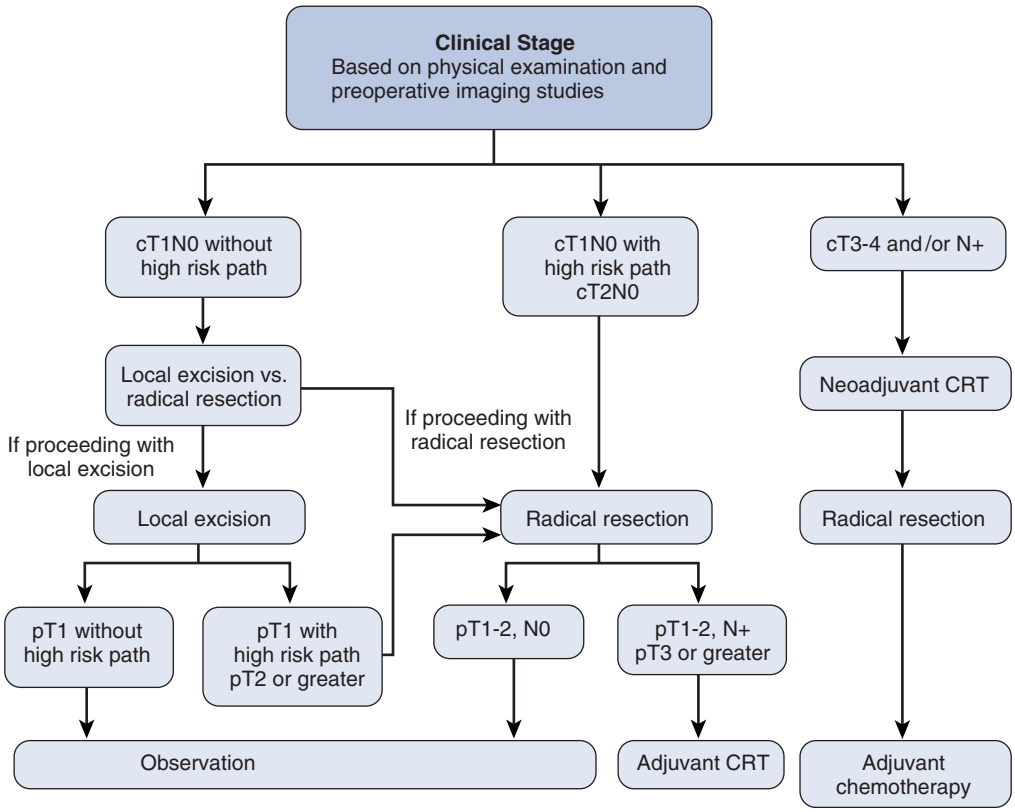

FIGURE 3 Treatment algorithm based on clinical stage of disease for patients with rectal cancer and no evidence of distant metastasis. *C,* clinical stage; *P,* pathologic stage. *High-risk path* refers to (1) poor differentiation, (2) the presence of lymphovascular or perineural invasion, or (3) deep submucosal invasion (sm2 or sm3). Note: Local excision can be considered in patients who have a significant medical contraindication to major abdominal surgery or who make the informed decision to avoid the short-term morbidity, functional consequences, and possible stoma associated with radical surgery with full knowledge that local excision is associated with a significantly higher recurrence rate and may compromise their chances of cure.

*This includes cancer cells confined within the glandular basement membrane (intraepithelial) or mucosal lamina propria (intramucosal) with no extension through the muscularis mucosae into the submucosa.

[†]Direct invasion in T4 includes invasion of other organs or other segments of the colorectum as a result of the direct extension through the serosa, as confirmed on microscopic examination (for example, invasion of the sigmoid colon by a carcinoma of the cecum) or, for cancers in a retroperitoneal or subperitoneal location, direct invasion of other organs or structures by virtue of extension beyond the muscularis propria (i.e., respectively, a tumor on the posterior wall of the descending colon invading the left kidney or lateral abdominal wall; or a mid or distal rectal cancer with invasion of prostate, seminal vesicles, cervix, or vagina).

[‡]Tumor that is adherent to other organs or structures, grossly, is classified cT4b. However, if no tumor is present in the adhesion, microscopically, the classification should be pT1-4a depending on the anatomical depth of wall invasion. The V and L classifications should be used to identify the presence or absence of vascular or lymphatic invasion whereas the PN site-specific factor should be used for perineural invasion.

[§]Dukes B is a composite of better (T3 N0 M0) and worse (T4 N0 M0) prognostic groups, as is Dukes C (Any TN1 M0 and Any T N2 M0). MAC is the modified Astler-Coller classification.

Note: cTNM is the clinical classification, pTNM is the pathologic classification. The y prefix is used for those cancers that are classified after neoadjuvant pretreatment (e.g., ypTNM). Patients who have a complete pathologic response are ypT0N0cM0 that may be similar to Stage Group 0 or I. The r prefix is to be used for those cancers that have recurred after a disease-free interval (rTNM).

BOX 1: Criteria for local excision of rectal cancers

Tumor Location and Size
<4 cm and <40% of the circumference of the rectum
<8 cm from the anal verge

Clinical Features
Mobile, nonfixed
T1/N0 or T2/N0* on pretreatment imaging

Histologic Features
Well to moderately differentiated
No lymphovascular or perineural invasion
No mucinous component
T1 or T2 on final histologic examination

*Adjuvant chemoradiation should be administered to patients with T2 lesions (the results of ACOSOG Z6041, which evaluated the role of neoadjuvant chemoradiation followed by local excision, are not yet available).

submucosa has been correlated with the potential for lymph node involvement. Invasion of the upper, middle, and lower thirds of the submucosa have been reported to be associated with a 3%, 8%, and 23% risk of lymph node metastases in T1 lesions, respectively.

Although an increasing utilization of local excision has been reported, local excision alone of T2 tumors is associated with an unacceptably high rate of recurrence (upwards of 20% and as high as 47%) and should only be considered in patients at prohibitive risk for laparotomy. Adjuvant and neoadjuvant chemoradiation have been utilized in addition to local excision for T2 tumors. These approaches have been justified by prospective registration data. In the CALGB 8984 study, the rates of local recurrence and distant metastasis after local excision of T2 tumors followed by chemoradiation were 18% and 12%, respectively. The 10-year overall survival for patients with T2 tumors was reported to be 66%, with a disease-free survival rate of 64%. The use of neoadjuvant chemoradiation for T2 tumors followed by local excision has been evaluated in another prospective multicenter registration study (ACOSOG Z-6041). In this study, 44% of patients with T2 tumors achieved a complete pathologic response after neoadjuvant therapy. Local recurrence rate and overall survival have not yet been reported.

Consideration of these approaches must weigh the risks of local and distant failure against the benefits of avoiding a laparotomy and the risks of TME. Moreover, clinicians must recognize that failure after local excision is frequently unsalvageable. When feasible, salvage often requires multimodality treatment, including multivisceral resection, pelvic irradiation, and chemotherapy, and is associated with potentially lasting treatment-related morbidities and only modest long-term success. Indeed, in an analysis from our institution, the 5-year overall and disease-free survival rates were 59% and 35%, respectively, after salvage for failure after local excision; this is concerning given that most of these patients had relatively favorable disease at the time of initial local excision.

Total mesorectal excision remains the primary treatment for most rectal cancers, including early-stage lesions. When appropriate, every effort is made to preserve sphincter function and reestablish intestinal continuity. For proximal rectal lesions, selective mesorectal excision (at least a 5-cm mesorectal margin) is recommended. For low- and midrectal cancers, TME and a mucosal margin of at least 2 cm is preferred. Lesser mucosal margins may be associated with acceptable outcomes as well and are often necessary if intestinal continuity is to be restored during resection of more distal tumors. If the distal location of the tumor allows resection with a clear margin without violation of the sphincter complex but precludes a stapled anastomosis, a hand-sewn coloanal anastomosis can be performed, albeit with poorer anticipated functional outcomes. Abutment or involvement of the sphincter complex mandates abdominoperineal resection and permanent colostomy.

Locally Advanced Disease

Patients with T3 or T4 tumors or nodal disease are treated with neoadjuvant 5-fluorouracil or capecitabine-based chemoradiation.

This approach is supported by data from randomized control trials that established improved local control with surgery after neoadjuvant radiotherapy compared to surgery alone (Swedish Rectal Cancer Trial and Dutch Colorectal Cancer Group Trial) and with preoperative versus postoperative chemoradiotherapy (German Rectal Cancer Study Group Trial CAO/ARO/AIO-04). To date, only the Swedish trial has demonstrated a survival benefit with preoperative radiotherapy. Both the Swedish and Dutch trials utilized short-course radiation (25 Gy in five fractions over a week), followed shortly thereafter by surgery, whereas the German trial and most long-course chemoradiation trials utilized 50.4 Gy in 28 fractions, followed by a break of 6 to 8 weeks prior to surgery. In the German Trial, at a median follow-up of 134 months, the cumulative incidence of local recurrence was 7.1% in the preoperative treatment group and 10.1% in the postoperative treatment group ($P = 0.048$). There was no difference in the incidence of distant metastases (29.8% vs 29.6%) or overall survival (59.6% vs 59.9%) between groups. Our preferred approach to the management of stage 2 or 3 rectal cancer includes 45 Gy of preoperative radiation delivered in 25 fractions with a boost to the tumor bed of 5.4 Gy in three fractions with concomitant infusional 5-FU or capecitabine. Surgical resection is performed 6 to 8 weeks after the completion of chemoradiotherapy.

A more nuanced approach to the use of preoperative radiation therapy may emerge in the near future. A pooled analysis of prospective adjuvant combined modality trials in rectal cancer in the United States and a more recent report from the Mercury Study Group in Europe suggest that some patients with stage II or III rectal cancer may not need radiation therapy. This hypothesis will be tested in the forthcoming Preoperative Radiation and Evaluation before Chemotherapy and TME (PROSPECT trial sponsored by the Alliance for Clinical Trials in Oncology Foundation). In this study, patients will be randomized to a "Standard Arm" or "Selective Arm." In the latter, preoperative radiation will be omitted in patients with a good response to preoperative chemotherapy.

As with earlier-stage rectal cancers, the cornerstones of surgical therapy are total mesorectal excision and sphincter preservation, when possible. The latter is feasible for the majority of patients, including many with low T3 tumors. Indeed, in a review of our own experience, low anterior resection was possible in 44% of patients with pretreatment T3 tumors within 3 cm of the anal verge following neoadjuvant chemoradiation with a local control rate of 90%. Adjuvant chemotherapy is generally given to patients with stage 2 or 3 disease in accordance with recommendations from the National Comprehensive Cancer Network (NCCN), though randomized data supporting this practice in rectal cancer specifically are lacking. In our experience of 725 cT3-T4 N0-N+ patients treated with neoadjuvant chemoradiation followed by radical surgery, at a median of 65 months, 18.3% developed distant metastases.

The safety of a nonoperative approach in patients who have a good response to neoadjuvant chemotherapy has also been explored in the recent literature. The rate of complete pathologic response following neoadjuvant long-course chemoradiation is reported to be around 17%. A study from Brazil and a recent small trial from the Netherlands both suggest that patients with a *complete clinical response* who are followed very closely do well with low rates of local and distant recurrence. However, in our experience, the applicability of this approach is limited by the inability to reliably identify those patients who have had a *complete pathologic response*.

Disseminated Disease

Patients with metastatic disease represent a highly heterogeneous group. Long-term survival and even clinical cure are possible in patients with limited disease amenable to surgical resection. More challenging still are those patients who present with multiple foci of distant metastatic disease. In this group, systemic therapy is the cornerstone of treatment, and prolonged survival can be achieved in a subset of patients treated with contemporary chemotherapy regimens. The management of these patients must be multidisciplinary, and in the patient with a symptomatic primary tumor, consideration should be given to diversion or endoscopic stenting prior to initiation of chemotherapy. In our experience, the latter is of limited utility for all but the highest rectal cancers. Stenting of lower lesions is too frequently associated with complications of pain, stent migration, and poor sphincter control, and the creation of a colostomy is usually preferable.

The role of resection of the primary tumor in the setting of stage IV disease remains controversial. Advocates for a more aggressive approach cite the risk of bleeding and perforation in patients receiving systemic therapy. Opponents of a more aggressive surgical approach invoke the risks of delaying systemic therapy. The absolute risk of complications requiring surgical intervention in this cohort has been evaluated in the multiinstitutional prospective National Surgical Adjuvant Breast and Bowel Program (NSABP) Trial C-10. In this study of asymptomatic stage IV patients with intact primary tumors, the rate of major morbidity was 16%, with 11% of patients requiring surgery during treatment with systemic therapy. There were two deaths related to the primary tumor. In other retrospective studies, the rate of primary tumor-related complications in patients treated with systemic therapy has been similar. Features that reliably identify patients who will require, or benefit from, more aggressive surgery remain elusive, and treatment decisions must be individualized.

SURGICAL THERAPY

Transanal Excision

Optimal exposure is mandatory to perform an adequate transanal excision. The patient can be placed in either lithotomy position or in the prone jackknife position. Anterior tumors are sometimes more easily accessed with the patient in prone jackknife position. A self-retaining retractor is placed to efface the anus. Local anesthetic is injected circumferentially in the intersphincteric plane to relax the sphincter. A combination of bivalve and deep curved handheld retractors are then used to expose the lesion.

A traction suture is placed, optimally 2 or more centimeters above the lesion, which aids in drawing the tumor forward into the operating field. The margins of resection are then marked with the electrocautery. A full thickness excision down to the level of the perirectal fat is performed. The defect is usually closed with absorbable sutures, though this is not mandatory. Care must be taken to ensure that the rectal lumen is not compromised during this closure, and if there is any concern for this, proctoscopy should be performed.

Total Mesorectal Excision

The goals of radical surgery for rectal cancer should include (1) resection of the tumor with an adequate distal and circumferential margin, (2) resection of sufficient regional nodal tissue to allow for accurate postoperative staging and good local control, and (3) autonomic nerve preservation. Notions regarding the adequacy of a distal margin continue to evolve. In particular, the implications of a less than 2 cm distal mucosal margin after neoadjuvant chemoradiotherapy are uncertain, although retrospective literature suggests that a negative margin of less than 1 cm is adequate for local control after neoadjuvant chemoradiation and TME in patients undergoing sphincter-preserving surgery (coloanal anastomosis). It appears that in this situation, margin extent likely has less of an impact on outcome than was the case in the preneoadjuvant therapy era. We aim for at least a 2 cm distal mucosal margin unless sphincter preservation requires less. With regards to the radial margin, en bloc resection of adjacent structures (e.g., vagina, bladder, ureter) is justified in appropriately selected patients if R0 resection can be achieved. It cannot be overemphasized that sharp dissection is a must in TME; there is no role for blunt dissection. When the tumor is adherent to other organs, en bloc resection should be performed because local

recurrence and survival are compromised if tumor adhesions are violated.

In preparation for TME, the patient is placed in the supine position, with lower extremities in stirrups. The buttocks are positioned so that they extend beyond the edge of the operating table, and a cushion is placed beneath the sacrum to elevate the coccyx. Systemic antibiotics with a sufficiently broad spectrum of activity to cover enteric and skin flora and 5000 units of subcutaneous heparin are administered. In the reoperative setting or in the presence of bulky tumors or inflammatory change in the pelvis, the placement of ureteral stents under cystoscopic guidance aids in the more ready intraoperative identification of the ureters.

A laparotomy incision is made down to the level of the pubic bone. Superiorly, the incision is extended above the umbilicus to a level that allows safe mobilization of the splenic flexure. A thorough exploration of the abdomen is undertaken to exclude the presence of metastatic disease and should include visualization or palpation of the liver and lesser sac and entire small bowel. The sigmoid colon and descending colon are mobilized from the retroperitoneum along the white line of Toldt. The left ureter is identified coursing through the retroperitoneum just lateral to the mesorectum in the intersigmoid fossa and is protected. Full mobilization of the rectosigmoid is achieved by dividing the peritoneum along the right side of the mesorectum. The right ureter is identified as it courses over the right iliac vessels and is protected. The superior rectal artery, the terminal branch of the inferior mesenteric artery, is then identified as it courses inferiorly through the mesocolon and is ligated. The rectosigmoid junction is divided with a linear stapler, and the intervening mesorectum between the divided bowel wall and divided superior rectal artery is transected.

The rectum is retracted anteriorly, and the plane between the fascia propria of the mesorectum and the pelvic fascia is developed sharply. The hypogastric nerves are identified where they descend over the sacral promontory and are preserved. Dissection is carried down to the pelvic floor. Care is taken to avoid injury to the presacral veins during posterior dissection. The correct posterior plane then guides the surgeon to the lateral plane. The nervi erigentes are identified along the pelvic sidewall and are preserved. The middle rectal arteries, if encountered, can usually be cauterized, particularly in the irradiated patient, but they are ligated if troublesome bleeding is encountered. The lateral dissection continues to the level of the levator muscles. Anteriorly, the peritoneum overlying the cul-de-sac is incised. Dissection is continued by sharply dividing the rectovaginal septum or the rectovesical septum under Denonvillier's fascia. In this manner a bloodless anterior plane between the rectum and the vagina or bladder (and prostate in males) is developed and carried down to the levator ani muscles.

Reconstruction

If sphincter preservation is to be attempted, the splenic flexure is mobilized. Undue downward traction on the transverse colon and the omentum are avoided to minimize the risk of splenic injury. If the proximal colon does not readily reach the distal rectal stump, maneuvers to provide greater length include division of the inferior mesenteric artery at its origin (if it has not been previously divided) and division of the inferior mesenteric vein. Provided there is good perfusion through the Arc of Riolan, these maneuvers generally allow for a healthy and tension-free anastomosis. After creation of the anastomosis, the pelvis is filled with saline. The colon above the anastomosis is occluded, and air is insufflated into the distal rectum to confirm the integrity of the staple line.

When the laxity of the proximal colon is sufficient and the pelvis is wide enough, we prefer reconstruction with a colonic J pouch after resection of lower tumors (anastomosis <8 cm from the dentate line). While data from five randomized trials comparing colonic J pouch and straight anastomoses have not conclusively demonstrated improved functional outcomes, a subset of patients likely benefit, particularly in the first 18 months after surgery. In patients who have undergone preoperative radiation therapy and those with tumors below the peritoneal reflection, we perform a diverting ileostomy.

Abdominoperineal Resection

Lower tumors involving the sphincter complex require abdominoperineal resection. The transabdominal portion of the operation is identical to that described above, excluding the formation of an anastomosis. Additionally, mobilization of the splenic flexure is usually unnecessary prior to creation of a descending colostomy.

Perineal Dissection and Closure

An elliptical skin incision extending from the perineal body to the coccyx that is wide enough to encompass the anal sphincter complex is used. The superficial fascia between the subcutaneous tissue and the ischiorectal fat is divided bilaterally. The coccyx is palpated, and dissection proceeds until the tip of the coccyx is exposed. On the ventral aspect, the anococcygeal ligament is divided, releasing the attachments of the superficial external sphincter muscle. Further dissection in this plane exposes the Waldeyer fascia, which, if it has not been divided from above, is divided transversely, allowing access to the presacral plane of dissection. Blunt dissection without division of the Waldeyer fascia should be avoided because it can result in bleeding from the presacral venous plexus. The anal canal and rectum are retracted anteriorly, and dissection proceeds to the level of the ventral curve of the sacrum, with guidance from the abdominal operator.

Having freed the rectum posteriorly, attention is directed laterally. The ischiorectal adipose tissue is divided on both sides, close to the lateral pelvic walls. As the levator ani are approached, branches of the inferior hemorrhoidal vessels are encountered and divided. The levator ani are divided circumferentially, with the ischial tuberosities defining the lateral extent of the dissection. The rectosigmoid can often be delivered through the perineal defect at this point to facilitate the remaining anterior dissection. The anterior subcutaneous tissues and decussating fibers of the external sphincter are divided, allowing identification of the superficial transverse perineal muscle. Care must be taken to avoid injury to the membranous urethra. The dissection is performed in the plane dorsal to the bulbocavernosus muscle. In males, this is the most difficult portion of the perineal dissection because the anorectum is closely apposed to the membranous urethra, prostate, and seminal vesicles. Intermittent palpation of the urinary catheter assists in keeping the dissection along a safe plane.

Closure of the perineal wound requires particular attention to detail because wound complication rates exceed 30% in multiple series. It bears emphasis that the levator ani muscles cannot be approximated if the proper dissection has been performed. Presacral drainage is accomplished with closed suction catheters brought out through stab wounds to one side of the perineal closure. The subcutaneous tissues and skin are approximated with interrupted sutures in multiple layers. In patients at higher risk for wound failure (e.g., prior irradiation, obesity, diabetes mellitus), closure with a muscle or myocutaneous flap may be justified.

Laparoscopic and Robotic Proctectomy

An increasing body of literature suggests oncologic equivalency of laparoscopic and open proctectomy for rectal cancer. Data demonstrating clear advantages of the laparoscopic approach, however, are lacking. The Conventional versus Laparoscopic Assisted Surgery in Colorectal Cancer (CLASICC) trial from the United Kingdom randomized 794 patients with colorectal cancer (381 of whom had rectal cancer) to laparoscopic assisted or open resection. No differences in 3-year local control or disease-free or overall survival were seen. The outcomes of the Colorectal Cancer Laparoscopic or Open Resection (COLOR II) and ACOSOC Z6051 trials (now sponsored by the Alliance for Clinical Trials in Oncology Foundation) are eagerly awaited. Robotic-assisted approaches are also gaining popularity. Theoretical

advantages include the improved visualization and technical control afforded by the robotic instrumentation. Disadvantages include longer operating times and increased cost. Greater experience may allow for the identification of patients who benefit most from these approaches.

Tumors of the Anal Canal

Marco Ettore Allaix, MD, Nora Eve Joseph, MD, and Alessandro Fichera, MD, FACS, FASCRS

GENERAL CONSIDERATIONS

The surgical anal canal extends from the level of the pelvic floor (the anorectal ring or the junction of the puborectalis portion of the levator ani muscle with the external anal sphincter) to the proximal margin of the anal verge. Thus defined, the anal canal corresponds to the extent of the sphincter complex and is approximately 4.0 cm in length. At midpoint is the dentate line, which is defined macroscopically by the anal valves and bases of the anal columns. Microscopically, the anal canal is divided into three zones based on characteristic histologic features. The upper zone lies proximal to the dentate line and is lined by colorectal type glandular mucosa. Extending distally from the dentate line is the mid or anal transition zone (ATZ) defined by a specialized or transitional type epithelium. The third and most distal zone is comprised mostly of non-keratinized and occasionally keratinized squamous mucosa (Figure 1).

The ATZ has been intensively studied for its role in continence and as a potential site for neoplastic degeneration after stapled ileoanal anastomosis in patients with ulcerative colitis. In the literature, this epithelium has been variously classified as transitional, intermediate, or cloacogenic. The ATZ epithelium may also contain mucin-producing cells, endocrine cells, and melanocytes.

The arterial blood supply of the anal canal derives from the superior, middle, and inferior rectal arteries, whose terminal branches reach the anal submucosa. Three main arterial trunks in the right anterior, right posterior, and left lateral positions can be isolated below the dentate line. They originate primarily from the superior rectal artery. The middle rectal veins drain the upper anal canal into the systemic system via the internal iliac veins. The inferior rectal veins drain the lower anal canal, communicating with the pudendal veins and draining into the internal iliac veins.

Lymphatic drainage of the anal canal varies based on the level: below the dentate line drainage is to the inguinal lymph nodes; above, lymphatic drainage goes to the mesorectal, lateral pelvic, and inferior mesenteric nodes.

With focus primarily on anal neoplasms, presenting symptoms are often nonspecific and may include pain, bleeding, discharge, pruritus, and ulceration. Frequently, anal tumors are completely asymptomatic and are diagnosed only incidentally, or because of palpable inguinal lymph nodes.

The macroscopic appearance of an anal lesion may be nonspecific also: it may be flat or raised, and the surface may be verrucous, erythematous, or scaly. An ulcerated mass is usually very suspicious of malignant degeneration.

Diagnosis of anal neoplasm requires a high index of suspicion, particularly in patients with known risk factors who present with new symptoms. For a definitive diagnosis, a biopsy of the suspicious area is often indicated, unless the patient has severe immunocompromise.

Imaging is used for cancer staging. Magnetic resonance imaging of the pelvis and endoanal ultrasound scan define tumor size and invasion and the involvement of local lymph nodes. Distant metastatic spread can be assessed with computed tomographic scan of the chest, abdomen, and pelvis.

The various elements of the anal canal account for the different neoplasms that are described: (1) squamous cell tumors, including condyloma acuminatum, flat squamous dysplasia, Bowen's disease, and invasive squamous cell carcinoma and its variants; (2) adenocarcinoma and its variants, including rectal-type adenocarcinoma, the so-called anal gland adenocarcinoma, fistula-related mucinous adenocarcinoma, and intraepithelial adenocarcinoma (i.e., Paget's disease); (3) neuroendocrine neoplasms, including carcinoid tumor, small cell carcinoma, and non–small cell high-grade neuroendocrine carcinoma; (4) malignant melanoma; (5) mesenchymal tumors; and (6) malignant lymphoma. Although these anal canal tumors as a group account for only about 1.5% of all gastrointestinal neoplasms, their diagnosis and management can be challenging for pathologists and clinicians alike.

SQUAMOUS NEOPLASMS

Condyloma Acuminatum (Anal Wart)

Condyloma acuminatum, or anal wart, is caused by human papilloma virus (HPV). HPV is the most common sexually transmitted infection. Its incidence rate has increased over the past 30 years. In the United States, the prevalence rate of anogenital HPV is estimated to be 15%, equal to 24 million individuals. In addition, 500,000 to 1 million new cases of genital warts are believed to occur annually, resulting in 600,000 healthcare provider visits per year. Currently, more than 100 different HPV types have been sequenced and officially classified, about one third of which have been found to infect the anogenital epithelium.

Although the natural history and the potential for progression to squamous dysplasia and squamous cell carcinoma still needs to be completely elucidated, condyloma acuminatum (anal wart) is generally regarded as a premalignant lesion. The incidence rate of squamous cell carcinoma of the anus in patients with anal condyloma has been reported to be up to 4%. The key histologic features of condyloma acuminatum are a verrucous architecture composed of papillary excrescences and hyperkeratosis as well as the presence of koilocytic changes within a maturing squamous epithelium. Koilocytes are epithelial cells displaying characteristic changes secondary to HPV infection: vacuolated cytoplasm, wrinkled, hyperchromatic nuclei and perinuclear halos. Binucleated and trinucleated epithelial cells are also often present (Figure 2). Koilocytic changes may be absent, however, when the viral infection subsides.

Although many anal condylomata, particularly those of perianal skin, are caused by low-risk HPV (types 6 or 11) and should therefore be regarded as low risk for progression, those lesions in the anal canal are often associated with high-risk HPV (such as 16) and are more likely to progress to an invasive cancer. This is particularly true in patients with immunocompromise.

Several different medical and surgical approaches have been proposed for the treatment of anal condylomata with limited clinical data to support. No consensus has been reached on a gold standard, and whether treatment eliminates infectivity is not even clear, given the fact that both topical and surgical treatments are only aimed at eradication of the visible lesions. Topical treatments include podophyllotoxin, imiquimod cream, and trichloroacetic acid. Invasive therapies include cryotherapy, argon plasma beam treatment, and surgical excision/fulguration. Repeated sessions are needed with cryotherapy that is mainly indicated for small lesions. Surgical excision/fulguration and argon plasma beam treatment are highly effective in the short term. It is mandatory to submit several samples to the pathologists for definitive diagnosis of these lesions that may harbor an invasive component. Skin bridges must be left intact

between wounds to minimize scarring and to avoid anal stenosis (Figure 3).

The many topical treatments have very limited efficacy in the presence of large lesions and are associated with significant side effects. They should be considered only in addition to surgical eradications or in patients with compromised conditions that would not tolerate surgery. Podophyllin has potential oncogenic and teratogenic effects and should not be applied on the cervix and in the anal canal or used during pregnancy. Marrow suppression, hepatic dysfunction, neurologic effects, hallucinations, psychosis, nausea, vomiting, diarrhea, abdominal pain, and genital burns have been rarely described. Trichloroacetic acid may cause an intense burning sensation and ulceration to the dermis and is therefore not recommended for large warts. 5-Fluorouracil has limited use because of its severe local effect and teratogenicity. Conflicting results have been reported with interferon, which is an expensive drug with significant systemic side effects. Imiquimod is not recommended during pregnancy or for internal use. Mild to severe erythema may occur; other side effects include localized erosions, an impetigo-like reaction, and an itching or burning sensation.

Overall recurrence rates between 20% and 50% have been reported irrespective of the treatment approach. Still unclear is whether disease recurrence is the result of recrudescence, reinfection, or other factors such as individual immune response or inadequate treatment. The presence of genital HPV types in plucked pubic and perianal hair suggests that an endogenous reservoir for HPV may play a role in recurrence. Thus, if only the visible lesions are destroyed, latent HPV likely remains in the surrounding tissue. The lack of antiviral activity of most recommended topical therapies supports this hypothesis.

The immune system appears to play a major role in regression of genital HPV disease. In patients with spontaneous regression, significant differences are present in the epidermal and dermal concentration of CD4+ activated memory lymphocytes compared with those without regression. Although there is an association of serum antibodies to HPV proteins with HPV-related diseases, their role is uncertain because their presence does not correlate with wart regression. Evidence suggests that T cells in male and the female genital epithelium secrete protective antibodies against many HPV infections, but the significance of this is unclear. Anal condylomata in patients with immunosuppressed conditions treated with surgery has a higher recurrence rate and recurrence at a faster pace than in patients with a competent immune system. In patients with human immunodeficiency virus (HIV)-seropositive conditions, CD4 counts should be maximized to prevent early recurrence.

Many pharmacologic topical treatments have been proposed to reduce recurrence after surgical treatment. Imiquimod and interferon are the only drugs that exhibit antiviral activity. Both have shown lower recurrence rates compared with other therapies. In particular, adjuvant interferon treatment can reduce recurrence after surgical excision and is more effective in patients with condylomata present for more than 6 months and in the presence of HPV subtype 6 or 11. Further evidence shows that, particularly in patients with immunocompromise, immunostimulation may lead to a reduction in the size of lesions and in recurrence after surgery.

First described by Buschke in 1886, and later by Buschke and Lowenstein in 1925, the "giant condyloma of Buschke and Lowenstein" (or verrucous carcinoma) is a rare form of condyloma that refers to a slow-growing neoplasm that has a tendency to recur and to form abscesses and fistulae. It is an intermediate form between condyloma acuminatum and squamous cell carcinoma. This tumor does not appear to arise from malignant transformation of a condyloma but represents a low-grade form of squamous cell carcinoma. Like conventional condylomata, these lesions are more likely to be associated with low-risk HPV. The histologic appearance on a biopsy specimen may be identical to that seen in common condyloma acuminatum (surface hyperkeratosis, prominent acanthosis and papillomatosis, with orderly arrangement of the epithelial layers). However, excision specimens often demonstrate an endophytic component that is not present in ordinary condylomata. The biology of such lesions is typically that of local invasion without metastasis. The treatment consists of complete wide local excision often requiring

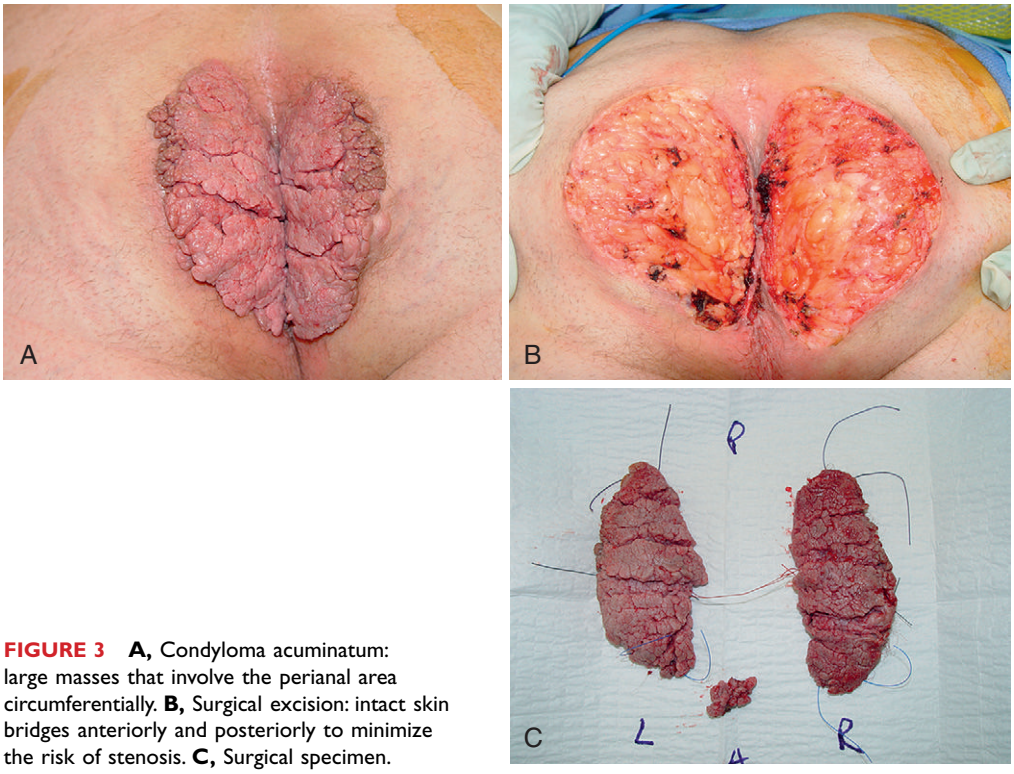

FIGURE 3 **A,** Condyloma acuminatum: large masses that involve the perianal area circumferentially. **B,** Surgical excision: intact skin bridges anteriorly and posteriorly to minimize the risk of stenosis. **C,** Surgical specimen.

flap closure. An abdominoperineal resection is required in case of deep tissue involvement (Figure 4). The role of chemoradiotherapy is still unclear and seldom indicated.

Anal Intraepithelial Neoplasia

Anal intraepithelial neoplasia (AIN) is often a precursor to invasive squamous anal carcinoma. The disease process may involve both the perianal skin and the anal canal, including the anal transition zone, but anal canal lesions without evidence of perianal involvement are very unusual. It is a multifocal disease process strongly associated with human papillomavirus (usually HPV types 6, 11, 16, and 18). Strong etiologic and clinical similarities are seen between AIN and cervical (CIN) and vulvar (VIN) intraepithelial neoplasia.

AIN is characterized by cellular and nuclear abnormalities within squamous epithelial cells limited to the basement membrane. Histologic features include nuclear atypia such as pleomorphism, enlargement and hyperchromasia as well as increased mitotic activity above an expanded basal layer. The extent of basal layer expansion, or loss of maturing epithelium, is the basis for grading dysplasia in tissue biopsies of anal lesions. AIN I refers to nuclear abnormalities confined to the lower one third of the epithelium and is considered a low-grade dysplastic lesion. AIN II and III are high grade lesions with AIN II limited to the lower two thirds and AIN III involving the full-thickness of the epithelium, or carcinoma in situ (Figure 5). In anal cytology the Bethesda grading system categories dysplastic lesions as low-grade squamous intraepithelial lesions (LSIL) and high-grade intraepithelial lesions (HSIL). LSIL is equivalent to AIN I seen in a tissue biopsy and HSIL encompasses AIN II and III.

The exact prevalence rate of AIN in the general population is unknown, but it is thought to be less than 1%. Identified risk factors for AIN include HPV infection, anal warts, multiple sexual partners, men who have sex with men, anal receptive intercourse, cervical dysplasia or cancer, smoking, and immunosuppression (such as in transplant and HIV).

Although AIN I and II have been known to have the potential to regress, AIN III very rarely regresses. The risk of progression of AIN to invasive anal cancer approximates 10% at 5 years in patients with immunocompetent conditions and up to 50% in patients with immunosuppressed conditions. Those at the highest risk of invasive cancer are those with multifocal disease or immunocompromise.

A high index of suspicion is required for diagnosis of AIN. Around 10% of AIN lesions are diagnosed as an incidental finding after excision of an "innocent" anal tag or condyloma-like lesion. AIN III lesions are usually flat, and their appearance is variable. The presence of ulceration in an AIN lesion suggests invasion. Symptoms include pruritus and anal discharge; other symptoms of pain, bleeding, and tenesmus suggest invasion.

No consensus exists about the best management of AIN. The primary goal is to prevent the development of anal cancer and minimize symptoms. Proposed strategies range from watchful waiting to aggressive surgery.

Conservative strategies are supported by the high recurrence rates seen after aggressive attempts at complete eradication. This is particularly true in patients with HIV and is likely the result of persistent HPV infection. Also, the rate of progression of high-grade AIN to invasive cancer is relatively low with the possibility of detection of invasive disease at an early and still treatable stage.

Ablative therapies used in AIN include CO_2 laser ablation, cryotherapy, and electrocautery fulguration. All the options are burdened by high recurrence rates and significant morbidity.

Excision of small lesions for histologic evaluation is preferred to purely ablative therapy because the latter precludes the possibility of a definitive diagnosis to guide further management. In the authors' practice, for definition of the extent of disease at diagnosis, anal mapping and anal pap smear with excision/ablation of the suspicious areas is performed. This should be done with high-resolution anoscopy (HRA). The advantage of HRA is more accurate identification of the suspicious lesions and minimization of damage to surrounding healthy tissue. In brief, this technique is based on the principle that, with the application of acetic acid, dysplastic tissue exhibits

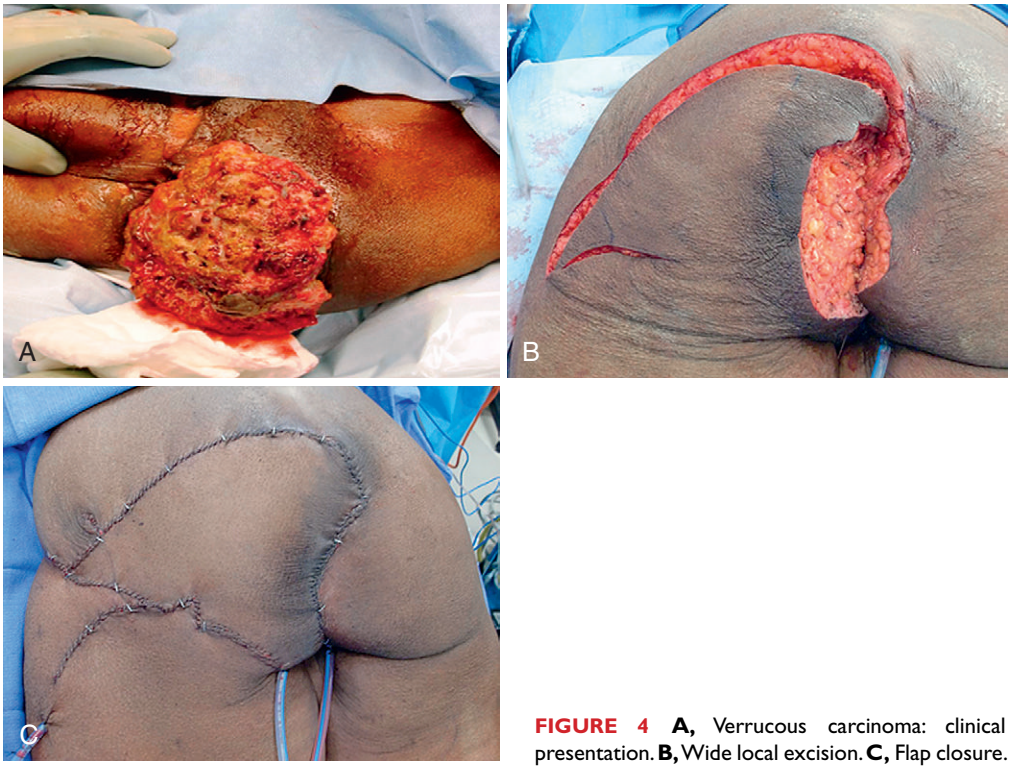

FIGURE 4 **A,** Verrucous carcinoma: clinical presentation. **B,** Wide local excision. **C,** Flap closure.

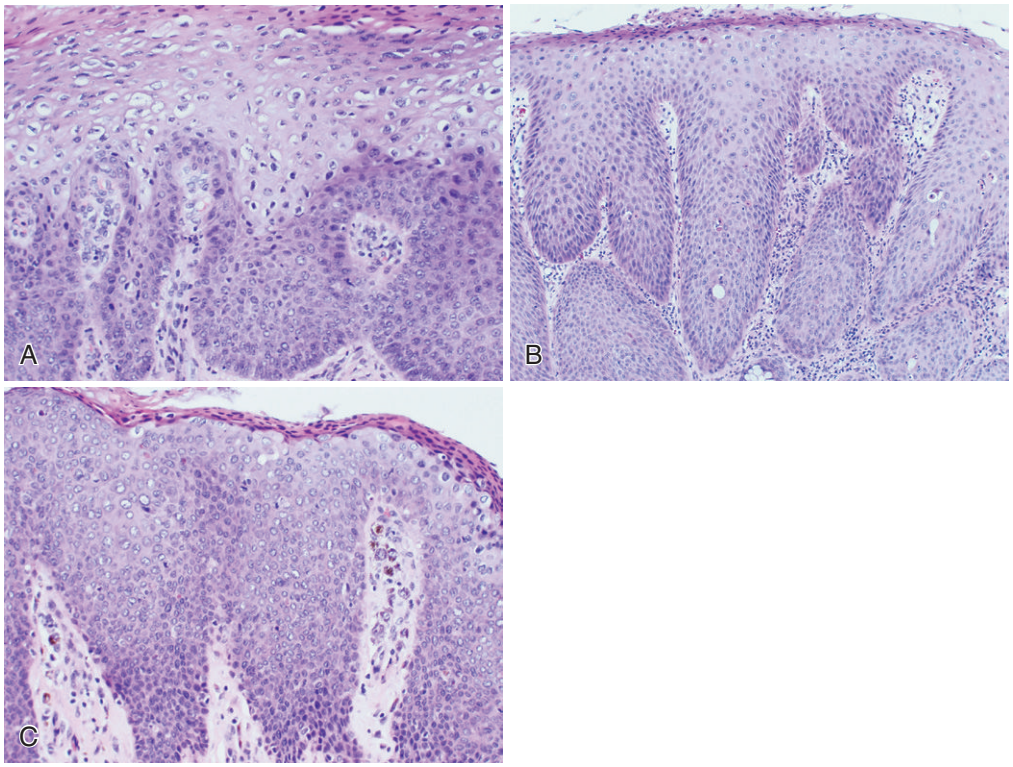

FIGURE 5 **A,** Human papilloma virus (HPV) infected epithelial cells can become dysplastic. The earliest form of dysplasia, or anal intraepithelial neoplasia I (AIN I), is limited to the lower one third of the epithelium. **B,** In AIN II, the grade of dysplasia increases as evidenced by expansion of cellular abnormalities and increased mitotic activity into the lower two thirds of the epithelium. **C,** Dysplastic cells take over the entire epithelium in AIN III, the highest grade of dysplasia. Note the complete loss of an identifiable basal layer with the top of the epithelium identical in appearance to the bottom. Further progression leads to invasive squamous cell carcinoma.

distinct changes and patterns in the anal mucosa. After application of 5% acetic acid to the anal canal and perianal skin, tissues that harbor AIN turn acetowhite. Acetowhitening alone is nonspecific. It sets the background on which the clinicians identify the characteristic vascular changes of low-grade and high-grade dysplastic lesions. Lugol's solution may be applied in areas of diagnostic uncertainty. Areas that do not take up Lugol's solution are considered at high risk for harboring high-grade dysplastic tissue. A biopsy of these areas should be obtained.

After the initial diagnosis is reached and invasive cancer has been ruled out, the authors continue to follow the patients with anal pap smear, excision of the suspicious areas, and fulguration of the less concerning lesions.

Other treatments, such as photodynamic therapy, immunomodulation therapies with imiquimod cream and cidofovir gel, and HPV immunotherapy, have been proposed. Although they are promising, the data are too limited to draw any definitive conclusions regarding their long-term efficacy.

Bowen's Disease

Bowen's disease is synonymous with AIN III. Patients with anal-margin Bowen's disease typically present with minor symptoms, such as burning or pruritus. Up to a third of the patients report a mass or bleeding. Clinically, Bowen's disease presents as erythematous, occasionally brown-red pigmented, noninfiltrating, scaly, or crusted plaques, that sometimes have a moist surface or even nodules (Figure 6). Differential diagnosis is extensive and includes different benign dermatologic conditions like psoriasis, eczema, and leukoplakia. The standard treatment is wide surgical excision. To ensure clear resection margins, a systematic four-quadrant biopsy technique, with intraoperative frozen sections including intraanal biopsies, has been advocated. Despite a wide excision, recurrence rates up to 30% have been reported. The major disadvantage of wide local excision is the difficulty to primarily close the wound; skin flaps may be necessary. Given the multifocality of these lesions, anal mapping is often performed in the authors' practice. Four-quadrant biopsies are obtained, starting at the dentate line, at the anal verge, and on the perianal skin (Figure 7). They are sent separately to the pathologist for permanent section.

FIGURE 6 Bowen's disease: clinical presentation as brown-red pigmented, noninfiltrating, scaly plaques, with a moist surface and nodules.

Squamous Cell Carcinoma

Traditionally squamous cell carcinoma of the anal canal occurs more frequently in women than in men (1.5 vs 1.0/100,000). Epidemiologic studies have shown that most anal cancers are associated with HPV infection, predominately oncogenic types 16 and 18. Anal intercourse is among the presumed mechanisms by which HPV is introduced into the anal canal. Other risk factors include

FIGURE 7 Anal mapping for Bowen's disease. Four-quadrant biopsies are obtained, starting at the dentate line, at the anal verge, and on the perianal skin. They are sent separately to the pathologist for permanent section.

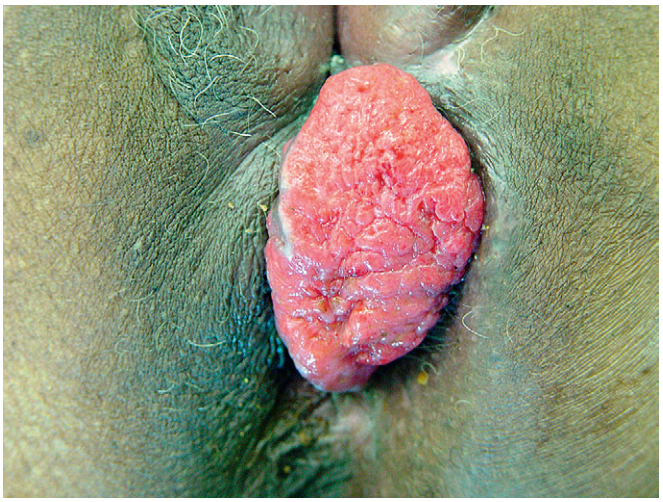

FIGURE 8 Anal squamous cell carcinoma: fungating mass at the anal verge.

immunosuppression (transplant, immune disorders, and HIV infection), an increasing number of sexual partners, a history of anogenital warts, previous lower genital tract dysplasia or carcinoma, and a history of smoking.

The clinical presentation is nonspecific (Figure 8). Anal bleeding appears to be the most common presenting symptom. Squamous cell carcinomas (SCC) are defined histologically by invasion of tumor cells beyond the basement membrane. Upon resection each tumor is given a grade and pathologic stage according to the TMN staging system (Figure 9). Although previous editions of the WHO classified three subtypes of SCC's current guidelines recommend a generic line diagnosis of "squamous cell carcinoma" due to low reproducibility and lack of prognostic relevance. However, the WHO does suggest adding a comment regarding the presence of additional histologic features such as degree of keratinization, cell size, basaloid features and adjacent AIN.

Before 1974, the management of squamous cell carcinoma of the anal canal consisted of primary surgical treatment in the form of an abdominoperineal resection. Since then, Dr Norman Nigro introduced his regimen. In his original description in three patients, radiation was given as a 3000-rad full-pelvis dose calculated to the mid plane of the pelvis, delivered in 15 treatments of 200 rad each in a 3-week period. The day after the start of radiation therapy, patients were given 25 mg/kg body weight of 5-fluorouracil daily continuous infusion for 5 days. Also, on the first day, the patients were given mitomycin-C, 0.5 mg/kg body weight. This protocol has undergone several modifications over the years, but it has completely revolutionized the treatment of squamous cell carcinoma of the anal canal, turning it into a "medical disease," with surgery indicated only as salvage therapy for persistent or recurrent disease. Combined modality therapy is delivered to the primary tumor and the locoregional lymph nodes, achieving complete response and 5-year overall survival rates as high as 92%. The presence of inguinal lymph node metastases at diagnosis reduces 5-year overall survival rates to 58%. Approximately, 10% to 15% of patients eventually have distant metastases develop, most commonly in the liver and lungs, and lymph node metastases occur in 10% to 25% of cases.

Controversy persists about the approach to the inguinal lymph nodes. Some authors favor prophylactic inguinal irradiation, and others reserve inguinal irradiation only for patients with histologically proven inguinal metastases. Inguinal irradiation has a 48% rate of acute and late morbidity. Moreover, in series of patients treated with the "Nigro protocol" avoiding the inguinal fields, inguinal

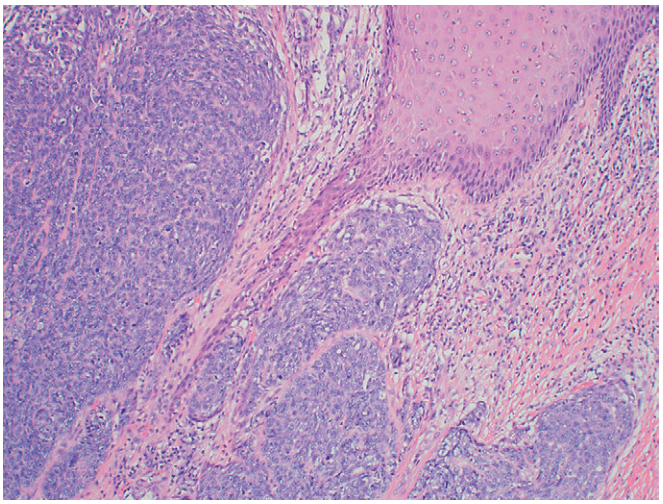

FIGURE 9 Although some residual nonneoplastic epithelium is present in the upper right hand corner, the majority of cells are malignant squamous cells invading through the lamina propria and submucosa (not identified in this image).

metastases were observed in 7% to 8% of patients, with the hypothetical potential risk of overtreating 92% to 93% of patients. Irrespective of the treatment the patient has undergone, surveillance of the inguinal lymphonodal stations remains critically important to detection of early inguinal metastases. Because lymph node size at the imaging studies is not a reliable predictor of metastases, the use of sentinel lymph node biopsy has improved staging of the inguinal status in these patients and is considered the procedure of choice for correct staging.

Inguinal lymph node dissection is associated with high morbidity: an overall wound infection rate of 24%, an incidence rate of moderate to severe infection of 16%, and lower extremity edema in 40% of patients. Superficial groin dissection involves only the inguinal nodes, and a deep groin dissection includes also the iliac and obturator nodes. Through a diagonally oriented skin incision from a point medial to the anterior superior iliac spine down to the apex of the femoral triangle, the fat and lymph nodes are dissected from the

femoral triangle, starting medially at the lateral edge of the adductor longus and proceeding laterally. The femoral vessels are preserved, and the saphenous vein is ligated and divided. Finally, the lymph nodes are dissected free from the femoral nerve. The deep groin dissection begins with the division of the inguinal ligament. The deep circumflex iliac vessels are ligated, and the peritoneum is separated from the preperitoneal fat and nodes by means of blunt dissection. Then, the chain of lymph nodes along the external iliac vessels is dissected until the origin of the internal iliac vessels. The dissection incorporates the nodes overlying the obturator foramen. After the lymph nodes have been removed, the inguinal canal is reconstructed to prevent hernias.

Although in the era of improved antiviral therapy, the disease-related outcomes are similar (5-year overall survival rate about 71% to 75%), tolerability of combined modality therapy seems to be worse in patients with HIV-positive conditions in the setting of low CD4 T-cell counts. The "Nigro protocol" has been proven to be very effective, but a small percentage of patients still do not respond to it and an equally small percentage eventually have local recurrence. Interestingly, patients that do not respond have a worse outcome after salvage surgery, typically an abdominoperineal resection, even when an R0 resection is achieved. The 5-year overall survival rate after salvage surgery for persistent disease is 31% to 33%, compared with 51% to 82% after surgery for local recurrence. This is likely the result of more aggressive tumor biology. When to declare a patient a non-responder is another topic of controversy. The radiation oncology literature clearly shows that the effects of treatment may continue for several months. In the authors' practice, a biopsy is not performed for 6 months to a year after the end of treatment.

Options for patients with metastatic anal cancer are limited and primarily involve combination chemotherapy. A regimen consisting of 5-fluorouracil and cisplatin has been the most frequently studied and results in overall response rates of around 60%, most of which are partial responses. The median survival time is approximately 12 months.

ADENOCARCINOMA

Adenocarcinoma of the anal canal accounts for about 10% of all anal canal cancers. Most of these neoplasms show a colorectal phenotype and originate from the columnar epithelium in the upper portion of the anal canal or from the glandular cells of the ATZ zone (Figure 10). Adenocarcinoma can also arise from anal glands and within established fistulas. The WHO categorizes these entities as extramucosal (perianal) adenocarcinomas.

Although the distinction between these tumors and the truly lower rectal adenocarcinomas directly extending into the anal canal is often very difficult, the difference is purely semantic because the treatment algorithm is the same. For stage II and III lesions, the treatment consists of neoadjuvant 5-fluorouracil–based combined modality therapy, then surgery often as an abdominoperineal resection, finally followed by 5-fluorouracil–based consolidation chemotherapy. For stage I, surgery alone is sufficient, and as in rectal cancer, for small very superficial T1 lesions with favorable histologic features, the role of local excision is currently debated.

Paget's Disease

Perianal Paget's disease is a rare clinical entity with only a few hundred cases reported in the literature. In its early stages symptoms are often limited, therefore, diagnosis and treatment is usually delayed. In addition, the condition can be confused with eczema or dermatitis, thus further delaying treatment. In many patients, the disease is present several years without progressing. Histologically, pale tumor cells with abundant clear cytoplasm and large nuclei are seen infiltrating throughout non neoplastic squamous epithelium

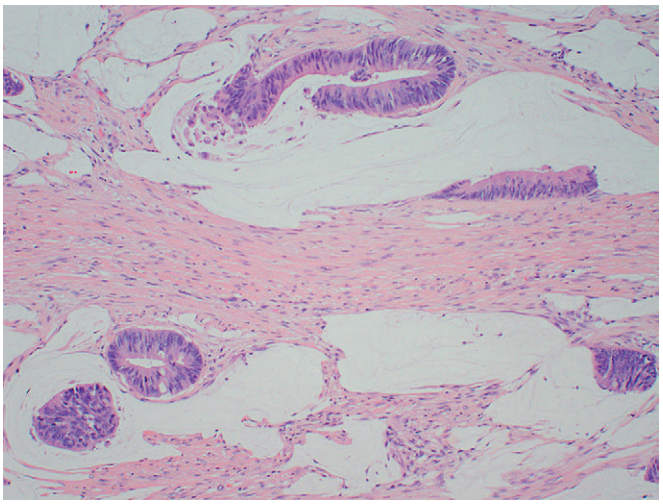

FIGURE 10 Invasive mucinous adenocarcinoma. Note the malignant glands arising from columnar epithelium floating in mucin pools.

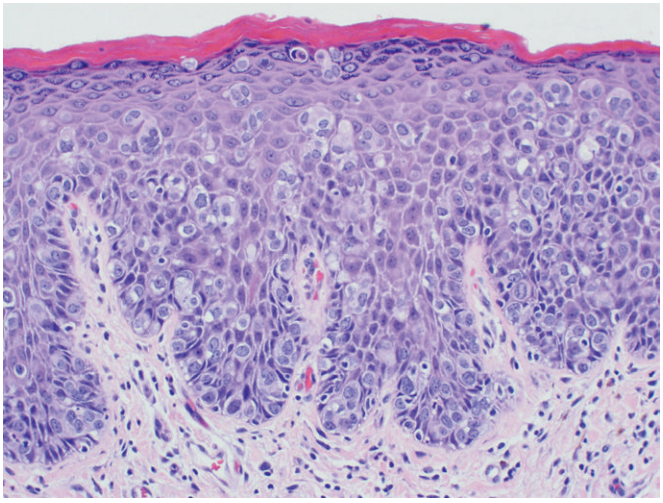

FIGURE 11 Extramammary Paget's disease. Many individual, large, pale cells represent adenocarcinoma in normal external squamous mucosa of the anal skin.

(Figure 11). There are two proposed etiologies. The first is a true primary lesion of apocrine glands exhibiting epidermotropism. These lesions are seen primarily in white women over the age of 50, have a high local recurrence rate and often express markers of apocrine cells. The other lesions are considered synchronous or metachoronous lesions in patients with internal malignancies (33% to 86% have colorectal adenocarcinoma, or carcinomas of the Bartholin glands, urethra, bladder, vagina, cervix, endometrium, or prostate).

Staging classification of perianal Paget's disease and stage-appropriate treatment protocols have been proposed. Prognosis remains good for stage I (Paget's cells found in perianal epidermis and adnexa without primary carcinoma), but it progressively worsens for stage II (invasive cutaneous disease penetrating the basement membrane into the underlying stroma or synchronous localized malignancies: i.e., IIa adnexal malignancy, IIb visceral malignancy) and for stages III and IV, where regional involvement and distant metastatic disease are present, respectively.

The treatment of Paget's disease is surgical. However, because Paget's disease typically extends microscopically beyond the visible

lesion, it is difficult to obtain a negative margin without sacrificing large skin areas. Consequently, recurrence rates between 30% and 70% after surgery have been reported.

Nonsurgical approaches have been advocated in selected cases, for those patients who are medically unfit for surgery or wish to avoid radical surgery or those who have multifocal widespread disease precluding complete resection.

Radiotherapy can be used as a primary treatment or in the adjuvant setting. Recurrence rates from 0 to 60% have been reported, with no apparent differences between primary treatment and adjuvant therapy.

Systemic chemotherapy is used when surgery is not recommended, in cases of advanced disease, or in a neoadjuvant setting to reduce the tumor mass before surgical excision. Applied in combination with radiotherapy, it appears to improve responses and prevent recurrences, but the use of systemic chemotherapy alone requires further investigation.

Mohs' micrographic surgery has been associated with lower recurrence rates (8% to 28%) and less morbidity compared with standard surgical excision. It is typically performed in steps. A small scalpel is used to cut around the visible tumor. A very small surgical margin is used, usually with 1 to 1.5 mm of "free margin" or uninvolved skin. After each surgical removal of tissue, the specimen is processed, cut on the cryostat and placed on slides, stained with hematoxylin and eosin, and then read by the pathologist who examines the sections for cancerous cells. If cancer is found, its location is marked on the map (drawing of the tissue) and the surgeon removes the indicated cancerous tissue from the patient. This procedure is repeated until no further cancer is found.

Recent series with CO_2 laser treatment have reported recurrence rates similar to surgical excision but with significant post-treatment pain.

MELANOMA

Anal melanomas account for about 4% of anal canal tumors and less than 1% of all melanomas. Frequently it is not pigmented and does not have a macroscopically suspicious appearance. Management of anal melanoma remains a major challenge, and the prognosis is dismal. Despite the fact that most patients present with localized and apparently curable primary tumors, the mean survival time is only 2 years. Surgery is the treatment of choice because anal melanoma does not respond to chemoradiation. The extent of surgical resection (abdominoperineal resection vs local excision) does not seem to significantly impact outcome, as patients often die of distant metastases.

NEUROENDOCRINE TUMORS

Neuroendocrine neoplasms may occasionally occur in the anal canal. Most such tumors probably originate from neuroendocrine cells residing in colorectal type mucosa, although neuroendocrine cells are known to exist in ATZ mucosa as well. Because these lesions are often small, the treatment is typically a local excision.

MESENCHYMAL TUMORS

The most common types of mesenchymal tumors in the anal canal are smooth muscle tumors and gastrointestinal stromal tumors (GISTs). The treatment is typically just a local excision because the vast majority of them are small.

MALIGNANT LYMPHOMA

Primary lymphoma of the anal canal is rare. However, cases of both Hodgkin's disease and non-Hodgkin's lymphomas are reported. Patients with immunocompromise are particularly at risk. In this population, the lymphomas are mainly B-cell type and high grade. The treatment is chemoradiation.

The Use of Positron Emission Tomographic Scanning in the Management of Colorectal Cancer

Nelya Brindzei, MD, and
Julio Garcia-Aguilar, MD, PhD

INTRODUCTION

The introduction of positron emission tomography (PET) scanning has been one of the most important advances made in oncology imaging over the last two decades. PET has revolutionized cancer treatment with its ability to identify tumors based on their biologic—metabolic or molecular, rather than anatomic—characteristics. An understanding of the science behind PET imaging is important in order to grasp the current and future clinical applications of this technology. PET and integrated PET/computed tomographic (CT) scan imaging are now used in multiple aspects of colorectal cancer care, including screening, diagnosis, staging, monitoring of response, diagnosis of recurrence, and posttreatment surveillance. In this chapter, we review the evidence supporting applications of PET imaging in the management of colorectal cancer.

BACKGROUND

PET imaging takes advantage of the photons emitted in the process of positron-electron annihilation. The reaction of a positron emitted from a proton-rich unstable isotope, with a nearby electron, leads to the simultaneous emission of two annihilating photons in opposite directions. These photons are identified with two separate detectors in a PET camera, located diametrically opposite one another. Both photons are detected within a short period of time, indicating that an annihilation effect has occurred somewhere in the area between detectors. The data from multiple pairs of opposing detectors is mathematically integrated and reconstructed tomographically, providing the images seen in PET scans.

The positron-emitting radioisotopes used in PET imaging are short-lived, which minimizes the radiation absorbed by the patient and makes it possible to repeat the examination within a short period of time, even on the same day. These radioisotopes combine with tracers that accumulate preferentially or selectively in tumor versus healthy tissue.

The radiotracer most commonly used in oncologic evaluation is [^{18}F]-2-fluoro-2-deoxy-D-glucose (FDG), which uses the radionuclide fluorine-18 attached to a glucose analog. FDG takes advantage of the fact that cancer cells preferentially use glycolysis as the source of energy at a much higher rate than healthy cells. This is known as Warburg's effect. FDG competes with normal glucose for transport across the cell membrane, but unlike glucose, FDG cannot be metabolized and accumulates inside the cell. The resultant emission of photons, and therefore the intensity of the PET signal, is proportional to the accumulation of FDG within cells. The relatively higher accumulation of FDG in the more metabolically active cancer cells results in differential intensity signal between the tumor and the adjacent healthy tissue. Tissue activity can be measured at a fixed point and normalized to body surface area, a technique known as standardized uptake value (SUV). These measurements are relatively simple, and the values are reproducible as long as they are taken at the same time point. Tissue activity can also be quantified kinetically with measurement of the constant rate of uptake of tracer by the tumor, a technique known as the Gjedde-Patlak analysis. This measurement is more precise than SUV but requires dynamic data acquisition, which can be influenced by patient movement. In general, there is no significant advantage to the Gjedde-Patlak plot model, and SUV is routinely used in clinical practice.

The use of a radiotracer as a marker of glucose metabolism, which is enhanced in all cancers, has extended the clinical applications of FDG-PET to many different malignancies. However, the targeting of a metabolic process that is enhanced in, but not exclusive to, cancer cells represents the main limitations of its use: low sensitivity and specificity. FDG-PET may provide inadequate differentiation between inflammation and tumor, or between a benign polyp and an invasive cancer. FDG-PET can also provide low signals in slow-growing tumors, or tumors with low cellularity such as mucinous carcinomas. On the other hand, PET imaging may be inaccurate in distinguishing the focal FDG uptake of a tumor from the normal high physiologic background uptake in some metabolically active organs such as bowel or brain. Remember that FDG competes with normal glucose for uptake into the cell and that patients are required to fast for a number of hours before the study. FDG-PET can also provide false-negative results in patients with diabetes with elevated serum glucose levels.

In hopes of overcoming the lack of specificity of FDG-PET, a new generation of radiotracers is under investigation. These tracers are directed against a variety of cellular processes or molecular targets, such as proliferation (fluorothymidine), hypoxia (fluoromisonidazole [FMISO]), angiogenesis (arginine-glycine-aspartate [RGD] peptides), cell surface antigens *(Her2 neu* or carcinoembryonic antigen [CEA]), or cellular receptors (epidermal growth factor receptor [EGFR] or somatostatin), which may be more tumor-specific than glucose metabolism. Some of these new tracers require isotopes with a half-life that matches the kinetics of the compound in which they are embedded, be it a monoclonal antibody (such as ^{89}Zr-Trastuzumab, ^{64}Cu-antiCEA), a small peptide (^{11}C-Erlotinib), or a receptor ligand (^{68}Ga-somatostatin analogues). However, these new PET modalities have not been fully incorporated into clinical practice. FDG-PET is currently the only form of PET used in clinical evaluation of colorectal cancer.

The main advantage of PET imaging—the detection of biologic changes that precede anatomic abnormalities—also represents its main drawback: the lack of anatomic correlation. Since 1999, the biologic information provided by PET scans can be integrated electronically with the detailed anatomic images obtained simultaneously in a CT scan. The recent technologic advances in PET detectors and the CT component, such as contrast enhancement and multidetector scanners, have improved resolution and reduced scanning time. The integration of PET and contrast-enhanced CT scan provides better results than the sum of its parts; therefore, the standalone PET is rarely performed today.

DETECTION OF COLORECTAL CANCER

The colon normally demonstrates a relatively high metabolic background activity, but a focal increase in FDG uptake over background often indicates the presence of relevant neoplasm defined as invasive cancer, polyps with high-grade dysplasia, or polyps greater than 1 cm in diameter. However, FDG-PET is incapable of differentiating adequately between inflammation, benign polyps, or cancer. Because of

this, a focal increase in FDG uptake requires subsequent endoscopic examination.

Incidental colorectal focal FDG uptake is observed in 1% to 3% of FDG-PET/CT scans obtained for an unrelated reason, and follow-up colonoscopy detects cancer or polyps in almost half of these patients. A prospective study investigating the clinical significance of an incidental FDG uptake in FDG-PET/CT scans with a colonoscopy performed within 30 days reported that 23% of patients had colorectal cancer and 20% had polyps. In the remaining 56% of cases, the study results were falsely positive. The false-positive rate was higher for FDG uptake found in the right colon, which is probably related to the higher physiologic FDG uptake in the region of the terminal ileum. The maximal SUV (SUV-max) values varied significantly and were unable to discriminate between malignant and nonmalignant lesions. Other studies have reported similar rates of neoplastic lesions among patients with incidental focal colonic FDG uptake on FDG-PET/CT scans. They have also confirmed that a high SUV-max is not a good predictor of malignancy. Although these data support the need for follow-up colonoscopy in patients with incidental FDG uptake in the colon, the true accuracy of FDG-PET/CT in diagnosis of colorectal cancer is unknown because, in most of these series, patients without focal FDG uptake did not undergo colonoscopy. A recent study reported findings of advanced colonic neoplasms in 53% of patients who underwent colonoscopy after incidental focal FDG uptake was noted on PET/CT scans obtained for unrelated reasons. The rate of advanced colorectal neoplasms was only 6% among a subset of patients without focal FDG uptake on PET/CT who underwent colonoscopy for unrelated reasons, most of them for screening purposes. On the basis of these data, the authors concluded that FDG-PET/CT scan has an accuracy of 76% in diagnosis of advanced colonic neoplasia.

SCREENING FOR COLORECTAL CANCER

Conclusive evidence now shows that screening reduces colorectal cancer mortality. Although colonoscopy is the preferred method for colorectal cancer screening, computed tomographic colonography (CTC) has shown excellent diagnostic performance in detection of both cancers and polyps, and is an accepted option for colorectal cancer screening when colonoscopy is incomplete or contraindicated. However, similar to colonoscopy, CTC requires bowel cleansing and distension during the examination. The development of alternatives that could detect clinically relevant lesions, while sparing bowel cleansing, could simplify screening and increase compliance.

FDG-PET/CT scan has been proposed as a potential tool for colorectal cancer screening because it correlates the increased focal FDG uptake characteristic of neoplastic tissue with the anatomic definition of the integrated CT scan. However, CTC is so accurate in detecting colon cancer and polyps that, when the CT component of the FDG-PET/CT scan is performed with cleansed and distended bowel, the added value of the FDG-PET component is negligible. FDG-PET could have a role in screening for colorectal cancer and polyps by adding specificity to a CTC performed in noncleansed, nondistended colon. A recent retrospective study of 84 patients who had PET/CT scan with noncleansed and nondistended bowel, followed by colonoscopy (n = 79) or sigmoidoscopy (n = 5), reported that FDG-PET identified all carcinomas and 83% of all relevant adenomas. The SUV-max in all carcinomas and adenomas with high-grade dysplasia was 5 or more. False-positive FDG uptake occurred in 48 of 107 examinations (45%). Many of the false-positive results had stool as correlate on CT scan, and most of these false-positive results (41 of 48, or 85%) were correctly identified with the CT component. The authors concluded that, with a standardized cut-off value (e.g., SUV-max, ≥5), FDG-PET/CT scan provides promising accuracy in colorectal cancer screening. However, although the adoption of FDG-PET/CT scan for screening may potentially help patients avoid the discomfort of bowel cleansing and distension, it may increase the proportion of false-positive results and unnecessary colonoscopies compared with CTC. Therefore, in the absence of prospective data, the role of FDG-PET/CT scan in screening for colorectal cancer remains undefined.

TUMOR STAGING AND TREATMENT PLANNING

Surgery is the primary therapy for most patients with colorectal cancer. However, with the development of safer radiotherapy techniques and more effective chemotherapeutic agents, a higher proportion of patients are now being treated primarily by nonsurgical means. Because decisions regarding initial treatment are based primarily on disease stage, the need for accurate clinical staging is increasing. FDG-PET/CT scan is used selectively in specific clinical scenarios, such as detection of occult disease in patients with potentially resectable metastases based on conventional anatomic imaging, and selection of patients with locally advanced rectal cancer for neoadjuvant therapy.

Between 20% and 25% of patients with colorectal cancer have distant metastasis at the time of the initial diagnosis. Until recently, median survival without treatment for patients with stage IV disease was less than 12 months. With the introduction of more effective chemotherapy agents, median survival for patients with metastatic colorectal cancer is now measured in years. A subset of patients with metastasis confined to the liver or lungs, and amenable to complete surgical resection, can now be cured. Detection of disseminated disease in patients with potentially resectable metastasis based on conventional anatomic imaging could help to avoid unnecessary, expensive, and potentially morbid surgery.

Early studies assessing the utility of FDG-PET before hepatic resection for liver metastasis reported that PET diagnosed extrahepatic disease, directly influencing the treatment plan in as many as 25% of patients. Recently, a number of retrospective and prospective studies have compared the performance of FDG-PET/CT scan with conventional imaging modalities in preoperative assessment of patients with metastatic disease. The combined results of these series suggest that FDG-PET/CT scan has greater diagnostic accuracy (sensitivity, 78% to 100%; specificity, 78% to 100%) than contrast-enhanced CT scan (sensitivity, 75% to 98%; specificity, 25% to 100%) when the patient is used as the unit analysis. However, no differences are seen in accuracy between tests when individual lesions are used as the unit analysis. This discrepancy probably reflects the relatively high rates of false-positive lesions on FDG-PET and false-negative lesions on contrast-enhanced CT scan. Similar to FDG-PET, FDG-PET/CT scan impacts management in up to 30% of patients with potentially operable distant metastasis appreciated by conventional anatomic imaging. The results of studies comparing the accuracy of PET-CT with magnetic resonance imaging (MRI) in detection of hepatic and extrahepatic metastasis are mixed: some studies report higher accuracy for MRI, and others report higher patient-level estimate for FDG-PET/CT scan accuracy. However, the results of studies comparing the diagnostic accuracy of these different imaging modalities should be interpreted with caution because these studies are very heterogeneous in terms of patient characteristics, FDG-PET/CT scan equipment and techniques, image interpretation, and reference standards.

In a recent meta-analysis of prospective studies comparing different imaging modalities in patients with known or suspected untreated liver metastasis, the sensitivity estimates on a per-lesion basis were 74.4% for CT scan, 80.3% for MRI, and 81.4% for FDG-PET. These differences were not statistically significant. On a per-patient basis, FDG-PET had a sensitivity of 94.1%, significantly higher than CT scan (83.6%), but not MRI (88.2%). Specificity estimates for all three modalities were similarly high. The number of studies on FDG-PET/CT scan was too small to reach meaningful conclusions. In the

subgroup analysis, MRI was more accurate than CT scan in the diagnosis of liver lesions smaller than 1 cm in diameter. The authors concluded that MRI was the preferred first-line modality for imaging of the liver because of its relatively high accuracy, anatomic definition, and ability to detect small lesions. FDG-PET/CT scan was considered a second-line modality in patients requiring additional workup to exclude extrahepatic disease. However, this meta-analysis included few series reporting FDG-PET/CT scan data. It is possible that, with the newer multidetector scanners, FDG-PET/CT scan may be the most accurate and cost-effective imaging technique for evaluation of patients with suspected colorectal liver metastasis.

Patients with locally advanced rectal cancer are now commonly treated with neoadjuvant chemoradiation therapy (nCRT), and selection for neoadjuvant therapy is based on clinical tumor, node, metastasis (TNM) staging. Only patients with tumors that penetrate into the mesorectum (T3) or metastasize to the mesorectal lymph nodes (N+) are candidates for nCRT. In some patients, rectal cancer spreads to pelvic lymph nodes located outside the tissues that are usually removed with total mesorectal excision (TME). Identification of nodal metastasis to the mesorectal and iliac nodes is important, not only in selection of patients for nCRT but in planning of surgical resection. Therefore, accurate local and regional clinical TNM staging is crucial in selecting the optimal therapy for patients with rectal cancer. Because the treatment options for rectal cancer are more diverse than those for colon cancer, identification of distant metastasis in patients with seemingly localized rectal cancer can potentially have a greater treatment impact, compared with patients with colon cancer.

FDG-PET/CT scan, even with contrast enhancement, cannot delineate the different layers of the rectal wall. Thus, similar to CT scan and MRI, FDG-PET/CT scan is not accurate in defining the depth of tumor invasion in the bowel wall, or distinguishing tumors localized to the bowel wall, from those that penetrate into the perirectal fat. FDG-PET/CT scan is also less accurate than MRI for assessing the relationship of the tumor to the fascia propria of the rectum and predicting tumor involvement of the circumferential resection margin. However, FDG uptake correlates well with tumor specimen measurements on pathologic specimens, compared with CT scan or MRI. Preliminary studies suggest that, compared with MRI, FDG-PET/CT scan may reduce interobserver variability in delineating gross tumor volume in patients with rectal cancer, enabling better planning of preoperative radiotherapy.

Although scatter uptake from the primary tumor limits assessment of the perirectal lymph nodes, multiple studies have investigated the contribution of FDG-PET and FDG-PET/CT scan to preoperative staging of rectal cancer with CT scan or MRI. In an early study of 37 patients with rectal cancer initially staged with MRI or endorectal ultrasound and spiral CT scan, FDG-PET/CT scan identified discordant findings in 14 patients (38%). FDG-PET resulted in upstaging seven patients (50%) and downstaging three (21%). The most common discordant findings between the CT scan and FDG-PET/CT scan were lymph node metastasis, for which FDG-PET/CT scan was always accurate. FDG-PET/CT scan changed the treatment plan in 10 patients (27%). These results were confirmed by a later series, which also reported up to 31% change in tumor staging and 12% change in management.

With a qualitative analysis (focal increase in FDG uptake at a location corresponding to regional lymph node chains, compared with surrounding tissues), FDG-PET/CT scan detected nodal metastasis with a sensitivity of 85% at the patient level when compared with histopathology of the resected specimen. However, the specificity was only 42%. Quantitative interpretation of FDG-PET images, and the use of contrast-enhanced CT scan, increased specificity but decreased sensitivity. In a study with an SUV threshold of 1.5-fold, comparing surrounding tissue with diagnosed nodal metastasis, PET/CT scan showed a sensitivity of 53% and specificity of 90% compared with histopathology. As expected, the specificity could be increased to 100% by raising the threshold from 1.5-fold to 3.5-fold compared with healthy tissue, but the sensitivity dropped even further to 24%. In nodes of more than 1 cm in diameter, PET/CT scan had a sensitivity of 30% and a specificity of 95%. Recent series have reported that FDG -PET/CT scan is as accurate as CT scan, but less accurate than high-resolution pelvic MRI, in nodal staging of rectal cancer. Consequently, FDG-PET/CT scan adds little information to other imaging modalities, such as multidetector, contrast-enhanced CT scan and MRI, in preoperative staging of rectal cancer, except in identifying distant metastasis in patients with high-risk tumors.

ASSESSMENT OF TUMOR RESPONSE

The development of more effective chemotherapeutic drugs and the widespread use of nCRT in rectal cancer have accentuated the importance of assessing tumor response when making therapeutic decisions. FDG-PET is a functional study that can detect metabolic and molecular changes in response to therapy, before volume reduction becomes measurable with conventional anatomic imaging. FDG-PET has been proven very valuable for assessing response to therapy in tumors such as Hodgkin's lymphoma, in which fibrosis cannot be reliably distinguished from residual disease with CT scan. The role of FDG-PET in assessment of colorectal cancer response to therapy, both in the locoregional and metastatic setting, has been studied broadly in recent years.

Some patients with rectal cancer treated with nCRT and TME have no detectable cancer cells in their surgical specimens. Therefore, the nominal value of surgery in these patients has been questioned. If responders could be identified clinically, surgery might be deferred indefinitely, sparing these patients unnecessary morbidity. Unfortunately, the correlation between clinical examination and pathologic analysis is inexact, and some patients with a clinical response have viable cancer cells in their surgical specimens. The discordance between a clinical complete response (cCR) and a pathologic complete response (pCR) is currently the primary limiting factor to an organ preservation approach for patients with rectal cancer who achieve a sustained response to nCRT.

Extensive study of the role of FDG-PET in assessment of rectal cancer response to nCRT has yielded conflicting results. Earlier studies showed a possible correlation between PET parameters and tumor regression, but in most series, PET did not accurately identify patients with a pathologic complete response to chemoradiation therapy (CRT). A recent large prospective series of patients treated with nCRT and TME reported that 70% of patients showing a complete response on FDG-PET had residual tumor on histopathologic examination. For patients with a complete response on CT scan, 50% had residual tumor in the surgical specimen. Conversely, of patients with an incomplete response on PET or CT scan, 16% and 19%, respectively, had pCR in the surgical specimen. It can be concluded that neither FDG-PET nor CT scan are sufficiently accurate in distinguishing between partial and complete rectal cancer response to CRT. Some studies have reported that a decrease in FDG uptake in PET performed early in the course of nCRT is associated with lower risk of tumor recurrence and improved patient survival. However, recent studies have not confirmed these findings.

Changes in SUV, metabolic volume, and lesion glycolysis in post-chemotherapy FDG-PET imaging, compared with baseline, have been correlated with response to chemotherapy in patients treated for colorectal liver metastasis. A number of studies have reported significant differences in one or more of these parameters between responders and nonresponders. However, similar to rectal cancer response to nCRT, FDG-PET/CT scan cannot distinguish with certainty patients with metastasis who achieve a pCR in response to systemic chemotherapy from those with residual disease.

The diagnostic accuracy of most imaging modalities in identification of liver metastasis is lower in patients after chemotherapy, compared with chemo-naive patients. The drop in accuracy after

chemotherapy is more significant for FDG-PET and FDG-PET/CT scan compared with other imaging modalities such as MRI or CT scan. A recent meta-analysis of the published series on preoperative imaging of colorectal liver metastasis concluded that MRI appears to be the most appropriate preoperative imaging modality for detection of liver metastasis after chemotherapy. CT scan was the second-best imaging modality. PET-CT scan was not particularly useful in the postchemotherapy setting.

RECURRENT COLORECTAL CANCER

More than one third of patients with colorectal cancer treated with curative intent have recurrence within 5 years of surgery. Most recurrences develop in distant organs, such as the liver or lungs, or locally at the site of the primary tumor. Chemotherapy or radiation can prolong survival and improve quality of life for some of these patients, but surgical resection with negative margins is the only curative treatment for recurrent colorectal cancer. Therefore, identification of patients with isolated resectable recurrences could potentially increase survival in patients with colorectal cancer. A systematic review of several prospective randomized trials concluded that close surveillance improves survival through early detection of recurrences and second primaries in selected patients who are at high risk of recurrence after treatment for primary colorectal cancer. Most professional societies recommend surveillance consisting of periodic clinic visits, measurement of plasma CEA levels, and abdominal CT scans.

The diagnosis of tumor recurrence is often challenging because conventional imaging cannot distinguish between surgical changes or benign incidental lesions and tumor recurrence. FDG-PET/CT scan is especially valuable in diagnosis of tumor recurrence because it combines FDG uptake—a marker of the enhanced glycolytic activity characteristic of cancer cells—and the anatomic definition of the CT scan. In addition, FDG-PET can occasionally detect small foci of increased FDG uptake in structures that appear normal on conventional imaging. Therefore, FDG-PET/CT scan has the potential to impact the treatment of these patients by finding previously undiagnosed recurrences but also by detecting disseminated disease in patients already diagnosed with seemingly localized colorectal cancer recurrences.

A meta-analysis of the literature assessing the use of FDG-PET without CT scan integration in the diagnosis of recurrent colorectal cancer showed an overall sensitivity of 97% and an overall specificity of 76%. These findings changed management in 29% to 40% of patients who had been previously diagnosed with tumor recurrence, based on CT imaging. Furthermore, a decision analysis suggested that FDG-PET was cost-effective in the management of recurrent colorectal cancer. A more recent meta-analysis of a series comparing FDG-PET, FDG-PET/CT scan, CT scan, and MRI for detection of recurrent disease in patients with high suspicion of recurrent colorectal cancer, based on symptoms or rising CEA levels, suggested that FDG-PET and FDG-PET/CT scan had higher diagnostic performance compared with CT scan. PET/CT scan seems to be more accurate than MRI in detection of lymph node recurrences in a lesion level analysis. In patients who had both tests, integrated FDG-PET/CT scan had a higher diagnostic performance compared with FDG-PET alone.

Altered pelvic anatomy and presacral abnormalities are common on CT scan or MRI after TME for rectal cancer, and FDG-PET/CT scan is particularly accurate in distinguishing benign scar from recurrent tumor in these patients. The FDG findings are clinically relevant, as they may change clinical management for many of these patients. However, false-positive results, mainly from FDG uptake in displaced pelvic organs, are not uncommon, and may result in unnecessary treatments.

FDG-PET, particularly when integrated with contrast-enhanced CT scan, is useful for investigating unexplained CEA elevation in patients undergoing surveillance after curative resection for colorectal cancer. The accuracy of FDG-PET/CT scan in detection of tumor recurrence in patients with elevated CEA is independent of the CEA level.

Despite its diagnostic accuracy in patients suspected of colorectal cancer recurrence based on symptoms, rising CEA levels, or conventional imaging, information on the utility of FDG-PET/CT scan for surveillance after curative resection is limited. One study randomized 130 patients who had undergone curative surgery for colon or rectal cancer to conventional surveillance or surveillance with FDG-PET/CT scan. The proportion of patients with recurrence was similar in both groups, but recurrences were detected after a shorter time interval (12.1 vs 15.4; $P = 0.01$) in the FDG-PET cohort. In addition, more patients in the PET group had curative resection. Unfortunately, the study did not provide survival data; thus, the real benefit of routine use of FDG-PET/CT scan in the surveillance of patients after curative treatment of colorectal cancer remains unknown.

SUMMARY

The use of FDG-PET in the management of patients with colorectal cancer is increasing, but its indications are not well defined. At this time, the information available does not support its use for colorectal cancer screening, even in the subset of patients who have a complete colonoscopy, because of the high false-positive rate of the PET component and the lack of advantage shown by the CT component over CTC. The main role of FDG-PET/CT scan in clinical staging is limited to detection of nodal or distant metastasis in patients at high risk.

The greatest impact of FDG-PET/CT scan is in the management of recurrent colorectal cancer, because it can facilitate diagnosis in patients suspected of recurrence based on symptoms, rising CEA, or conventional imaging. In addition, it may be helpful in selecting patients with resectable metastasis for surgical therapy, by identifying those with disseminated disease who will not benefit from surgery. However, at the present time, FDG-PET/CT scan is not cost-effective as a primary tool in routine surveillance after curative resection for colorectal cancer.

FDG-PET and FDG-PET/CT scan measurements, before and after treatment, are able to detect partial tumor response. However, neither modality can predict pathologic complete response with enough accuracy to be considered clinically useful. Therefore, although FDG-PET and FDG-PET/CT scan may be useful in assessing the efficacy of systemic therapy, they cannot be used to select patients for nonoperative management. Future studies should focus on increasing PET resolution, identifying the optimal time to assess tumor response, increasing the rate of tumor response, and using more specific molecular radiotracers.

The Use of Neoadjuvant and Adjuvant Treatment for Colorectal Cancer

David Cosgrove, MBBCh

OVERVIEW

Colorectal cancer (CRC) is a common malignancy and a major public health problem in the United States; an estimated 142,820 new cases are projected to occur in 2013. Although the rate of mortality from CRC has been steadily declining since 1990, there are still more than 50,000 U.S. deaths from the disease each year. Screening for CRC can lead to diagnosis at an earlier stage, potentially curative therapy, and a reduction in cause-specific mortality, but population compliance with screening guidelines remains disappointingly low; only approximately 50% of all eligible adult patients report completion of recommended screening tests.

Surgical resection is the foundation of a curative treatment approach to CRC. Despite appropriate surgical intervention in early-stage disease, the emergence of distant metastatic disease is common. The cause of this recurrence is the presence of micrometastatic spread before or during the surgical intervention, with a tumor burden below the threshold of detection of standard diagnostic tools. The goal of neoadjuvant and adjuvant therapy is to eradicate these micrometastases and enhance the potential for long-term survival. However, the majority of patients undergoing curative-intent surgical resection for this disease do not derive any discernible benefit from adjuvant treatments, either because surgery alone is truly curative (i.e., there are no micrometastatic deposits) or because the disease recurs in spite of additional treatments (i.e., the micrometastatic deposits prove refractory to eradication). Unfortunately, at the time of writing, the ability to predict which patients are more likely to benefit from adjuvant therapy is limited. Physicians still rely on the anatomic tumor stage to assess the recurrence risk, even though the available staging systems consist of broad categories, each of which contains a wide spectrum of actual recurrence risks. Molecular assessment of tumor cells and surrounding stroma has the potential to refine the prognostic armamentarium and could serve to identify individual patients likely to benefit from specific adjuvant therapies, but such assessments are still investigational for the most part and have yet to influence clinical decision making in this arena. Such assessments have a more robust role in clinical decision making for patients with metastatic CRC.

CRC is subdivided into colon cancer and rectal cancer with regard to the specifics of adjuvant treatment options. Because of the unique anatomic challenges to complete surgical clearance posed by lesions in the rectum, radiation therapy has served as a treatment adjunct to reduce local recurrence, whereas it has no role in the adjunctive treatment of true colon lesions. These clinical scenarios are discussed separately in this chapter.

STAGING

Despite the limitations just noted, formal CRC staging remains essential to establish the likely risk of recurrence in an individual patient and to implement appropriate curative-intent treatment. The National Comprehensive Cancer Network® (NCCN®) recommends that the preoperative workup for CRC should include a colonoscopy; complete blood cell counts; liver and kidney function tests; carcinoembryonic antigen (CEA) serum level; computed tomographic (CT) scan of the chest, abdomen, and pelvis; and pathologic assessment of the tumor tissue. Patients presenting with a rectal cancer should additionally undergo rigid proctoscopy and formal pelvic imaging, with either magnetic resonance imaging or endoscopic ultrasonography, to accurately define the depth of tumor invasion and degree of lymph node involvement. Accurate preoperative staging in rectal cancer is of particular importance because radiation therapy will be incorporated in the neoadjuvant setting, which can often lead to an anatomic downstaging of the primary tumor and lymph node metastases before curative resection and final pathologic staging. Positron emission tomography (PET) is not considered standard in the staging workup of localized CRC; however, it may be utilized as a confirmatory test if suspect findings on CT scans suggest the presence of distant metastatic disease.*

CRC is staged on the TNM staging system (T, primary tumor; N, regional lymph nodes; M, distant metastasis), adopted by the American Joint Committee on Cancer (AJCC). The 2010 revision of this staging system is outlined in Table 1. The importance of accurate staging is reflected in Table 2, which outlines the predicted 5-year survival rates among patients with a diagnosis of nonmetastatic CRC. In all patients represented in this table, except those with truly stage I disease, a conversation about the relative risks and benefits of adjuvant therapy is warranted. As discussed in the following sections, the more aggressive the disease biology, or the more widespread its extent, the greater the potential benefit of such therapy.

ADJUVANT THERAPY FOR COLON CANCER

Stage III Colon Cancer

Adjuvant chemotherapy has been an accepted standard of care in stage III colon cancer since 1990, when a survival benefit over surgery alone for such patients was defined in both the National Surgical Adjuvant Breast and Bowel Project (NSABP) C-01 study and the North Central Cancer Treatment Group (NCCTG) trial. The specific

TABLE 1: American Joint Committee on Cancer TNM classification of colon cancer

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ: intraepithelial or invasion of lamina propria*
T1	Tumor invades submucosa
T2	Tumor invades muscularis propria
T3	Tumor invades through the muscularis propria into pericolorectal tissues
T4a	Tumor penetrates to the surface of the visceral peritoneum†
T4b	Tumor directly invades or is adherent to other organs or structures†,‡
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastases
N1	Metastasis in one to three regional lymph nodes
N1a	Metastasis in one regional lymph node
N1b	Metastasis in two to three regional lymph nodes
N1c	Tumor deposit(s) in the subserosa, mesentery, or nonperitonealized pericolic or perirectal tissues without regional nodal metastasis
N2	Metastasis in four or more regional lymph nodes
N2a	Metastasis in four to six regional lymph nodes
N2b	Metastasis in seven or more regional lymph nodes
Distant Metastasis (M)	
M0	No distant metastasis
M1	Distant metastases
M1a	Metastasis confined to one organ or site (e.g., liver, lung, ovary, nonregional node)
M1b	Metastases in more than one organ/site or the peritoneum

From American Joint Committee on Cancer: AJCC Cancer Staging Manual, *7th ed, New York, 2010, Springer.*

*Note: This includes cancer cells confined within the glandular basement membrane (intraepithelial) or mucosal lamina propria (intramucosal) with no extension through the muscularis mucosae in the submucosa.

†Note: Direct invasion in T4 includes invasion of other organs or other segments of the colorectum as a result of direct extension through the serosa, as confirmed on microscopic examination (e.g., invasion of the sigmoid colon by a carcinoma of the cecum) or, for cancers in a retroperitoneal or subperitoneal location, direct invasion of other organs or structures by virtue of extension beyond the muscularis propria (i.e., respectively, a tumor on the posterior wall of the descending colon invading the left kidney or lateral abdominal wall; or a mid or distal rectal cancer with invasion of prostate, seminal vesicles, cervix, or vagina).

‡Note: Tumor that is adherent to other organs or structures, grossly, is classified cT4b. However, if no tumor is present in the adhesion, microscopically, the classification should be pT1-4a, depending on the anatomic depth of wall invasion. The V and L classifications should be used to identify the presence or absence of vascular or lymphatic invasion whereas the PN site-specific factor should be used for perineural invasion.

chemotherapy combinations used in these studies (semustine, vincristine, and fluorouracil in NSABP C-01; 5-fluorouracil [5-FU] and levimasole in NCCTG) ultimately proved too toxic and were replaced with the fluoropyrimidine 5-fluorouracil and leucovorin (5-FU/LV), a combination that provided an outcome superior to those of the prior agents, when given for a total of 6 months after surgical resection. This regimen was the standard until the early 2000s, when the advent of a number of newer chemotherapeutic agents that produced benefit in patients with metastatic colon cancer drove many researchers in large clinical trials to assess the additional benefit from other combinations.

The original trials in stage III colon cancer had used a strict endpoint of overall survival rate; however, a meta-analysis carried out in follow-up to these studies confirmed that 3-year disease-free survival (DFS) was an acceptable surrogate for 5-year overall survival, and so researchers in subsequent studies of adjuvant colon cancer utilized this endpoint, which has been approved by the U.S. Food and Drug Administration.

One such study demonstrated that the 5-FU prodrug capecitabine was a safe and efficacious alternative to bolus 5-FU/LV in patients with stage III disease. Researchers in three major trials have assessed the efficacy of combining oxaliplatin with a fluoropyrimidine in this group, and researchers in three other trials have assessing the integration of irinotecan into a fluoropyrimidine-based regimen. A number of investigators have attempted to add a monoclonal antibody (so-called targeted therapeutic agents) to cytotoxic chemotherapy in the adjuvant setting, mostly with disappointing results.

The pivotal Multicenter International Study of Oxaliplatin/5-FU/LV in the Adjuvant Treatment of Colon Cancer (MOSAIC) demonstrated that folinic acid and oxaliplatin plus infusional 5-FU/LV (FOLFOX) was superior to 5-FU/LV alone, with improved DFS at 5 years for patients with stage III disease (hazard ratio, 0.78; $P = 0.05$), albeit with an increased risk for peripheral neuropathy, diarrhea, and febrile neutropenia. Certain patients with stage II disease (those presenting with T4 lesions, perforation, obstruction, or undifferentiated tumors) also gleaned a survival benefit with the addition of oxaliplatin, although patients with stage II disease in general experienced no overall improvement in outcome with FOLFOX. The NSABP C-07 study cemented the beneficial role of oxaliplatin-containing regimens as adjuvant therapy for patients with stage III colon cancer. Substituting infusional 5-FU for capecitabine has no detrimental effect on this benefit, as outlined in the Roche No. 16968 ("XELOXA") trial, in which almost 2000 patients were randomly assigned to receive either bolus 5-FU/LV or the XELOX combination of capecitabine (Xeloda) and oxaliplatin (Eloxatin). An incremental increase in 3-year DFS of 4% was noted in the patients who received XELOX, a similar magnitude of benefit to that seen in the prior studies (Table 3).

Although irinotecan-containing and oxaliplatin-containing regimens offer equivalent outcomes in the treatment of metastatic colon cancer, the studies of irinotecan in the adjuvant setting (Pan-European Trials in Alimentary Tract Cancers [PETACC-3] and the Action to Control Cardiovascular Risk in Diabetes [ACCORD] study) have surprisingly failed to demonstrate and survival benefit over 5-FU/LV alone. Similarly, adding the vascular endothelial growth factor (VEGF)–targeted agent bevacizumab (approved in the treatment of metastatic colon cancer) to FOLFOX in the adjuvant setting did not lead to any improvement in DFS or overall survival in two large studies (NSABP C-08 and AVastin adjuvANT [AVANT]). The epithelial growth factor receptor (EGFR)–targeted agent cetuximab, also approved for the treatment of wild-type *KRAS* metastatic colon cancer, had no effect on survival endpoints over chemotherapy alone.

According to the current body of literature, the standard adjuvant protocol for stage III colon cancer is an oxaliplatin-containing regimen (FOLFOX; 5-FU, leucovorin, and oxaliplatin [FLOX]; or XELOX) administered for 6 months after the patient recovers from surgery. Capecitabine or 5-FU/LV alone should be considered in only patients who are not good candidates for oxaliplatin therapy (because of preexisting neuropathy, borderline performance status). Elderly patients should also not be considered for oxaliplatin regimens, inasmuch as metaanalysis of the MOSAIC and NSABP C-07 findings revealed no DFS or overall survival benefit for patients older than 70 years. Typical practice suggests that physically fit elderly patients should nonetheless be offered oxaliplatin, ideally within the FOLFOX regimen.

Stage II Colon Cancer

Although adjuvant chemotherapy has an established role in treatment of stage III colon cancer, there is much less certainty of that role in treatment of stage II disease. As noted in Table 2, the predicted 5-year survival rate in most patients with fully resected stage II disease is excellent, from 80% to 90%, and so adjuvant chemotherapy would have to have a profoundly beneficial effect to reach a statistically significant improvement in survival endpoints. Because most of the original adjuvant chemotherapy trials (including MOASIC and

NSABP C-07) enrolled both patients with stage II and patients with stage III disease, and because the benefits accrued in those trials were clinically and statistically significant only for those with stage III disease, a number of prospective studies dedicated to stage II colon cancer were undertaken. The QUick And Simple And Reliable (QUASAR) trial in the United Kingdom enrolled more than 3000 patients, mostly with stage II disease, and randomly assigned them to receive adjuvant chemotherapy (5-FU/LV with or without levimasole); there was a 3% improvement in 5-year overall survival, although the trend was not statistically significant in patients with stage II disease (hazard ratio, 0.86; 95% confidence interval [CI]: 0.54 to 1.19). The International Multicentre Pooled Analysis of B2 Colon Cancer Trials (IMPACT B2) involved pooled data from more than 1000 patients with T3 N0 disease, assigned to observation or adjuvant 5-FU/LV, and it revealed no difference in 5-year overall survival (80% to 82%). Of the patients enrolled in the MOSAIC trial, as noted previously, 40% had stage II disease. These patients did not glean any additional benefit from adjuvant oxaliplatin therapy; the overall survival rate at 6 years was 87% in both study conditions.

Although most of these studies hint at only a very small benefit from adjuvant chemotherapy in unselected patients with resected stage II disease, there is room for further risk stratification within this group. There are well-established clinicopathologic variables that indicate which patients with stage II disease are at higher risk: namely a T4 primary tumor, bowel obstruction or perforation, poorly differentiated histologic features, inadequate lymph node sampling, perineural or lymphovascular invasion, and markedly elevated CEA level. These are recognized prognostic factors for patients with stage II colon cancer, but data to indicate that adjuvant chemotherapy in these cases will improve outcomes are lacking. Professional society guidelines, including those from the American Society of Clinical Oncology (ASCO) and NCCN®, acknowledge this lack of evidence and stress that medically fit patients with resected stage II colon cancer, who have high-risk features, should be made aware of the risks and benefits of adjuvant chemotherapy in their individual cases.

Advances in the identification of tumor molecular factors have increased the expectation of truly prognostic or predictive biomarker development that can more appropriately risk stratify patients with stage II colon cancer. Research areas with promise include *KRAS* and *BRAF* mutations, 18q deletion, microsatellite instability, hypermethylation, and thymidylate synthase overexpression, and a number of commercial gene assays have been developed (Coloprint, Oncotype DX Colon), but none have thus far provided any predictive utility to guide chemotherapy choices. One subset of patients has been clinically assessed: those with defective mismatch repair (MMR-D) or microsatellite instability (MSI-H), akin to the phenotype of patients with Lynch's syndrome. This subset represents about 15% to 20% of all patients with colon cancer, and they have an excellent prognosis but have exhibited resistance to 5-FU–based chemotherapy. Of note, more modern combination regimens have not been fully explored in this population, and investigations are ongoing.

At this time, unselected patients with resected stage II colon cancer should not routinely be offered adjuvant chemotherapy because the survival benefit is minimal in large studies. It is appropriate to review the risks and benefits of adjuvant therapy with patients, in view of their clinicopathologic characteristics and any available molecular data, and to consider individual cases in the context of comorbid conditions and anticipated life expectancy. This conversation can be facilitated by two web-based tools (Adjuvant! Online and Numeracy), which each provide a visual representation of calculated therapy benefits, although both are informed by somewhat limited datasets and are not necessarily directly applicable to individual patients.

NEOADJUVANT AND ADJUVANT THERAPY FOR RECTAL CANCER

Cancers arising within the rectum, although molecularly similar to other colon cancers, exhibit higher rates of local recurrence after curative intent surgical resection than those arising elsewhere in the

colon. The rationale for this increased recurrence risk is thought to be multifactorial, including both tumor-related factors, such as challenging anatomic location and local lymphatic invasion, and surgery-related factors, such as excision of the mesorectum and extent of lymphadenectomy. Total mesorectal excision (TME) is the preferred approach for all but the smallest rectal tumors and requires meticulous sharp dissection and avoidance of disruption of the mesorectum; this should ideally be undertaken at high-volume surgery centers to minimize variation. A number of studies suggest that TME, in combination with appropriate adjunctive therapies, can reduce local recurrence from rectal cancer to below 10%.

The historically high local recurrence rates in rectal cancer, and their rates of associated morbidity and mortality, prompted the study of both preoperative and postoperative radiation therapy for these tumors in recent decades. Two approaches have been predominantly assessed in the preoperative setting: short-term, high-dose radiation delivered immediately before surgical resection, typically delivered in a dose of 5 Gy daily for 5 days, or combined-modality therapy with radiosensitizing chemotherapy doses concomitant with 50.4 Gy total radiation dose over 5 to 6 weeks, with a subsequent 3- to 4-week interval before surgery. Both approaches are associated with decreased locoregional failure, but only the longer duration chemoradiotherapy has resulted in tumor downstaging, tumor shrinkage, and improved sphincter-preservation. The short-course radiation approach has been assessed in two large European trials: a Swedish study randomly assigned more than 1100 patients to receive 5 days of high-dose radiation (total 25 Gy) 1 week before surgery or to undergone surgery alone; in patients who received radiation, the local recurrence rate was reduced (11% vs 27%, $P < 0.001$), and the overall survival advantage at 5 years was higher (58% vs 48%, $P = 0.004$). A subsequent Dutch study assessed similar radiation doses, although this time in conjunction with quality-controlled TME surgery, and once again demonstrated an improved local recurrence rate (2.4% vs 8.4% at 2 years, $P < 0.001$), but there was no overall survival effect. This perhaps highlights the critical importance of adequate surgery in terms of survival in this disease.

Short-course radiation therapy is commonly used in Europe, but longer duration combination therapy is still preferred in the United States. Initial studies demonstrating its effect were undertaken in the adjuvant setting, in which 5-FU–based chemotherapy with concomitant irradiation proved better than irradiation or surgery alone in preventing both local and distant recurrences. Prolonged infusional 5-FU and twice-daily oral capecitabine are considered equivalent in terms of radiosensitization, although no trial data are available to compare the two. The appropriate sequencing of therapy was assessed in a large German study, in which patients were randomly assigned to receive standard, infusional 5-FU plus irradiation either before or after definitive TME. Preoperative combined modality therapy resulted in a lower rate of local recurrence (6% vs 13% at 5 years), a lower toxicity rate (acute and chronic), and a higher rate of sphincter preservation than did postoperative therapy. Preoperative chemoradiotherapy has thus become the standard of care for patients with stages II and III rectal cancer. Studies are ongoing to assess the effect of additional cytotoxic therapy or biologic agents delivered concomitantly with this standard approach or in the adjuvant setting to reduce distant metastases. Current practice in the United States is to deliver adjuvant FOLFOX to all patients with resected rectal cancer, independent of response to preoperative therapy.

Surveillance

As noted previously, therapy for localized colon and rectal cancers is undertaken with curative intent. Despite this, up to 50% of these patients experience relapse with distant (and occasionally local) metastases. Some patients exhibit only solitary or oligometastatic deposits at this relapse and are candidates for salvage surgery, once again with curative intent, especially if the deposits are confined to the liver or lungs. Long-term DFS and even cure remains possible. Because of this, posttreatment surveillance is deemed important, although data on the effect close surveillance actually has on overall survival are relatively lacking.

BOX 1: NCCN Clinical Practice Guidelines In Oncology (NCCN Guidelines®) for Colon Cancer and NCCN Guidelines® for Rectal Cancer : Surveillance After Curative Surgery

- History and physical examination every 3 to 6 months for 2 years, then every 6 months for a total of 5 years
- CEA every 3 to 6 months for 2 years, then every 6 months for a total of 5 years*
- Chest/abdomen/pelvis CT annually for 5 years for patients at high risk for recurrence
- Colonoscopy at 1 year, unless no preoperative colonoscopy due to obstructing lesion, then colonoscopy in 3 to 6 months
 - If advanced adenoma found, repeat in 1 year
 - If no advanced adenoma found, repeat in 3 years, then every 5 years

*For rectal cancer, consider proctoscopy every 6 months for 3 to 5 years for patient post LAR or transanal excision.

CEA, Carcinoembryonic antigen; *CT,* computed tomographic scan.

Most professional society guidelines mirror those recommended by the NCCN (Box 1), and reflect the reality that recurrence is most common in the first 18 to 24 months after completion of adjuvant therapy: for patients with stage II and III colon cancer and stages I through III rectal cancer, history and physical examination, along with serum CEA if the patient is a candidate for further intervention, every 3 to 6 months for 2 years, then every 6 months for years 3 to 5; colonoscopy within 1 year of resection, unless not completed preoperatively, in which case it should occur within 3 to 6 months, and subsequent colonoscopies dependent on findings at most recent procedure; and chest, abdomen, and pelvis CT annually for 5 years after resection in patients deemed to be at high risk for recurrence (although in practice, the majority of patients undergo this testing). PET-CT is not incorporated into routine surveillance guidelines.

Proctoscopy every 6 months for 3 to 5 years can also be considered for patients with rectal cancer post low anterior resection or transanal excision. The NCCN surveillance recommendations for patients with stage I colon cancer are simply colonoscopy at 1 year after resection and subsequent colonoscopies dependent upon findings.*

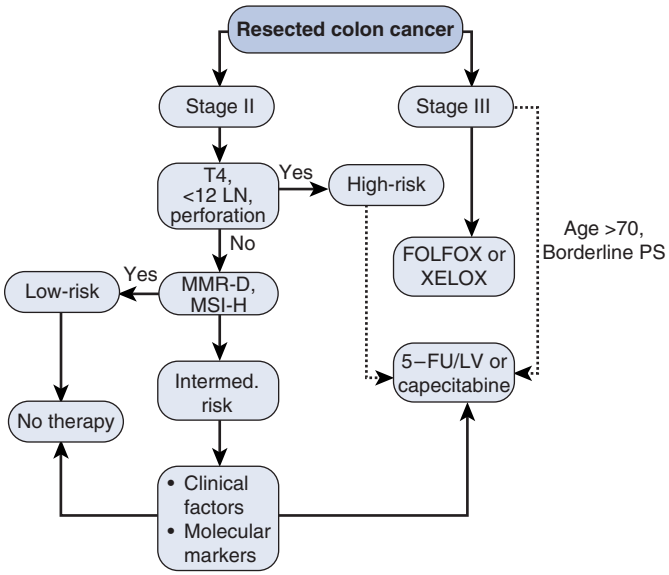

FIGURE 1 Algorithm for use of adjuvant treatment for colorectal cancer. *FOLFOX,* folinic acid, 5-fluorouracil, oxaliplatin; *5-FU/LV,* 5-fluorouracil and leucovorin; *LNs,* lymph nodes; *MMR-D,* defective mismatch repair; *MSI-H,* microsatellite instability; *PS,* performance status; *XELOX,* capecitabine and oxaliplatin.

Recommendations

The magnitude of benefit from adjuvant therapy in these diseases is correlated with the risk of relapse on the basis of pathologic stage, and basic recommendations are outlined algorithmically in Figure 1.

Rectal Cancer. Preoperative chemoradiotherapy is the appropriate treatment; adjuvant chemoradiotherapy is also an option if surgical intervention is urgent, but it is associated with an inferior compliance rate and somewhat increased short- and long-term toxic effects.

Stage III Colon Cancer. Adjuvant chemotherapy for 6 months is the appropriate treatment; FOLFOX and XELOX are considered standards of care in patients fit enough to complete a planned 6-month course.

Stage II Colon Cancer. Adjuvant chemotherapy for 6 months should be discussed as a treatment option and may be recommended for patients with high-risk features. FOLFOX and XELOX are, again, the standard choices in such patients. For patients without these defined high-risk features, other clinical and basic molecular assessments will inform the risk-benefit discussion of adjuvant therapy.

The Management of Colorectal Polyps

Rebecca R. Cannom, MD, MS, and Genevieve B. Melton, MD, MA

OVERVIEW

A colorectal polyp is a macroscopically visible lesion or mass that results from pathologic epithelial elevation of the colonic mucosa. A number of other lesions can present as luminal masses, such as lipomas, carcinoid tumors, and leiomyomas. These lesions are covered by normal mucosa and, by definition, are not polyps. Most colonic polyps are asymptomatic; however, these are of clinical concern because of their malignant potential.

The term *polyp* is nonspecific, and the importance of any one colorectal polyp is based on its histopathology, which determines the patient's risk of malignancy and, therefore, further treatment and follow-up. On the basis of clinical information or, in a few cases, genetic testing, colorectal polyps can be classified as either sporadic or hereditary, with the latter comprising a variety of familial syndromes that are potentially malignant conditions. Larger polyps may necessitate prompt treatment for hemorrhage, obstruction, or intussusception. Flexible endoscopy is a safe and highly effective treatment modality for colorectal polyps that in most cases allows for complete excision or histologic evaluation of the polyp.

HISTOPATHOLOGY AND NATURAL HISTORY OF POLYPS

Hyperplastic Polyps and Serrated Adenomas

Hyperplastic polyps are considered nonneoplastic polyps. They contain an increased number of glandular cells in contrast to adenomas, which have decreased numbers of goblet cells. Hyperplastic polyps occur as a result of normal epithelial cells accumulating on the mucosal surface and typically appear pale and sessile. These are the most frequently identified polyp on flexible sigmoidoscopy, with the rectum the most common location. Conflicting data are found as to whether hyperplastic polyps identified on screening endoscopy confer an increased risk of future colorectal neoplasia; however, if a risk exists, it appears to be very small.

Factors associated with hyperplastic polyps and an increased risk of malignant disease are: large size (>1 cm diameter), right colon hyperplastic lesions, mixed adenoma/hyperplastic histology, more than 20 hyperplastic colonic polyps, familial hyperplastic polyposis, and a family history of colorectal cancer. Serrated adenomas, in contrast, were previously classified as hyperplastic; they are now known to have the phenotype of a sporadic adenoma and are associated with an increased risk of colon cancer. Serrated adenomas are less common (0.5% to 4% of colorectal polyps) in comparison with hyperplastic polyps, frequently have a similar endoscopic appearance as hyperplastic polyps, and can be difficult to distinguish from normal mucosa. Serrated adenomas tend to be larger, have a right-sided location and increased incidence in females, and may have a separate oncogenic pathway, which includes *BRAF* genetic mutations and DNA methylation.

Hamartomas

A hamartoma is an outgrowth composed of normal mature cells that originate from below the mucosa. When sporadic, hamartomas are frequently called juvenile polyps because they are relatively common in children. This second histologic category of colorectal polyps is most commonly associated with one of three autosomal-dominant familial syndromes: Peutz-Jeghers syndrome, juvenile polyposis, and Cowden's syndrome. Although sporadic hamartomatous polyps are not considered premalignant, the aforementioned familial syndromes have a significant rate of cancer development, and therefore, patients with these syndromes should undergo regular colonoscopic surveillance.

The typical phenotype of patients with Peutz-Jeghers syndrome includes perioral hyperpigmentation and multiple hamartomatous polyps located in the small or large bowel. These polyps may cause intussusception, bleeding, or obstruction at a young age. After the third decade, patients with Peutz-Jeghers have a 2% to 13% risk of gastrointestinal (GI) cancer and therefore should undergo regular endoscopic surveillance.

Juvenile polyposis is diagnosed when a young patient has 10 or more hamartomatous GI polyps. Lesions may occur anywhere within the GI tract, although they are frequently in the colon. These polyps may twist and auto amputate, causing bleeding. Colon cancer affects up to 50% of those afflicted with juvenile polyposis and may occur in the fourth decade of life.

Cowden's disease, also known as multiple hamartoma syndrome, is characterized by hamartomatous neoplasms of the skin and mucosa, GI tract, bones, central nervous system, eyes, and genitourinary tract. A significant risk exists for skin, thyroid, endometrial, and breast cancer in Cowden's syndrome. Emerging evidence suggests an increased incidence of colorectal cancer as well.

Adenomas

Adenomas are the most common neoplastic polyp identified in patients undergoing colonoscopy, representing 50% to 65% of all colonic polyps. Approximately 10% to 25% of asymptomatic patients at average risk and older than 50 years have an adenomatous polyp. Histology of these adenomas is most commonly tubular (65% to 85%), but they may also be tubulovillous (10% to 25%) or villous (10%). Adenomas differ from hyperplastic polyps in that adenomas have cellular atypia. Therefore, identification of an adenoma on flexible sigmoidoscopy is an indication for a complete colonoscopy. Advanced adenomas are those that are greater than 1 cm or have villous architecture, severe dysplasia, or carcinoma. The prevalence rate of advanced adenomas ranges from 3.5% to 9.5%, depending on gender and age.

The molecular alterations that lead to the development of colorectal polyps, and colorectal cancer, known as the adenoma-carcinoma sequence, are increasingly understood. This relationship is supported by the following data: 1, almost all colon cancers arise within an adenoma; 2, the incidence rate of synchronous adenoma in colon cancer resection specimens is approximately 30%; 3, the risk of colon cancer increases with larger and increasing numbers of adenomatous polyps; 4, the incidence of colorectal cancer in patients with familial adenomatous polyposis is high; and 5, the risk of cancer in unresected polyps is 4% after 5 years and 14% after 10 years.

Most sporadic colorectal cancers (approximately 80%) develop from adenomas. The adenoma-carcinoma sequence, also known as the loss of heterozygosity or chromosomal instability pathway, is a cascade of sequentially accumulated genetic mutations. Our understanding of the genetic alterations leading to colon cancer represents one of the most advanced of all solid malignancies. One of the first mutations leading to sporadic adenomatous polyps is loss of the tumor suppressor adenomatous polyposis coli (APC) gene, the same mutation as in familial adenomatous polyposis (FAP). The next gene thought to be affected in the adenoma-carcinoma sequence is the oncogene *kras*, followed by the loss of deleted in colon cancer (DCC), which likely plays a key role in transitioning to an advanced adenoma. A mutation in the *p53* gene, which regulates the cell cycle that allows for time for either DNA repair or apoptosis, is the final step in development of cancer from an adenoma (Figure 1).

Sessile villous adenomas are frequently found in the rectum and may not be amenable to endoscopic polypectomy because of their size. For lesions in the distal rectum, transanal excision is generally preferred. For adenomas located too proximal for transanal excision, transanal endoscopic microsurgery (TEM) and now transanal minimally invasive surgery (TAMIS) are excellent means for local excision. An anterior resection is indicated in a patient with reasonable surgical risk with a rectal lesion that is not amenable to the aforementioned techniques or with a lesion that has concerning features for invasive malignancy, particularly palpable firmness.

Identification of an adenoma should prompt a complete colonoscopy as a result of the 20% to 40% risk of proximal neoplastic lesions. Recommendations for follow-up colonoscopy are made based on the number, size, and histopathology of the adenomas and other clinical factors such as personal risk factors and family history. Removal of adenomas reduces future colorectal cancer and the development of advanced adenomas.

COLONOSCOPIC POLYPECTOMY

Polypectomy has proven to be an effective means of colon cancer prevention, allowing for identification, removal, and histopathologic evaluation of the polyp. Most colorectal polyps are treated with endoscopic polypectomy, either with biopsy forceps or snare polypectomy, both of which can be either hot with electrocautery or cold. Snare excision typically provides a larger specimen, and the stalk (or base) can be evaluated histopathologically to better define the level of superficial malignancy if present. Large lesions may be removed with a piecemeal excisional technique, which allows for sequential excision of the entire lesion. A submucosal lift with the injection of saline solution (with or without epinephrine or methylene blue) into the submucosa can be helpful to remove larger lesions. This

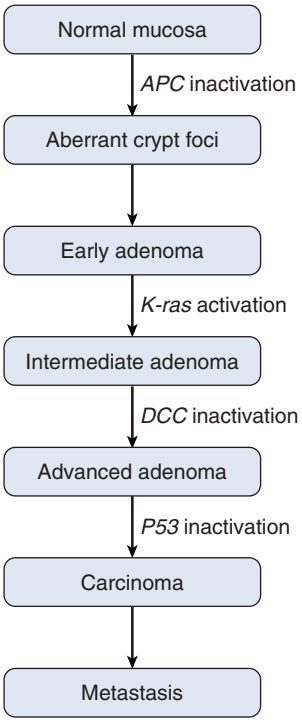

FIGURE 1 Adenoma to carcinoma sequence.

technique improves the safety of polypectomy by increasing the distance between the mucosa and the muscularis propria. It is critical to tattoo the area with India ink when large or suspicious polyps are removed because typically further endoscopic evaluation or resection is indicated.

Relative contraindications to colonoscopic polypectomy include anticoagulation therapy, bleeding diathesis, acute colitis, and evidence of invasive malignancy, such as central ulceration, a hard or fixed lesion, necrosis, or inability to raise the lesion with submucosal injection.

Complications related to colonoscopic polypectomy are uncommon and typically minor. The risk of death is 1 in 14,000. The most common serious complications are bleeding and perforation. Bleeding occurs in 4.8 in 1000 patients after colonoscopic polypectomy and may occur immediately or days later when clot dissolution occurs. Most postpolypectomy bleeds stop spontaneously and, when persistent, can usually be controlled with endoscopic clipping or cauterization. Rarely, interventional angiography or colectomy is necessary. Bleeding risk should be minimized by stopping warfarin and aspirin 5 days before polypectomy and clopidogrel 7 days before and possibly holding these agents for several days after polypectomy, although stopping any of these agents must be tailored to the patient's risk profile (e.g., patient with a mechanical mitral valve with a high risk of stroke off anticoagulation therapy).

Colonic perforation after polypectomy occurs in 0.1% of patients, most of whom undergo successful treatment with conservative treatment that includes inpatient observation, bowel rest, and intravenous antibiotics. These patients need to be followed closely as inpatients for any sign of clinical deterioration warranting laparotomy. One alternative approach is early laparoscopic primary repair of the defect, with colonoscopic assistance if the perforation is not easily identified on laparoscopy. The patient should be in lithotomy position, and if colonoscopy is necessary, minimal insufflation with carbon dioxide should be used. Contraindications to this approach include peritonitis, malignancy, and presence of significant fecal soilage.

Postpolypectomy syndrome has been reported to occur in up to 0.3% of patients after polypectomy, most often when cauterization has been used. The etiology is believed to be that the cautery causes a microperforation in the colonic wall and results in bacterial translocation. Patients typically present anywhere from 0 to 3 days after the polypectomy with abdominal pain and tenderness, fever, and leukocytosis. On computerized tomographic scan, fat stranding is typically seen in the mesentery and the colonic wall of the polypectomy site is thickened; however, unlike with colonic perforation, pneumoperitoneum is not present. Patients should be treated with bowel rest, intravenous antibiotics, and close observation until symptoms resolve. Recognition of postpolypectomy syndrome is important to avoid unnecessary laparotomy in these patients who may present with localized peritonitis.

TABLE 1: Current guidelines for colorectal cancer screening after polypectomy

Risk category	Recommended colonoscopy interval
1-2 Small tubular adenomas	5-10 years
3-10 Small adenomas or 1 Adenoma >1 cm or A polyp with villous or High-grade dysplasia	3 years
>10 Adenomas	<3 years
Sessile adenomas removed piecemeal	3-6 months

Recommendations for surveillance after polypectomy are based on the risk of recurrent neoplasia after the index polypectomy. In 2008, the American Cancer Society, in collaboration with the U.S. Multisociety Task Force on Colorectal Cancer and the American College of Radiology, updated their guidelines for screening and surveillance for colorectal cancer and polyps (Table 1).

Increased risk of neoplasia is defined as: (1) three or more adenomas removed; (2) high-grade dysplasia present in polyp; (3) villous features in polyp; (4) adenoma of 1 cm or more; or (5) large adenoma removed piecemeal. These patients should have a repeat colonoscopy at 3 years. Lower risk is defined by one or two (<1 cm) tubular adenomas without high-grade dysplasia. These patients may safely defer colonoscopy to 5 to 10 years (if no family history). The presence of hyperplastic polyps does not change the recommendation of 10-year follow-up for those patients with average risk (Figure 2).

Colonoscopy is the best method for detection and removal of most polyps, but the miss rate of polyps greater than 1 cm may be as high as 14%. However, the miss rate of cancer is considered less than 5%. Evidence shows that slower withdrawal of the colonoscope to at least 6 minutes improves neoplasia detection rates. Because of the aforementioned miss rate, if patients have development of symptoms such as bleeding, abdominal pain, or change in bowel habits, repeat colonoscopy is typically warranted.

APPROACH TO THE MALIGNANT POLYP

Up to 5% of polyps that appear benign contain invasive cancer. This risk of cancer correlates with increasing polyp size such that polyps greater than 2 cm have an approximately 30% risk of cancer. For this reason, the colon should be tattooed at the site of any large polyp or any suspicious polyp in the event that further treatment and evaluation are necessary.

A malignant polyp is defined as adenocarcinoma that invades into, but no deeper than, the submucosal layer of the bowel wall,

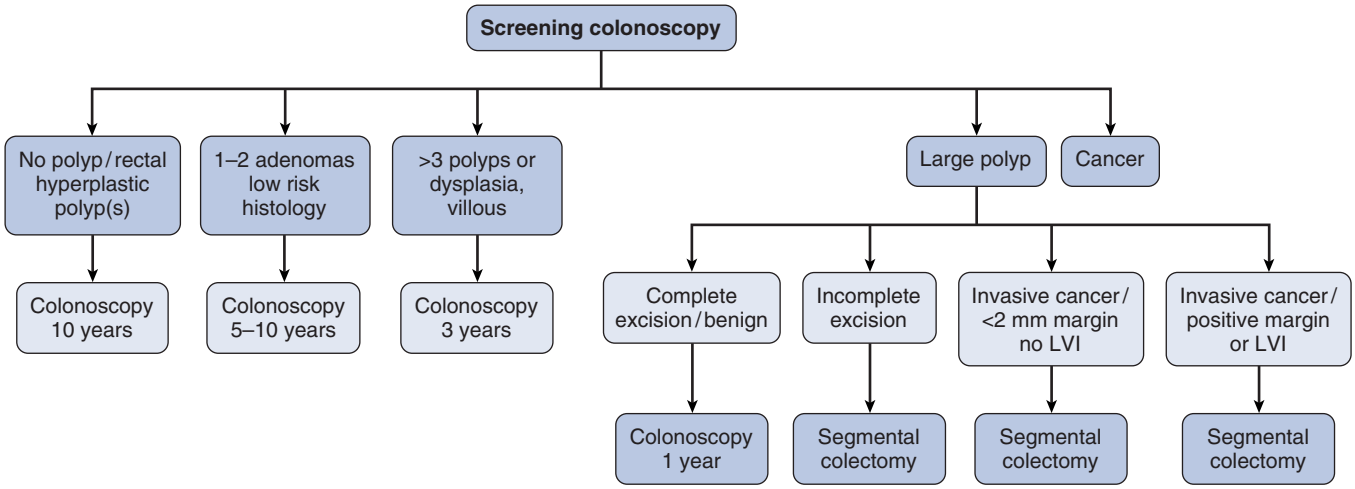

FIGURE 2 Algorithm for outcomes with screening colonoscopy. *LVI,* Lymphovascular invasion.

BOX 1: Summary of malignant colorectal polyps that should have an oncologic bowel resection

A. Lesions in Colon
- a. Pedunculated Haggitt level 4 with invasion into distal third of submucosa, or pedunculated lesions with lymphovascular invasion
- b. Lesions removed with margin <2 mm
- c. Sessile lesions removed piecemeal
- d. Sessile lesions with depth of invasion into distal third of submucosa (Sm3)
- e. Sessile lesions with lymphovascular invasion

B. Lesions in Middle Third and Upper Third Rectum
Same as lesions in colon

C. Lesions in Distal Third Rectum
- a. Pedunculated Haggitt level 4 with invasion into distal third of submucosa, or pedunculated lesions with lymphovascular invasion
- b. All sessile lesions

An alternative may be a per anal full-thickness excision plus chemoradiation.

TABLE 2: Pathologic features of malignant polyps

Haggitt level	Submucosal invasion in polyp head (1), neck (2), stalk (3), and base (4) or submucosal invasion in a sessile polyp (4)
Submucosal invasion	Invasion in upper third of submucosa (Sm1), middle third (Sm2), or deep third (Sm3)
Tumor grade	Well, moderately, or poorly differentiated
Tumor budding	Absence or presence of clusters of malignant cells in the submucosa remote from the main site of submucosal invasion

Listed in order of escalating risk of lymph node metastasis.

making the lesion a T1 colon cancer. This is different than a polyp containing carcinoma in situ or high-grade dysplasia, in which changes are confined to the mucosa and lamina propria. These entities have no metastatic potential and are cured with complete polypectomy.

The main reason to proceed with formal segmental resection when a malignant polyp has been removed with negative margins is to harvest the associated mesenteric lymph nodes. The risk of lymph node metastasis in malignant polyps ranges from 8% to 15%. In some patients, this risk may approach the mortality rate associated with undergoing a formal resection.

Traditionally, the Haggitt level was used to classify malignant polyps and to predict lymph node metastasis (Box 1); however, the risk of lymph node metastasis in Haggitt level 4 lesions varies based on the depth of submucosal invasion. Because of this, the submucosal invasion classification is being increasingly used. The depth of submucosal invasion is stratified into three levels: Sm1 (upper third of submucosa), Sm 2 (middle third), and Sm3 (lower third). Haggit levels 1 to 3 correspond with Sm1, but Haggit level 4 can be Sm1, Sm2, or Sm3. A malignant polyp with a Sm3 classification is an indication for formal resection. Other factors predictive of lymph node metastases or recurrence are high tumor grade, extensive tumor budding, and lymphovascular invasion (Table 2). In the absence of any of these features, the risk of adverse outcome is less than 1%; however, if a malignant polyp has one of these features, that risk increases to 20%. If two or more of these adverse features are present, the risk of adverse outcomes rises to 36%. Further evaluation of these features may better define patients who can be spared major surgery.

Criteria for close surveillance after endoscopic removal of a malignant polyp include: complete excision, a microscopic margin of greater than 2 mm, no lymphatic or vascular invasion, moderate to well differentiation, Haggit level 1 to 3, or Sm level 1 to 2.

All other malignant polyps that do not meet the aforementioned criteria should be considered for surgical resection. However, even with some high-risk features, patients with serious medical comorbidities may be best managed with close surveillance and nonsurgical treatment. An alternative to patients at high risk with a malignant rectal polyp may be per anal full-thickness excision (either with transanal excision or TEM) with adjuvant chemoradiation.

Management of Peritoneal Surface Malignancy

Marcello Deraco, MD, Dominique Elias, MD, PhD, C. William Helm MB.BChir, Olivier Glehen, MD, PhD, and Paul H. Sugarbaker, MD, FACS, FRCS

INTRODUCTION

Peritoneal metastases and peritoneal mesothelioma are included in a group of diseases collectively referred to as peritoneal surface malignancy. Over the past three decades, there has emerged an increasing optimism concerning improved management of cancer dissemination within the abdomen and pelvis. The results of treatment with systemic chemotherapy are poor, with an expected median survival time between 1 and 2 years. With a combination of cytoreductive surgery (CRS) and hyperthermic perioperative chemotherapy (HIPEC), long-term survival has been achieved in selected patients and the median survival of most diseases with peritoneal metastases (PM) has been doubled as a result of this multimodality treatment. In this chapter, five different diseases that frequently result in PM are discussed. The prognostic indicators useful in the selection of patients for treatment, the nature of these surgical interventions, and the results of treatment are presented.

PSEUDOMYXOMA PERITONEI AND PERITONEAL METASTASES FROM APPENDICEAL MALIGNANCY

The appendiceal malignant diseases constitute a wide spectrum of biologic aggressiveness. The tumors arising within this structure can be minimally aggressive or have invasive and metastatic capability. If a low-grade appendiceal malignancy is removed within an intact mucocele, recurrence does not occur. If rupture of the wall of the appendix occurs with either low-grade or high-grade disease, the tumor cells within are likely to disseminate to peritoneal surfaces. Sometimes, determination of whether intraperitoneal spread of mucus and neoplastic cells has occurred may be difficult or impossible. If the diagnosis of peritoneal dissemination of a high-grade or low-grade appendiceal malignancy disease has been established, a new treatment with curative intent is indicated in both groups of patients. Cytoreductive surgery is combined with HIPEC as a comprehensive management plan. In more than 1000 patients treated at the Washington Cancer Institute, the survival by quantitative prognostic indicators has been determined.

Management of Appendiceal Neoplasms With Peritoneal Dissemination

Current standard of care for patients with appendiceal mucinous neoplasms requires a comprehensive management plan. For patients with disseminated peritoneal adenomucinosis (DPAM), the first intervention is CRS and HIPEC. For patients with peritoneal mucinous carcinoma (PMCA), the first intervention is a short course of systemic chemotherapy with 5-fluorouracil and oxaliplatin. Cytoreductive surgery is a combination of visceral resections and peritonectomy procedures. After all visible evidence of abdominal and pelvic tumor has been surgically removed, an attempt to eradicate microscopic disease and small tumor nodules occurs with HIPEC. The CRS involves a series of visceral resections and peritonectomy procedures. The various combinations of surgical procedures are listed in Table 1. It should be emphasized that no organ or peritoneal surface is resected unless visible tumor is present. Oftentimes, with DPAM, the mucinous tumor is noninvasive and can be gauze débrided away from the involved visceral or parietal peritoneum; in this situation, the organ or peritoneal surface is not resected. These procedures have been diagrammed and described in several prior publications.

After CRS, several different local-regional chemotherapy regimens may be used to eradicate residual tumor nodules and free tumor cells within the peritoneal cavity. Over the past 23 years, an evolution of perioperative chemotherapy treatments has occurred at the Washington Cancer Institute. The regimen currently in use is hyperthermic intraperitoneal doxorubicin (15 mg/m^2) and mitomycin C (15 mg/m^2) plus systemic 5-fluorouracil (400 mg/m^2). As shown in Figure 1, *A*, an open method for chemotherapy administration that allows for manual distribution of the heat and chemotherapy solution is often used. In some clinical settings, a closed method may also be effective (Figure 1, *B*).

Outcome With Histopathology as a Quantitative Prognostic Indicator

The survival of patients with mucinous appendiceal neoplasm, when treated in a uniform fashion with CRS and HIPEC, is profoundly affected by the tumor's histologic type. With DPAM, noninvasive peritoneal surface tumor may become widely disseminate on peritoneal surfaces. In contrast, PMCA shows the same propensity for widespread intraperitoneal dissemination that is facilitated by large quantities of mucus, but this histopathology shows invasion into surrounding structures. Also, an intermediate (often called hybrid) type of disease exists in which 95% or more of the fields of view show DPAM but areas of PMCA exist. In the histologic assessment of prognosis presented in Figure 2, the intermediate type is included

with the PMCA group. The figure includes all patients with a complete and an incomplete cytoreduction that are in the database.

Outcome With Peritoneal Cancer Index as a Quantitative Prognostic Indicator

The peritoneal cancer index (PCI) is a quantitative prognostic indicator that is determined at the time of surgical exploration of the abdomen and pelvis. The PCI is determined according to a diagram to be between 0 and 39 (Figure 3).

Appendiceal neoplasms that show the DPAM histology have an excellent prognosis, with 90% survival rate at 20 years follow-up if the PCI is less than 20. With DPAM histology with PCI greater than 20, the survival rate is 60% at 20 years. When the appendiceal neoplasm shows PMCA histology, the PCI continues to show a statistically significant effect on the survival rate ($P = 0.0004$).

TABLE 1. Visceral resections and peritonectomy procedures that may be required for complete cytoreduction

Cytoreductive surgery	
Visceral Resections	*Peritonectomy Procedures*
Resection of prior abdominal incisions	Anterior parietal peritonectomy
Greater omentectomy ± splenectomy	Left upper quadrant peritonectomy
Rectosigmoid colon resection	Pelvic peritonectomy
Hysterectomy and oophorectomy	Right upper quadrant peritonectomy
Cholecystectomy	Lesser omentectomy with stripping of the omental bursa

Outcome With Completeness of Cytoreduction as a Prognostic Indicator

The completeness of cytoreduction score (CC score) functions as a major quantitative prognostic indicator for patients with mucinous appendiceal neoplasms. The assessment is performed after the cytoreductive surgery is complete. For mucinous appendiceal neoplasms, a complete cytoreduction is defined as CC 0 or CC 1 with residual tumor nodules less than 2.5 mm. The survival of patients with appendiceal neoplasms by CC score has a profound effect on 10-year survival rates for both DPAM (complete vs incomplete, 75% vs 25%) and PMCA (complete vs incomplete, 27% vs 6%).

PERITONEAL METASTASES OF COLORECTAL ORIGIN

Outcome of Peritoneal Metastases Treated With Modern Systemic Chemotherapy

In patients with primary colorectal cancer (CRC), 5% to 10% present with synchronous peritoneal metastases (PM). Unfortunately, in 75% of these patients, PM are not diagnosed before the CRC resection. This fact shows the unsatisfactory preoperative radiologic detection of PM. With treatment with systemic chemotherapy, data from different registries show that the median survival time of these patients is currently only 8 months. The survival time is estimated at 4 months in the absence of surgery but at 14 months if the primary CRC is resectable.

In data from randomized trials in patients with many different anatomic sites of CRC metastases, the presence of PM is a poor prognostic factor. With folinic acid, 5-fluorouracil, and oxaliplatin (FOLFOX) or folinic acid, 5-fluorouracil, and irinotecan (FOLFIRI), median survival time was 12.7 months for patients with PM, whereas it was 17.6 months for patients without PM. All patients received the same mean number of treatment cycles in the two groups, indicating a relative resistance to treatment in the PM group. Addition of a targeted therapy (bevacizumab) prolonged median survival time by 3 months. In conclusion, systemic chemotherapy is a palliative treatment of PM of short duration, and patients with PM have an especially poor prognosis.

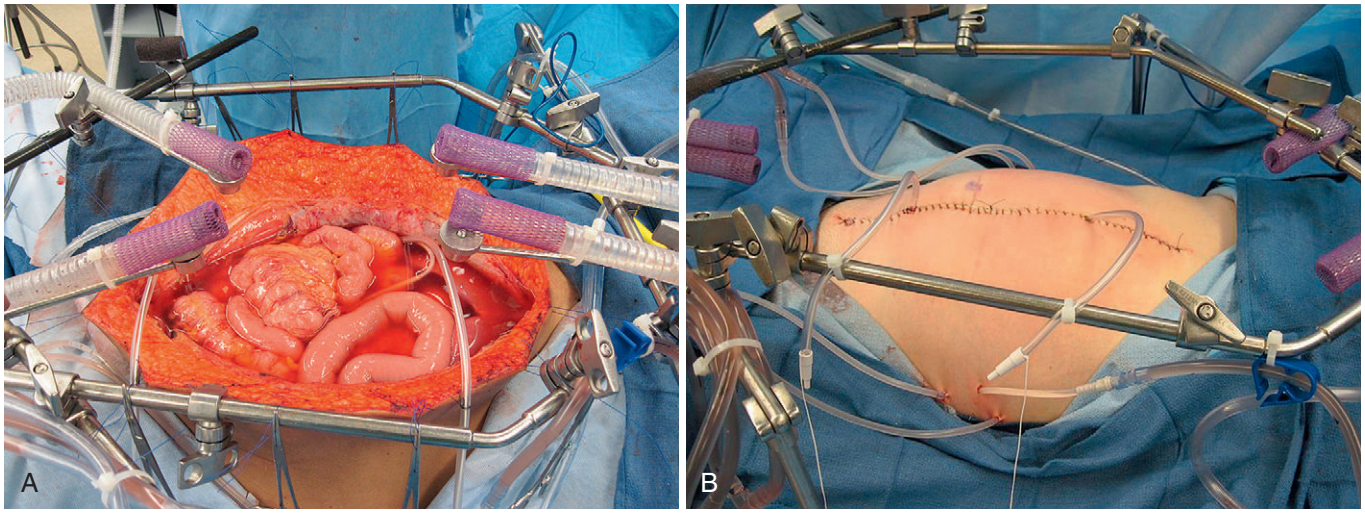

FIGURE 1 **A,** Hyperthermic intraperitoneal chemotherapy administered with an open technique allows continued manipulation of the abdominal and pelvic contents to achieve uniform distribution of heat and chemotherapy. A vapor barrier above the chemotherapy solution is created by four smoke aspirators. **B,** The closed method for hyperthermic perioperative chemotherapy is preferred by some surgeons.

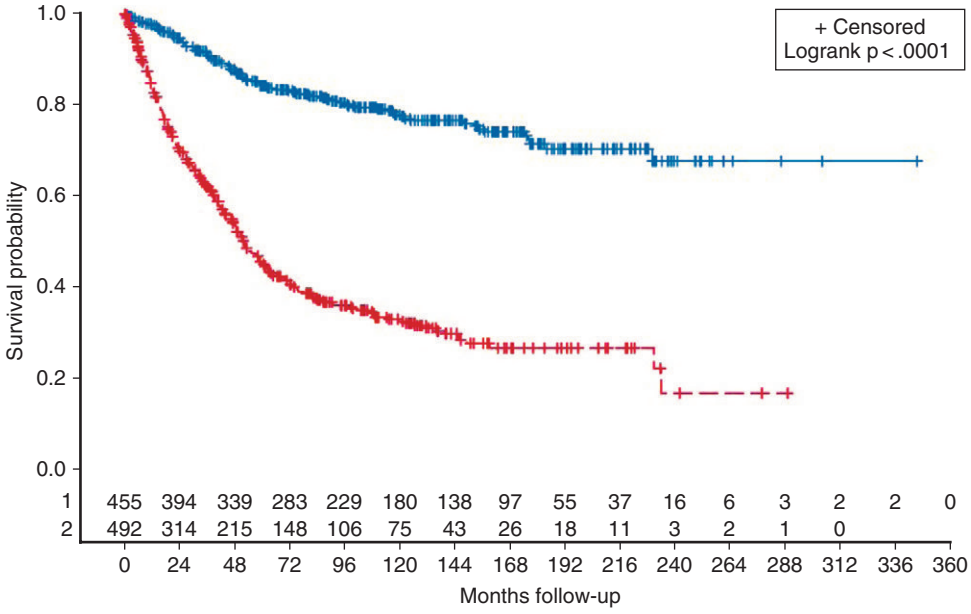

FIGURE 2 Peritoneal surface malignancy of appendiceal origin. Survival rate by histopathology of patients treated at Washington Cancer Institute. The graph includes all patients. The *blue line* (N = 455) indicates patients with disseminated peritoneal adenomucinosis (DPAM). The *red line* (N = 492) indicates patients with peritoneal mucinous adenocarcinoma (PMCA) and includes patients with intermediate type histology. *(From Sugarbaker PH: Epithelial appendiceal neoplasms,* Cancer J *15:225–235, 2009.)*

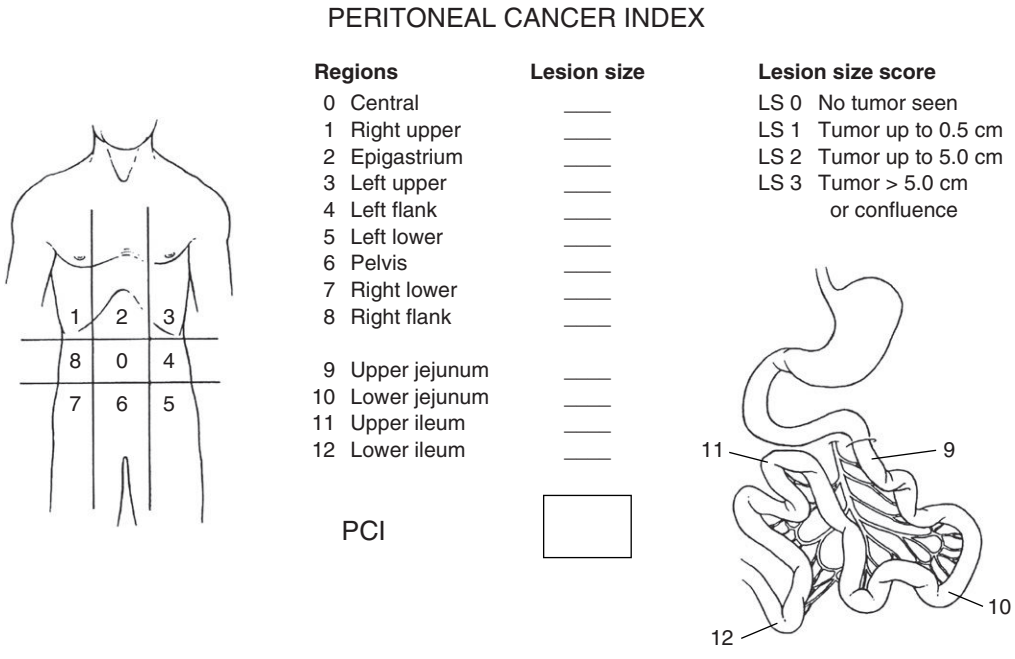

FIGURE 3 Diagram for determining peritoneal cancer index *(PCI)* at the time of abdominal exploration. The distribution of tumor is recorded in 13 abdominal and pelvic regions, and the extent of disease is estimated in each region.

Complete Cytoreductive Surgery With Hyperthermic Perioperative Chemotherapy for Colorectal Cancer Peritoneal Metastases

This new approach, when complete cytoreductive surgery (CCRS) is possible, allows cure for approximately 25% of patients. The rationale requires resection of PM measuring more than 1 mm and then treatment of the remaining peritoneal disease with HIPEC. HIPEC penetrates into tumor nodules on peritoneal surfaces only 1 to 2 mm in depth; therefore, it can only be used after resection of the macroscopic disease. In animal models, many demonstrations suggest the efficacy of this approach. For example, in rats with PM of colon origin, median survival time was 43 days with CCRS alone, 75 days ($P = 0.003$) with CCRS + HIPEC (mitomycin, 15 mg/m^2), and 97 days with CCRS + HIPEC (mitomycin, 35 mg/m^2).

Concerning HIPEC technology for CRC PM, the two main strategies are: (1) use of intraperitoneal mitomycin C over a long duration (≥60 minutes) at 41°C; and (2) use of intraperitoneal oxaliplatin with a shorter duration (30 minutes) at a higher temperature (43°C) and with the addition of systemic 5-fluorouracil.

Outcome of Treatment for Peritoneal Metastases From Colorectal Cancer

The French Registry published in 2010 a report on the cumulative experience (523 patients) of 23 centers from 1990 to 2007. Of course, these early data showed less than optimal results. Median survival time was 33 months, and 5-year survival rate was 30%, with a postoperative mortality rate of 3% and a grade 3 to 4 morbidity rate of 30% during the first 30 days.

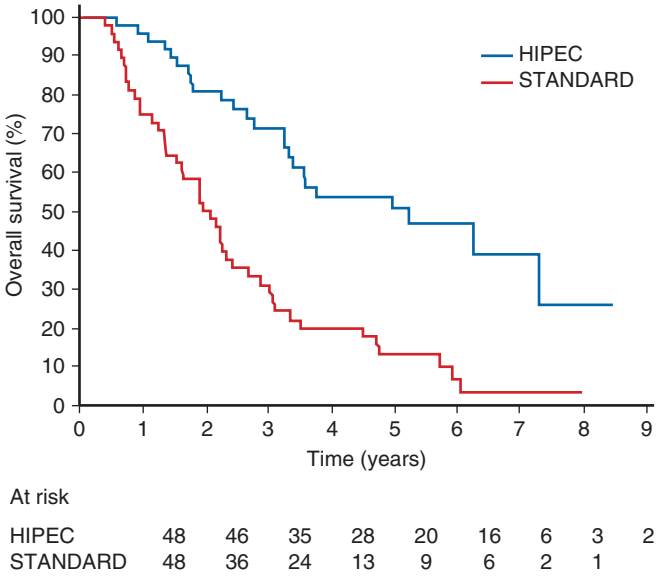

FIGURE 4 Overall survival rates of 48 patients with peritoneal metastases treated with complete cytoreductive surgery plus hyperthermic perioperative chemotherapy *(HIPEC)*, compared with 48 patients with similar peritoneal metastases conventionally treated with systemic chemotherapy. *(From Elias D, Lefevre JH, Chevalier J, et al: Complete cytoreductive surgery plus intraperitoneal chemohyperthermia with oxaliplatin for peritoneal carcinomatosis of colorectal origin,* J Clin Oncol *27:681–685, 2008.)*

Two major principles of management were demonstrated: (1) the need for CCRS; and (2) a low extent of disease measured by the PCI. After a CC-2 or CC-3 resection, the results were similar to those obtained with palliative chemotherapy alone. Also, when the PCI was more than 20, the results of treatment were similar to those obtained with palliative chemotherapy alone.

A retrospective study reported by Elias and coworkers compared patients with PM who had two different treatment strategies. All patients underwent a laparotomy that indicated that they had resectable PM. Forty-eight were conventionally treated with systemic chemotherapies, and 48 were treated with CCRS + HIPEC in an experienced center. After a mean follow-up period of 63 months, the 5-year overall survival rates were 13% in the systemic chemotherapy group and 51% in the CCRS + HIPEC group ($P < 0.05$; Figure 4). A randomized trial (acronym: Prodige 7) is currently comparing CCRS alone versus CCRS plus HIPEC.

Currently, the indications for CRS plus HIPEC include: (1) patients with a good performance status; (2) patients presenting with minimal or moderate PM (PCI ≤20) and without other sites of metastases (except for a few liver metastases that are easily resectable); and (3) patients whose disease does not show rapid progression during treatment with systemic chemotherapy.

Improving Survival With Treatment of a Minimal Extent of Disease

Because the survival results yielded by CCRS + HIPEC are high for patients with a low PCI (indicating a small extent of disease), it is logical to propose this treatment early in the natural history of PM. Unfortunately, early PM does not produce symptoms, radiologic imaging is unreliable, and there are no reliable biomarkers. The only way to detect early PM is to perform second-look surgery. This strategy is currently proposed for patients at high risk for progression of PM. A review of the literature and a prospective study that the authors conducted on this topic allowed definition of the "high-risk" patients as: (1) patients with perforation at the time of resection of the primary tumor, (2) patients with ovarian metastasis, and (3) patients with minimally resected or residual PM.

Currently, sufficient evidence exists to consider patients for second-look surgery with the following features at the moment of the curative surgery of the primary: ovarian metastases, perforated tumor, and synchronous resected PM. For the three groups of patients at high risk defined previously, PM were documented at second-look surgery performed at 1 year in 60% of patients. The extent of PM was minimal, and CCRS + HIPEC was performed with a low complication rate. Experience suggested that HIPEC was indicated even if no macroscopic PM was detectable. The survival results of the 41 patients at high risk treated with this second-look strategy are promising, with a 5-year survival rate of 90%, a disease-free survival rate of 44%, and only 17% with relapse inside the peritoneum. Currently, an ongoing randomized trial (acronym: Prophylochip) is comparing, after 6 months of standard systemic chemotherapy in these patients at high risk, the traditional strategy (watchful waiting) with the new strategy (second-look surgery plus HIPEC).

DIFFUSE MALIGNANT PERITONEAL MESOTHELIOMA

Diffuse malignant peritoneal mesothelioma (DMPM) is an aggressive malignancy that arises from mesothelial cells within the serosal lining of the peritoneum. It is the most common primary peritoneal tumor. Throughout its natural history, it remains confined to the peritoneal cavity in most patients. It rarely metastasizes systemically; however, in advanced stages, direct extension to the pleural cavity may be noted. Most patients die of complications directly related to intra-abdominal disease progression, usually bowel obstruction. Incidence rates among men range from 0.5 to about 3 cases per million population. Incidence of DMPM has been rising worldwide since 1970, and a 5% to 10% increase in annual mortality rate is estimated worldwide at least until 2020. In contrast to pleural mesothelioma, only 58% and 20%, respectively, of men and women with DMPM have past asbestos exposure.

Patients are usually diagnosed with an advanced disease, and the most common symptoms are ascites and abdominal pain accompanied by weakness, weight loss, anorexia, abdominal mass, fever, diarrhea, and vomiting. Computed tomographic scan shows ascites, diffuse abdominal masses, and peritoneal thickening.

According to the World Health Organization (WHO) classification, peritoneal mesothelioma can be broadly categorized as benign-borderline mesothelioma including multicystic and well-differentiated papillary mesothelioma or DMPM. Within the DMPM category, the most frequent variants are epithelial, sarcomatoid, and biphasic. Differential diagnosis of DMPM is challenging and must be distinguished from benign reactive lesions, metastatic neoplasms, and particularly adenocarcinomas. Immunohistochemical studies represent an important diagnostic aid and depend on the use of panels of markers that may be positive (thrombomodulin [CD141], calretinin, keratin 5/6, D2-40, podoplanin, mesothelin, and Wilms' tumor 1 protein [WT1]).

Recently, a staging system form DMPM has been proposed. The PCI is used to define the T category: T1 (PCI 1-10), T2 (PCI 11-20), T3 (PCI 21-30), and T4 (PCI 31-39). T1 N0 M0 was designated as stage I. T2 and T3, in absence of N1 or M1 disease, were categorized as stage II. T4, N1, and M1 were categorized as stage III. The 5-year survival rates associated with stage I, II, and III diseases were 87%, 53%, and 29%, respectively. Currently, there are efforts to validate this proposal for a staging system through the accumulation of data within a prospective multiinstitutional registry.

Treatment of Diffuse Malignant Peritoneal Mesothelioma

This disease is generally considered nonchemoresponsive. Numerous single-drug and combination regimens have been tested over the past decades with modest results. Cisplatin alone and pemetrexed in association with cisplatin are the most effective regimens, with response rates of 12% to 28%. The multimodality treatment consisting of CRS and HIPEC evolved during the last two decades as the most effective approach for DMPM, with more than 50% long-term survival rates. Currently, the combined treatment of CRS and HIPEC is considered the gold standard for DMPM management.

Cytoreductive Surgery and Hyperthermic Perioperative Chemotherapy

Cytoreductive surgery with peritonectomy procedures and multivisceral resections allows the removal of all the visible tumor implants (macroscopic cytoreduction). Currently, patients with normal-appearing lymph nodes receive retroperitoneal and pelvic lymph node biopsies, whereas regional lymphadenectomy is suggested in patients with lymph node positive disease.

Local-regional drug administration with hyperthermia treats the free tumor cells and very small residual cancer nodules. At the authors' institution, the HIPEC is performed with the closed abdomen technique with cisplatin (45 mg/L of perfusate) and doxorubicin (15 mg/L of perfusate) for 90 minutes at a temperature of 42.5°C. Patients over 70 years of age or with relevant comorbidities and those who had undergone previous systemic chemotherapy or extensive cytoreductive surgery received a 30% dose reduction of both drugs. Perfusate volume is 4 to 6 L, and mean flow is 700 mL/min.

Results of Treatment of Diffuse Malignant Peritoneal Mesothelioma

Because DMPM involves a widespread tumor distribution on nearly all peritoneal surfaces and because most patients are diagnosed with advanced disease, a complete parietal peritonectomy is almost always required. Visceral resections are required when there is tumor encasement. The combined approach consisting of CRS and HIPEC has modified the natural history of DMPM with a dramatic improvement in outcomes. An international multiinstitutional study testing the combined treatment reported a median survival time of 53 months with 5-year overall survival of 47% (Figure 5). The most significant prognostic factors independently associated with improved survival were: epithelial subtype compared with the biphasic or sarcomatoid, the absence of lymph node metastasis, the completeness of cytoreduction scores, and HIPEC versus no HIPEC. Females consistently show a better prognosis.

Treatment of Benign/Borderline Peritoneal Mesothelioma

In the surgical management of benign/borderline peritoneal mesothelioma, a complete parietal peritonectomy is almost always required, whereas only rarely are visceral resections necessary. Fertility-sparing surgery should be considered in young patients. The 5-year overall and progression-free survival rates were 90% and 79%, respectively, at the National Cancer Institute of Milan. In the authors' experience, that has been corroborated at other centers, definitive tumor eradication by means of peritonectomy procedures and HIPEC is recommended as the optimal treatment to prevent disease progression or transition to DMPM.

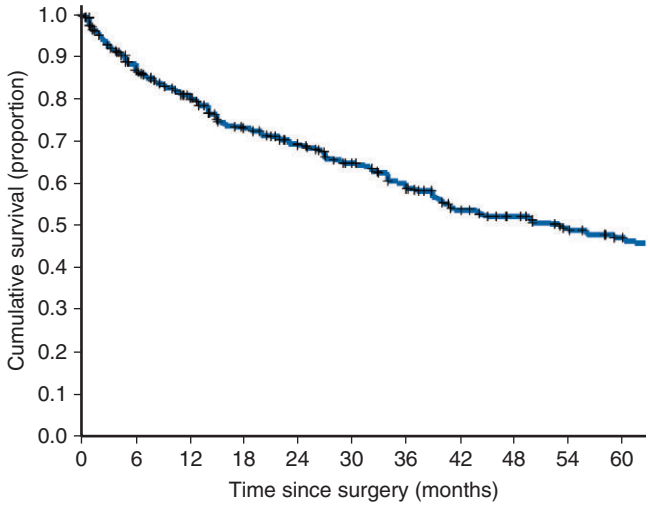

FIGURE 5 Survival with cytoreductive surgery and hyperthermic perioperative chemotherapy in patients with diffuse malignant peritoneal mesothelioma. Survival was determined from 401 patients in a multiinstitutional database. The 1-year, 3-year, and 5-year survival rates were 81%, 60%, and 47%, respectively. *(From Yan TD, Deraco M, Baratti D, et al: Cytoreductive surgery and hyperthermic intraperitoneal chemotherapy for malignant peritoneal mesothelioma: multi-institutional experience,* J Clin Oncol *20(27):6237–6242, 2009.)*

PERITONEAL METASTASES FROM EPITHELIAL OVARIAN CANCER

Epithelial ovarian cancer (EOC) includes cancers of three origins: ovary, Fallopian tube, and peritoneum. Most commonly, these cancers show the serous histologic subtype and share similar behavior, treatment, and prognosis. These cancers disseminate to adjacent structures by direct extension and by exfoliation of cancer cells into peritoneal fluid, resulting in PM throughout the abdomen and pelvis. Retroperitoneal lymphatic involvement becomes more common with advanced disease, and hematologic spread may occur later. The prognosis of women with EOC remains poor, with less than 50% surviving 5 years. Survival rates have changed little over the last two decades.

Extent of Disease as a Prognostic Variable

It has been recognized for many years that patients with microscopic or small-volume peritoneal metastasis have better survival than those with large-volume disease. Multiple studies have shown that frontline treatment outcome is better for patients whose disease presents with, or is surgically reduced to, no visible disease or minimal visible disease (<5 mm if possible; <1 cm at worst). In the case of recurrent disease, surgery has traditionally been reserved for a select group of patients with isolated or limited sites of recurrence that occurs after a long interval from primary treatment and is resectable. A recent study from the German Arbeitsgemeinschaft Gynäkologische Onkologie Studiengruppe (AGO) suggests that for recurrent disease, surgical resection to no visible disease must be achieved for significant survival advantage.

Role for Intraperitoneal Chemotherapy

An important consideration for treatment planning for EOC is its confinement within the peritoneal cavity for much of its life history,

not only at the time of diagnosis but also at the time of recurrence. Meta-analysis of seven randomized controlled trials in EOC investigating the use of intraperitoneal (IP) chemotherapy after frontline surgery has shown a survival advantage for IP chemotherapy. The Gynecologic Oncology Group 172 study recorded a median survival time of 66 months when IP treatments were used compared with 50 months in those receiving conventional intravenous (IV)–only chemotherapy after optimal surgery to less than 1 cm disease. Because adhesions form quickly after surgery, delay in delivery of the first dose of IP chemotherapy by even a few days after extensive surgery may prevent chemotherapy from reaching the entire peritoneal cavity and all cancer deposits. One way to overcome this deficiency is to use HIPEC at the time of surgery after all adhesions have been divided. HIPEC also treats free-floating cancer cells released by the surgery. In addition, the routine use of HIPEC eliminates the "lag time" after CRS before chemotherapy is usually given.

Series including well over 1000 patients with EOC treated with HIPEC have been reported. There are still no completed randomized controlled trials (RCTs), and the available studies are difficult to analyze and compare because of their heterogeneity, not only in populations treated but also in the variations in HIPEC technology. The HYPERO registry included 83 patients who had recurrent disease; 29% were platinum-resistant, and 85% had widespread peritoneal metastases. The median survival time of 23.5 months of patients treated with surgery and HIPEC was better than the 19.9-month median survival time for those with PM treated with surgery and further systemic chemotherapy in the AGO study. Not surprisingly, the amount of residual disease at the end of surgery before HIPEC is an important prognostic factor reported by many; this was supported in the initial report of the HYPERO registry (Figure 6).

Treatment of EOC, both frontline and at recurrence, requires combination treatment with surgery and chemotherapy. The principle aim of surgery is to prepare the patient for chemotherapy by leaving microscopic or small-volume disease. Because standard postoperative IV and IP chemotherapy has been shown to be less than curative in a large proportion of cases, HIPEC delivered at the time of optimal CRS alone or together with synchronous intraoperative intravenous chemotherapy and early postoperative chemotherapy should be further investigated. The results of several on going RCTs investigating HIPEC for EOC are awaited.

PERITONEAL METASTASES FROM GASTRIC CANCER

Peritoneal dissemination is the most frequent pattern of metastasis and recurrence with gastric cancers and occurs in 5% to 20% of patients being explored for potentially curative resection. Traditionally, there was a mutual agreement in the oncologic community that those patients with gastric peritoneal dissemination were incurable, with a median survival time of less than 1 year.

An Evolution of Curative Treatment Strategies for Gastric Cancer With Peritoneal Metastases

Since the 1980s, the development of CRS with peritonectomy procedures combined with HIPEC has given new hope for potential cure of PM. Recently, a collaborative effort of French institutions collected data from 159 patients and represents the largest experience of the treatment of PM from gastric origin. With a median follow-up period of 20.4 months, the overall median survival time was only 9.2 months, but the 5-year survival rate was 13% with some long-term survivors. These survival results are less encouraging than those obtained for other peritoneal surface malignancies, indicating a more aggressive disease process less responsive to this combined treatment modality and the need for improved patient selection. However, the combination of cytoreductive surgery with HIPEC is the only therapeutic strategy that can result in survivors at 5 years. Moreover, a recent phase III trial showed a significant benefit of HIPEC in addition to cytoreductive surgery for the treatment of gastric PM, especially when PM was synchronous.

Many prognostic factors have been identified for better patient selection for the combined procedure. The carcinomatosis extent assessed by the PCI demonstrated its significant influence on survival (Figure 7). Also, PCI was strongly correlated with the CC score. In the recent French study, a 5-year survival rate of 23% and a median survival time of 15 months were obtained in patients treated with complete macroscopic resection. Peritoneal metastases with localized or small tumor nodules seem to be the best indication for this combined procedure. In patients who had undergone complete cytoreductive surgery, the PCI represented the only strong prognostic factor. When the PCI was more than 12, despite a CCRS, no patient was alive at 3 years. These results suggest that this combined treatment for patients with extensive PM is not indicated even if complete cytoreductive surgery appears to be possible.

Laparoscopy may play an important role in the selection of patients by determining the extent of carcinomatosis. It may exclude patients with extensive small bowel involvement and avoid unnecessary laparotomy.

Another therapeutic method needs to be considered: neoadjuvant intraperitoneal and systemic chemotherapy (NIPS), developed by Yonemura, decreases the PCI and increases CCRS. These preliminary results from Japan are promising.

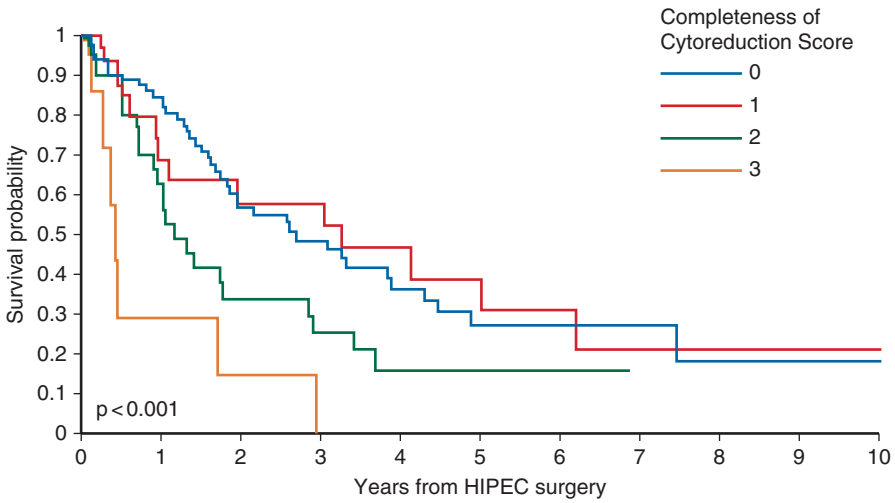

FIGURE 6 Overall survival by completeness of cytoreduction score in patients with peritoneal metastases from epithelial ovarian cancer. *0,* No visible disease; *1,* tumor nodules less than 2.5 mm in largest diameter; *2,* tumor nodules between 2.5 mm and 2.5 cm; *3,* tumor nodules greater than 2.5 cm. N=139 *HIPEC,* Hyperthermic perioperative chemotherapy *(From Helm CW, Richard SD, Pan J, et al: Hyperthermic intraperitoneal chemotherapy in ovarian cancer: first report of the HYPER-O registry,* Int J Gynecol Cancer *20:61–69, 2010.)*

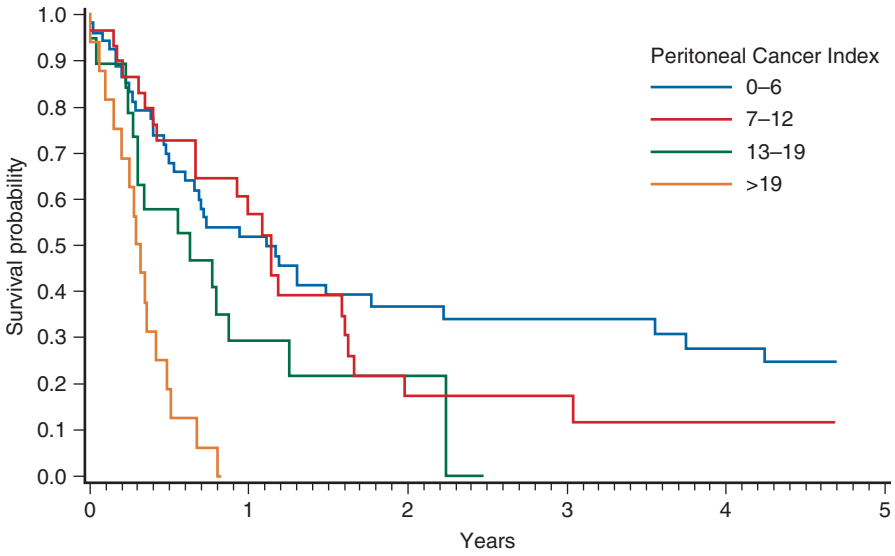

FIGURE 7 Survival of patients with peritoneal metastases from gastric cancer by the peritoneal cancer index. *Blue line,* peritoneal cancer index (PCI) 0-6; *red line,* PCI 7-12; *green line,* PCI 13-19; and *orange line,* PCI >19. *(From Glehen O, Gilly FN, Arvieux C, et al: Peritoneal carcinomatosis from gastric cancer: a multi-institutional study of 159 patients treated by cytoreductive surgery combined with perioperative intraperitoneal chemotherapy,* Ann Surg Oncol *17:2370–2377, 2010.)*

Importance of the Surgical Learning Curve

The institution in which the procedure was performed plays an important role in determining the postoperative course and survival. The assumption is reasonable that experience provides better patient selection, improved surgical expertise with a higher rate of complete cytoreductive surgery, and more knowledgeable postoperative management. A learning curve has been reported by several authors and institutions performing the combination of CRS with HIPEC for the management of PM. All interventional complex procedures have an inherent risk that experience undoubtedly diminishes but can never be abolished. Morbidity and mortality reported may reach 60% and 6.5%, respectively.

In conclusion, long-term survival for patients with PM from gastric cancer is a realistic goal in selected patients, and PM should not be considered a terminal event. The principal prognostic factors are PM extent (PCI) and the CC score. The high mortality emphasizes the necessity of strict selection of patients younger than 60 years and with good performance status. Patients who may benefit from CRS and HIPEC are those with PCI less than 12 after response to neoadjuvant systemic chemotherapy or NIPS, with no diffuse small bowel involvement shown on computed tomographic scan and laparoscopy, and with a high probability of complete macroscopic cytoreduction.

Prevention of Gastric Carcinomatosis

For many Korean and Japanese researchers, HIPEC has been performed in an adjuvant setting. In the meta-analysis of Yan and associates, these phase III trials showed the benefit of HIPEC, especially for T3, T4, and lymph node positive gastric tumors as reported. Yonemura and colleagues conducted a randomized controlled study of 139 patients with T3 or T4 gastric tumor allocated to three groups: HIPEC plus surgery, intraperitoneal normothermic chemotherapy plus surgery, and surgery alone. After a follow-up period of more than 5 years, the 5-year survival rate of patients treated with the combination of HIPEC and surgery was significantly higher at 60% than those of the other two groups, with similar morbidity rates. In Western countries, some groups show the benefit of HIPEC as adjuvant treatment for the prevention of PM recurrence in advanced gastric cancer. Prospective randomized studies are needed in Western countries to demonstrate the benefit of HIPEC in advanced stage of gastric cancer to prevent PM development.

The Management of Acute Appendicitis

Dylan Stewart, MD

OVERVIEW

Appendicitis is the most common cause of the acute abdomen. With more than 300,000 appendectomies performed in the United States annually, one expects surgeons to have great familiarity with the entity. However, no single abdominal condition presents in more different clinical scenarios than appendicitis, and it remains a source of diagnostic angst even in our modern surgical age. Appendectomy has long been the mainstay of treatment; however even this solid surgical dogma is now challenged by voices reporting successful nonoperative treatment. In addition, in the climate of increasing scrutiny of resource utilization, debates continue regarding the timing of surgery, the laparoscopic versus the open approach, and the duration of antibiotic therapy. Appendicitis continues to have significant morbidity and mortality, and debates aside, accurate diagnosis and timely intervention remain the goals of the evaluating surgeon.

HISTORICAL PERSPECTIVE

Appendicitis likely was as common at the dawn of surgery as it is today. However, its recognition as a clinical entity took a surprisingly long time, considering the relatively consistent pathologic features. One particular culprit may have been the highly influential French anatomist and surgeon Dupuytren, who attributed the disease to the cecum rather than the appendix. This French view of "perityphlitis" persisted despite decades of smaller, less authoritative voices championing a different pathologic explanation.

Hall of New York performed the first appendectomy in the United States in 1886, although his preoperative diagnosis was not appendicitis but an incarcerated hernia. The eventual recognition of appendicitis as the clinical entity was largely a result of the efforts of Harvard pathologist Reginald Fitz, who discarded the term typhlitis and presented 257 cases of appendicitis diagnosed pathologically. In his report, he also accurately predicted that appendectomy performed early in the disease process would likely provide ideal treatment.

ANATOMY AND PATHOPHYSIOLOGY

The appendix is considered a vestigial organ in humans, despite some evolutionary evidence to the contrary. It contains large amounts of lymphoid tissue but is thought to have no significant exocrine function. The appendix may be found in various anatomic positions, including under the ileocecal junction, in the pelvis or at the pelvic brim, and in the retrocecal space. The base is always located at the origin of the three taenia coli of the cecum. These anatomic positional differences make up part of the diagnostic challenge. Luminal obstruction is considered the pathologic hallmark of the process, either with lymphoid hyperplasia in children or with fecal concretions, adhesive bands, or tumors in adults. The obstruction leads to bacterial overgrowth, which causes an inflammatory response and may progress to venous congestion, arterial insufficiency, necrosis, and perforation.

PATIENT PRESENTATION AND DIAGNOSIS

History and Physical Examination

Much has been written about the presentation of acute appendicitis, and although "textbook" cases often are seen in emergency departments, in no way should deviation from the classic symptoms rule out the diagnosis. A feeling of malaise may be the first sign. Onset of pain is typically the first symptom, usually vague visceral pain that is described as epigastric. Nausea and anorexia then follow, and emesis, if it occurs at all, is usually noted after the onset of the pain. Emesis before onset of abdominal pain is considered much more typical of acute viral gastroenteritis. Anorexia is often thought of as a mainstay; however, many children are happily eating in the emergency department with right lower quadrant tenderness. As the inflammatory process progresses, somatic tenderness develops and localizes to the position of the appendix, be it in the right lower quadrant, the pelvis, or the retrocecal space. Either diarrhea or constipation may be reported, although a pelvic appendix is more likely to cause rectal irritation and loose stools. Urinary symptoms may also develop if the pelvic appendiceal inflammation irritates the bladder. Fever may not be present in the early stages (in fact, high fever is atypical) but may develop as the disease progresses to perforation or generalized peritonitis. Experienced clinicians know that the sequence of these symptoms (pain, nausea, followed by localized tenderness) is of paramount importance.

The differential diagnosis of appendicitis is vast and includes gastroenteritis, urinary pathology (infection or calculi), pelvic inflammatory disease, inflammatory bowel disease, diverticulitis, small bowel obstruction, cholecystitis, ovarian pathology including ectopic gestation, inflamed Meckel's diverticulum, and psoas abscess, to name but a few.

Patients in the earliest stages of appendicitis may not have tenderness on physical examination, but this becomes a near certainty as the disease progresses. Tenderness to moderate palpation in the right lower quadrant is the most convincing sign. A number of classical maneuvers to elicit pain in the evaluation of appendicitis are listed in Table 1.

Laboratory Examination

A single test value to confirm or rule out appendicitis does not exist. Typically, blood tests are ordered to search for other abnormalities and to learn of any fluid and electrolyte derangements in a potentially ill patient. The white blood cell count of the patient is normal or slightly elevated—significant elevation suggests perforation, abscess, or advanced disease. The differential may show predominance of neutrophils, even in relatively early cases. Urinalysis is usually obtained, but again results are nonspecific. Notation of pyuria may help to diagnosis pyelonephritis; however, this usually presents with higher fever and higher white blood cell count to begin with, and the pain is usually localized more to the costophrenic angle. Microscopic hematuria is quite common in appendicitis, although gross hematuria is more suggestive of nephrolithiasis. Urinary β-chorionic gonadotropin testing is mandatory in menstruating women and girls.

Imaging

In many patients, acute appendicitis is a clinical diagnosis, and no imaging is necessary. This is especially true for the young male patient, with a reliable and classic history of nausea, anorexia, and point tenderness in the right lower quadrant. No amount of imaging

TABLE 1: Physical examination maneuvers in the diagnosis of acute appendicitis

Test	Method
Iliopsoas test	Extension of right thigh with patient lying on left side elicits pain from retrocecal appendix on psoas muscle
Thigh rotation (obturator) test	Pain with internal rotation of thigh caused by inflammation of obturator internus by pelvic appendix
Rovsing's sign	Deep palpation in left lower quadrant elicits pain in right lower quadrant

should convince the surgeon to not operate on such a patient. Unfortunately, many of these children are irradiated to very minimal benefit and potentially significant risk. As the long-term dangers of ionizing radiation, especially in young children, are being discovered, the decision to image must be made thoughtfully and usually only after the emergency physician and surgeon have consulted.

Computed tomographic (CT) scan and ultrasound scan (US) have been extensively studied as diagnostic modalities for appendicitis. Both have clear advantages and disadvantages, and both examinations have a much better positive predictive value than their negative predictive value.

Ultrasound scan is fast, nonionizing, and relatively less expensive. It is also much more operator dependent and may be less useful in patients who are obese or in patients with overlying bowel gas. CT scan is more sensitive than US (94% vs 89% sensitivity), has less operator dependence, and may be more valuable in showing other intra-abdominal pathology. However, the dosage of radiation is significant, and early cases of appendicitis may not show significant findings. Significant interest exists in a limited abdominal CT scan with rectal contrast, but the accuracy of this method has not been proven superior to standard abdominal tomography and it fails to elucidate other potential pathologies.

In patients with a classic history, right lower quadrant pain, and no high suspicion for other pathology, exploration without further imaging remains perfectly appropriate. In patients with a less clear presentation, the author's practice is to proceed with US. If the US results are positive, the author proceeds to exploration. If the US results are normal and show no other pathology, it is the discretion of the surgeon to proceed with CT scan, observation, or exploration. Again, the key to the right imaging is to decide what tests to perform on the basis of early evaluation by the surgeon. A shotgun approach wastes time and resources and exposes the patient to excessive radiation. Often, even when the case is strongly suspicious for appendicitis, the patient has a CT scan to "get the attention" of the surgeon. Likewise, the fatigued surgeon may request scanning during early morning hours to "buy time." These practices should be condemned, and patients should undergo CT scan only when significant questions remain to be answered.

MANAGEMENT OF ACUTE APPENDICITIS

When appendicitis is suspected, patients should be appropriately resuscitated with fluids and electrolytes and prepared for the operating room. Antibiotics should be given; they have shown clear advantage in large systemic reviews. However, the decision to give antibiotics should be made only after the surgeon commits to operative exploration. Antibiotics may partially treat early appendicitis and therefore are not appropriate for patients when the diagnosis is in doubt and observation is planned.

TIMING OF SURGERY

Historically, acute appendicitis has been considered a surgical emergency. However, in the new era of work hour restrictions and attention to issues such as physician fatigue, this commandment is changing. Multiple retrospective studies have suggested no increased morbidity in patients who have appendectomy delayed for up to 24 hours. A recent survey of pediatric surgeons showed that more than 90% believed postponement of an overnight appendectomy until the next morning was appropriate surgical care.

The author's practice, once the diagnosis has been made, is to schedule urgent appendectomy within the next 8 hours. Once the decision to operate has been made, antibiotics are given and the patient undergoes fluid resuscitation.

Laparoscopic Versus Open Appendectomy

Multiple meta-analyses have evaluated the question of laparoscopic versus open appendectomy. All show equivalent efficacy in terms of safety, with laparoscopy having a distinct advantage in terms of postoperative wound infection, pain, and cosmesis. The debate is likely to be moot: as more and more surgeons become facile with laparoscopy, it is likely to become the de facto standard, and open appendectomy will likely follow the fate of open cholecystectomy into surgical history.

MANAGEMENT OF NONPERFORATED APPENDICITIS

Laparoscopic Appendectomy

The patient is prepped from xiphoid to pubis, with gastric and bladder catheters placed for decompression. In larger patients, the left arm is extended for ease of laparoscopy from the left side. Usually, one monitor is sufficient at the patient's right side, as surgeon and assistant stand side by side during the laparoscopic dissection (Figure 1). Typically, a three-port technique is adequate. A 12-mL trocar is placed in the umbilicus via Hasson's technique or with the Veress needle, as per surgeon preference. Two 5-mL ports are then placed with direct vision: one in the left lower quadrant, and one in the suprapubic position. Even in small children, adequate triangulation can be achieved in this configuration. A 3-mL instrument without a trocar may be used in the suprapubic position for small children. An additional 3-mL or 5-mL instrument may be placed in the right upper or lower quadrant, if needed for additional retraction. A four-quadrant exploration is performed to quickly rule out other intra-abdominal pathology. This is particularly helpful in young women and girls. The appendix is reliably found by following the taenia coli proximally. The inflamed appendix is grasped, and a window is created in the mesoappendix at the cecal junction. The appendix is ligated here with a gastrointestinal endoscopic stapler. The base of the appendix is usually relatively uninflamed. However, if extensive cecal inflammation exists, safe ligation of the appendiceal base may not be possible, and the surgeon must decide between drainage or, rarely, performance of ileocecectomy. The mesoappendix is then ligated with a vascular stapler, and the appendix placed in a retractable bag and removed. Routine irrigation is not used.

Open appendectomy remains one of the classic exercises in general surgery. An incision lateral to the rectus muscle is mandatory, with layer-by-layer entrance into the abdomen via a muscle-sparing approach. The appendix is found by sweeping a finger from lateral

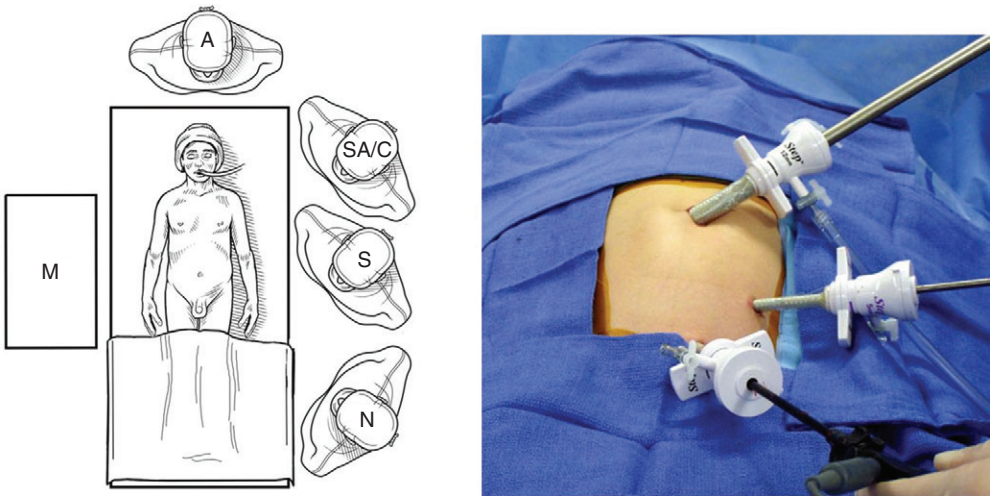

FIGURE 1 Arrangement for laparoscopic appendectomy. Surgeon *(S)* and surgical assistant/camera *(SA/C)* stand side by side once the diagnosis has been confirmed and the surgeon decides to proceed with appendectomy. The 3-port approach is shown in the photograph, with the largest (12-mm) port in the umbilicus and the 5-mm ports in the left lower quadrant and suprapubic positions. Positions of the anesthesiologist *(A)*, nurse *(N)*, and monitor *(M)* are also shown. *(Figure used with permission from Holcomb GW, Georgeson KE, Rothenberg SS:* Atlas of pediatric laparoscopy and thoracoscopy, *Philadelphia, 2008, Elsevier, Saunders p 77, Fig 14-2.)*

to medial in the right paracolic gutter, or by following the taenia as in a laparoscopic procedure. The appendix is externalized, ligated with absorbable suture, and resected, and a purse-string or Z-plasty–type suture is used to bury the appendiceal base into the cecum. The wound is closed in layers, and the skin is closed with absorbable suture. With perforation, the skin may be left partially open, or delayed primary closure may be used.

After surgery, most patients tolerate a diet immediately, and early ambulation and discharge should be the goal. Postoperative antibiotics in the setting of nonperforated appendicitis have no advantage and actually worsened clinical outcomes in a large, retrospective study.

MANAGEMENT OF PERFORATED APPENDICITIS

Typically, patients with ruptured or complicated appendicitis have either a delayed or unusual presentation. The diagnosis is confirmed with CT scan, which usually reveals right lower quadrant inflammation, phlegmon, or abscess (Figure 2). The surgeon must decide in these patients between early appendectomy and antibiotics and possibly percutaneous drainage, with interval appendectomy in 6 to 8 weeks time. A meta-analysis of 17 studies and more than 1500 patients published in 2010 suggested that patients treated with early appendectomy had more complications, including bowel obstruction, wound infection, and reoperation, than patients with delayed surgery and antibiotics. The vast majority of these studies were nonrandomized, however. Two recent randomized controlled trials (see Suggested Readings) in pediatric patients have addressed this issue. One trial found that the early appendectomy group had significantly reduced time away from normal activities as compared with the interval appendectomy group, and a reduced overall adverse event rate. Another study randomized children with a clear abscess on CT scan to immediate appendectomy versus percutaneous drainage and antibiotics. Here the authors concluded that early surgery was safe, with no differences in complications, length of stay, or hospital charges, and that in fact patients who went to the operating room immediately underwent fewer CT scans and had fewer healthcare visits.

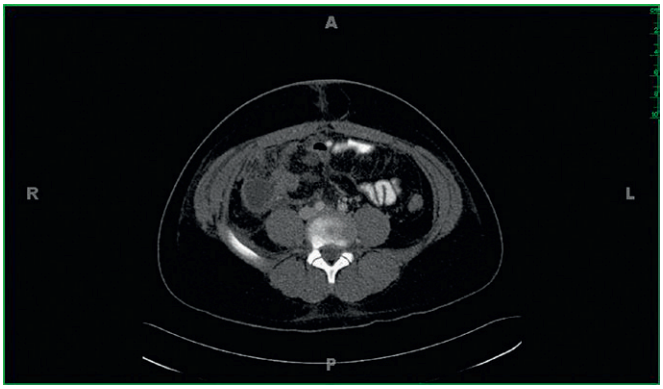

FIGURE 2 Computed tomographic scan of patient with an 8 day history of right lower quadrant pain. Fluid collection can be seen near the appendix.

Many studies have shown that laparoscopic appendectomy can be safely performed in the setting of abscess and right lower quadrant inflammation. As more surgeons develop experience with this technique, it seems likely to become the standard of care.

Antibiotics in Perforated Appendicitis

It is nearly universally accepted that patients with perforated appendicitis receive postoperative antibiotics. The well-known regimen of ampicillin, gentamicin, and clindamycin or metronidazole is the standard with which all others are compared. Length of treatment tends to vary by institution, and until recently, no prospective studies were available to guide the surgeon. Recently, a randomized, prospective trial in children looked at the efficacy of once-daily dosing of ceftriaxone and metronidazole, compared with the standard triple antibiotic regimen. The authors found no difference in the rate of abscess or wound infection and that the simpler regimen was more cost effective. In addition, the possible nephrotoxicity of the aminoglycoside is avoided.

In the future, postoperative antibiotic regimens will likely be based solely on the patient's condition, and not a predetermined time period. Many surgeons now believe that once the patient is afebrile, is tolerating a diet, and has a resolution of leukocytosis, the peritoneal inflammation is gone and antibiotics are no longer necessary or beneficial.

SPECIAL PATIENT SITUATIONS

Elderly

Appendicitis in the elderly is uncommon, with an estimated incidence rate in people more than 65 years old of 1 in 2000. As with children, diagnostic challenges may be found with patients unable to give a detailed history. The signs and symptoms of peritonitis at advanced ages may also be blunted, making the examination less reliable. CT scan is especially important in this group and may be instrumental in ruling out other pathologies in the elderly that can mimic appendicitis, such as diverticulitis and colonic neoplasms. Again, diagnostic laparoscopy can be extremely helpful in searching for alternate pathology if a healthy appendix is found.

Pregnancy

Acute appendicitis is the most common nonobstetric indication for surgery in the pregnant patient. As a disease primarily of young people of child-bearing age, it affects approximately 1 in 1500 pregnancies, with an equal distribution amongst all three trimesters. Diagnosis may be more difficult, however, later in gestation, as the appendix is moved cephalad by the expanding uterus and may reach the level of the gallbladder by the late third trimester. Patients tend to present with a more vague abdominal pain. Also, the physiologic leukocytosis of pregnancy makes laboratory evaluation less helpful. US is the first diagnostic test of choice. CT scan may be used, especially later in gestation, when the effects of ionizing radiation are less on the fetus, but should be reserved for very selected cases. Accurate and early diagnosis is especially important in these women because nonruptured appendectomy carries a low 5% fetal loss rate. Perforated appendicitis, however, may be associated with a fetal loss of more than 25%, which makes it best to err on the aggressive side when recommending surgical exploration.

Pregnancy is not a contraindication to laparoscopy, although a recent meta-analysis suggested it is associated with a higher risk of fetal loss. Access to the abdomen becomes more difficult when the uterus is in a more gravid state. Hasson's technique for entering the abdomen, minimized pneumoperitoneal pressures, dependent positioning, and mandatory obstetric consultation all help minimize the risks.

Negative Appendectomy

Historically, negative appendectomy rates of nearly 20% were expected and accepted, although this has changed in the era of CT scan and improved ultrasound imaging. If exploration is undertaken and a healthy appendix is discovered, a thorough search for alternate pathology must begin. Certainly, in open procedures, the appendix should be removed to avoid future confusion with a McBurney's incision.

Patients diagnosed with terminal ileitis and possibly Crohn's disease offer a special challenge because the rate of fistulization is high after appendectomy in patients with Crohn's disease. Generally, however, if the appendix appears uninvolved in the inflammatory process, it may be safely removed, again to help avoid future diagnostic confusion. If extensive involvement of the cecum or appendiceal base is found, the appendix should be left in situ with the rest of the inflammatory process. If uncomplicated inflammation of the ileum from Crohn's disease is suspected, ileocecectomy is not indicated. Only in cases of gross perforation of clear bowel obstruction should resection be performed.

HEMORRHOIDS

Vivek Chaudhry, MD, FACS, FASCRS, and Herand Abcarian, MD

ANATOMY

Hemorrhoids are a normal anatomy of the human anal canal. Fibrovascular cushions with subepithelial arteriovenous communications are present above the dentate line in all individuals. The three main cushions are located at the left lateral, right anterior, and right posterior positions. These cushions account for 15% to 20% of the resting anal pressure. During valsalva maneuvers, such as coughing and straining, they get engorged and aid in occlusion of the anal canal maintaining continence. Additionally, subepithelial sensory nerve endings in these cushions help individuals to discriminate among solid, liquid, and gas. Engorgement of the cushions during defecation allows safe dilation of the anoderm without tearing. *Internal hemorrhoids* arise from the superior hemorrhoidal plexus proximal to the dentate line and are covered by insensate columnar/transitional mucosa. Venous blood drains from the superior hemorrhoidal plexus to the superior rectal veins, through the inferior mesenteric vein draining into the portal system.

External hemorrhoids arise from inferior hemorrhoidal plexus below the dentate line and are covered by sensate skin. Venous blood

drains into the middle or inferior rectal veins, through the pudendal veins, into the internal iliac veins draining into the systemic circulation.

ETIOLOGY AND PATHOPHYSIOLOGY

Hemorrhoids are considered to be pathologic when they produce symptoms. Prolonged constipation, diarrhea, and straining and faulty bowel habits lead to overengorgement and bleeding from the thin, friable mucosa and subsequent prolapse from disruption of the sensory Treitz's muscle. With aging, the collagen content of the connective tissue fixing the hemorrhoids to the anorectal muscular wall degenerates, allowing for caudal sliding of the hemorrhoids and distal rectal mucosa with the shearing force of defecation. The exposed mucosa secretes mucus, causing perianal skin wetness, irritation, pruritus, and difficulty with maintaining hygiene (Figure 1). External hemorrhoidal plexus can also get enlarged, causing combined internal and external hemorrhoidal disease. External hemorrhoids rarely produce symptoms. Occasionally they can develop painful acute thrombosis or large skin tags and can cause difficulty in hygiene. A tense clot under the sensitive anoderm is extremely painful. Acute prolapse may result in mucosal edema, engorgement, pain, sphincter spasm, thrombosis, and gangrene of the hemorrhoid (Figure 2). Rarely, pylephlebitis can develop. Hemorrhoids are graded by the degree of prolapse and reducibility (Table 1).

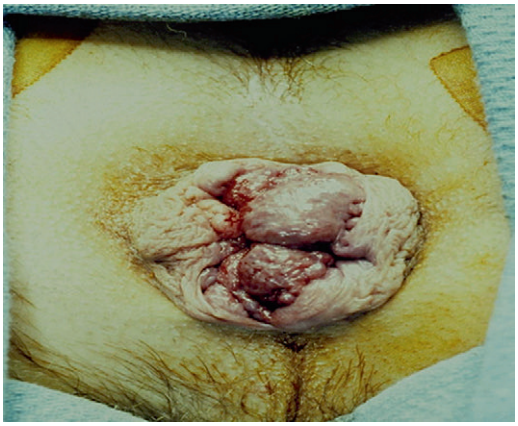

FIGURE 1 Grade II/III internal hemorrhoid.

FIGURE 2 Grade IV strangulated hemorrhoids. These are treated with excisional hemorrhoidectomy (preferred). Alternatively, they can be treated with multiple thrombectomies and multiple rubber band ligations.

INCIDENCE

The exact prevalence of symptomatic hemorrhoids is unknown due to underreporting and self-medication. Symptomatic hemorrhoids have been reported to be present in 4.4% of the U.S. population. Males and females are equally affected, with the peak incidence in the fifth to seventh decades. Symptomatic hemorrhoids have a familial correlation, although the exact contribution of genetic inheritance is unknown. Pregnancy and the postpartum state increase the risk due to increased blood volume, decrease in vascular and muscle tone, and pressure from the gravid uterus impeding venous drainage.

EXTERNAL HEMORRHOIDS

Acute Thrombosis

Acute thrombosis is due to the rupture of a vein in the external hemorrhoidal plexus, with tense hematoma formation presenting as an exquisite painful perianal subcutaneous nodule, usually, but not always, after a vigorous valsalva maneuver, such as in straining at a bowel movement or a vigorous workout at the gym. The pain increases or remains constant for 2 to 3 days, after which the swelling and pain decrease either due to spontaneous reabsorption of the clot or, less commonly, due to pressure necrosis of overlying skin and gradual decompression of the clot (Figure 3).

If the patient is seen with a painful thrombosis within 24 to 48 hours, the treatment of choice is immediate excision of the hemorrhoid (not evacuation of the clot) under local anesthesia. The patient who presents later, when natural reabsorption of the clot has started, is treated with Sitz baths; stool softeners; and topical anesthetics, astringents, and steroids to aid in rapid resolution of symptoms.

Quiescent External Hemorrhoids

Perianal skin tags are often related to prior episodes of thrombosed external hemorrhoids or sentinel pile of a healed fissure. Small skin tags require no treatment unless they become large enough to interfere with proper anal hygiene. In the case of external hemorrhoidal tags, they can be excised under local anesthesia. Removal of minor skin tags in an occasional patient fixated on cosmesis is discouraged.

TABLE 1: Classification of hemorrhoids

External hemorrhoids	Origin below dentate line, covered by skin/anoderm, sensate
Internal hemorrhoids	Origin above dentate line, covered by columnar mucosa, insensate
Grade I	Bleed and prolapse into the lumen of anal canal
Grade II	Prolapse outside anal canal: reduce spontaneously
Grade III	Prolapse outside anal canal: requires manual reduction
Grade IV	Prolapse outside anal canal: irreducible

FIGURE 3 Thrombosed external hemorrhoid. Note that the clot is spontaneously extruding from pressure necrosis of the dome of the hemorrhoid.

INTERNAL HEMORRHOIDS

The management of internal hemorrhoids can be divided into nonoperative (office) procedures and operative procedures.

Nonoperative Techniques

The principal of all nonoperative techniques is to produce fixation of the internal hemorrhoids to the muscular layer (Table 2). The most common nonoperative treatments of hemorrhoids include the following.

Rubber Band Ligation

Rubber band ligation (RBL) is suitable for Grades II and III hemorrhoids. This office procedure is performed in the Sims or prone jackknife position, using either a McGivney/Barron hemorrhoid ligator or a vacuum-assisted device (Figure 4). It is better to treat each hemorrhoidal complex individually to prevent postprocedural pain and undesirable protrusion. Placement of the band at least 5 mm cephalad to the dentate line reduces the incidence of postprocedural pain. Appropriately placed bans occasionally result in minor postprocedural discomfort for up to 24 hours, which is easily controlled by acetaminophen or nonsteroidal antiinflammatory drugs (NSAIDs). Severe pain immediately after the procedure usually indicates placement too close to the dentate line and is treated with cutting the band using a specifically designed cutting hook. Patients are instructed to rest for a few minutes after the procedure before assuming the upright posture to prevent vasovagal syncopal symptoms.

Minor complications of RBL include thrombosis of external hemorrhoids, which can be treated as described previously. Postband bleeding occurs in less than 1% of the patients and appears 3 to 7 days after banding. Rarely, if bleeding is more than a few drops and persists for a few hours, the patient must be examined and the source controlled with topical epinephrine followed by cauterization or suture.

Pelvic sepsis is a very rare (1:15,000) but life-threatening complication. Pain, fever, and urinary difficulty are the trifecta, which should serve as an early warning to this potentially lethal complication. Prompt examination under anesthesia, removal of the band with debridement of necrotic tissue, and hospitalization for intravenous (IV) antibiotics must be instituted. Failure to recognize this complication can result in death from overwhelming sepsis.

TABLE 2: Treatments of hemorrhoids by correcting bowel habits and patterns

Grades I and II	Grades II and III	Grades III and IV
• Dietary/lifestyle changes • High-fiber diet • Water • Stool softeners • Good stool habits • Office procedures	• Office treatments • Rubber band ligation • Sclerotherapy • Infrared coagulation • Transanal hemorrhoid ligation (THD)	• Surgical treatments • Ferguson hemorrhoidectomy utilizing scalpel, cautery, ligature • Stapled (PPH)

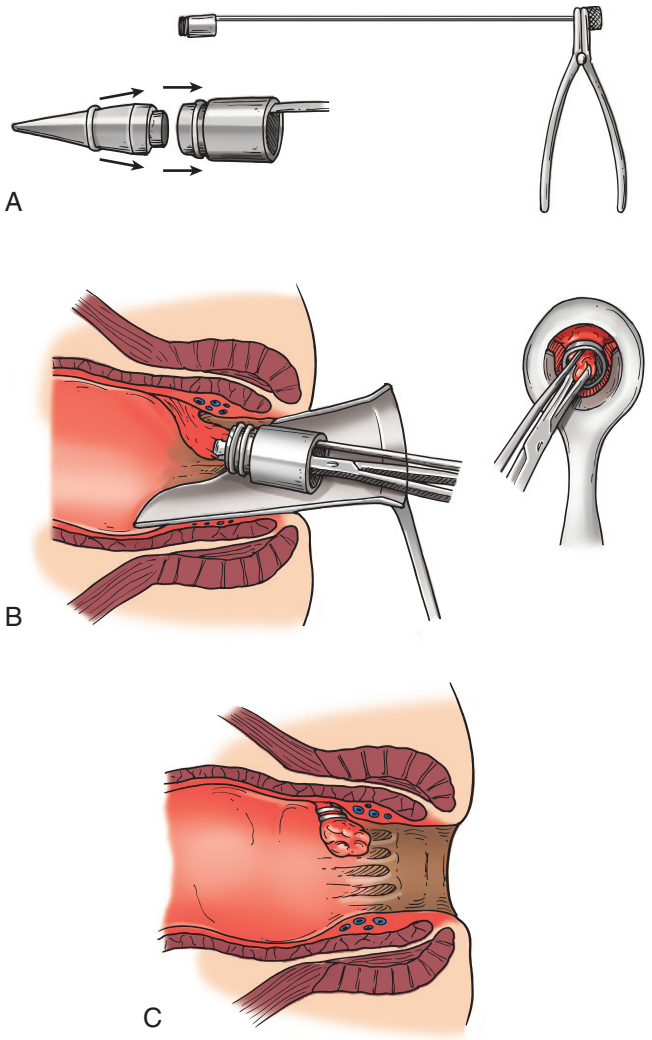

FIGURE 4 Rubber band ligation. **A,** Loading the rubber band on the applicator. **B,** Placement of the rubber band using a slotted anoscope. **C,** Appropriately placed band above the dentate line.

RBL enjoys universal acceptance. It is inexpensive, quick, well tolerated, and effective. A success rate of 80% to 100% has been widely reported, often with one session. It is superior to injection sclerotherapy in controlling prolapse, bleeding, and recurrent symptoms. Although multiple-band ligations at a single outpatient session have been reported to be safe and well tolerated, we continue to band

a maximum two pedicles, especially during the first encounter. If more than three sessions are required to control symptoms, hemorrhoidopexy or hemorrhoidectomy should be offered.

Injection Sclerotherapy

The indications for its use include acutely bleeding Grades I and II hemorrhoids, especially in patients who are on anticoagulants and in patients who are immunocompromised or coagulopathic. Advantages of injection sclerotherapy include possibility of treating all hemorrhoids at one setting with no need to stop anticoagulant therapy. The disadvantage is the need for repeat injection at least two or three times to achieve the desired effect. Injection sclerotherapy is carried out by injecting 3 to 5 mL of phenol in vegetable (almond or arachis) oil in the submucosal space of each hemorrhoidal apex. An 18-gauge spinal needle (bent 30 degrees 2 cm from the tip) or an angled hemorrhoidal needle are used with the patient in the left lateral or prone jackknife position, using a strong light and a side or end viewing anoscope (Figure 5). Accurate submucosal injection at the hemorrhoidal apex causes swelling of the mucosa, with obvious vessels crossing it "striation sign." If the mucosa has no swelling, the injection is too deep and can result in prostatic abscess, erectile dysfunction, or pylephlebitis. Pale white mucosa is due to intramucosal injection with resultant sloughing and ulceration and must be avoided. The injection is painless and well tolerated other than a sense of fullness. Though injection sclerotherapy can be repeated, it is more difficult to deliver therapeutic doses due to submucosal fibrosis and can result in stricture formation. It is encouraged to use an appropriate dose at the initial injection. An alternative is to use 1 to 2 mL of ethanolamine oleate directly into the hemorrhoid using a 25-gauge needle. Other sclerosants like 0.5 mL of 5% sodium morrhuate or 5% quinine urea have also been used. Efficacy is inferior to rubber band ligation.

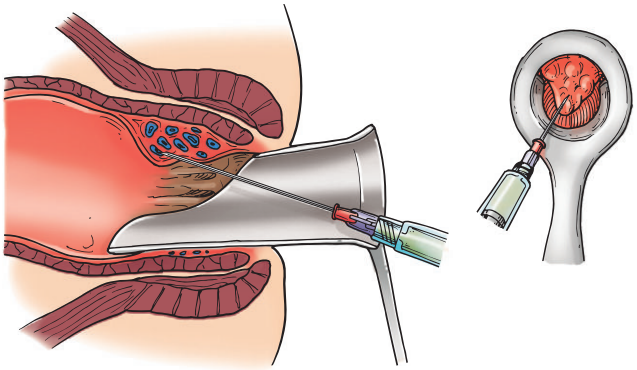

FIGURE 5 Injection sclerotherapy. Sclerotherapy needle (bent 2 cm from the tip) with bevel upward is inserted into the submucosa at the apex of the hemorrhoid bundle. "Striation sign" ensures correct plane of therapy. The mucosa swells without forming blebs or becoming "dead white."

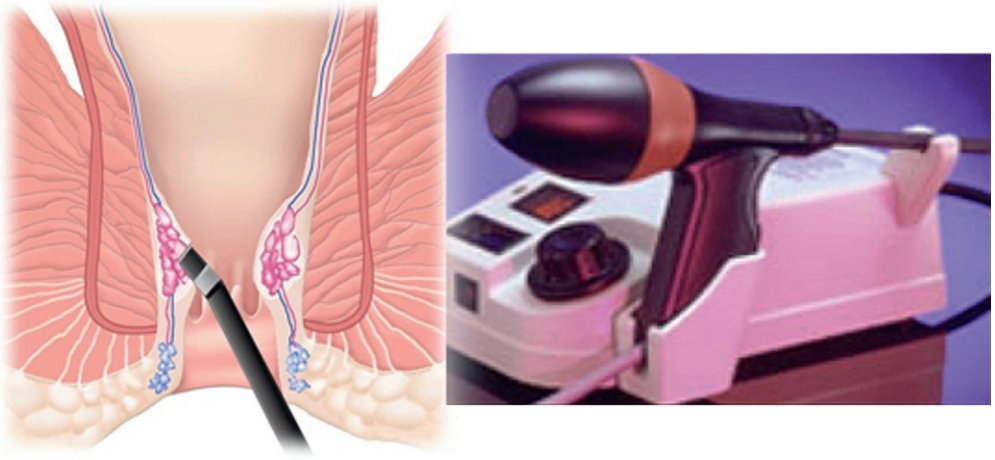
Infrared Coagulation

Infrared coagulation (IRC) is most effective in Grades I and II hemorrhoids (Figure 6). Infrared light energy from a tungsten-halogen lamp is converted to heat, which causes coagulation of the vessels, tissue destruction, and scarring. Four mucosal applications of 1.5 seconds are placed at the apex of each hemorrhoid to produce scarring and fixation and to reduce distal sliding of the mucosa. IRC is quick, easy, and well tolerated, with less pain than RBL and minimal risk of delayed hemorrhage or ulceration. It is more expensive and less efficacious than RBL, especially in treating prolapse. Most surgeons prefer RBL over IRC.

Other treatments like laser, monopolar and bipolar coagulation, Ultroid, and cryotherapy have all been tried and eventually abandoned due to high cost and low success rates.

Operative Techniques

These procedures are based on excision of hemorrhoids, as well as fixation of mucosal prolapse. These operations are most suitable for Grades III and IV hemorrhoids and in cases of prolapsed gangrenous hemorrhoids requiring immediate excision.



Open Hemorrhoidectomy

Open hemorrhoidectomy (Milligan Morgan hemorrhoidectomy) has been used since the 1840s. The hemorrhoid is dissected off from the underlying sphincter complex with ligation of the hemorrhoidal vessel at its apex. Care is taken in leaving anoderm bridges intact to prevent anal stenosis. The wound is left open to heal by secondary intention. This procedure has not gained popularity in the United States.

Closed Hemorrhoidectomy

Closed hemorrhoidectomy (Ferguson hemorrhoidectomy) is the most popular excision technique in the United States (Figure 7). It is

FIGURE 6 Infrared coagulation (IRC; Redfield Corporation). The sterile applicator is placed at the apex of the hemorrhoid bundle.

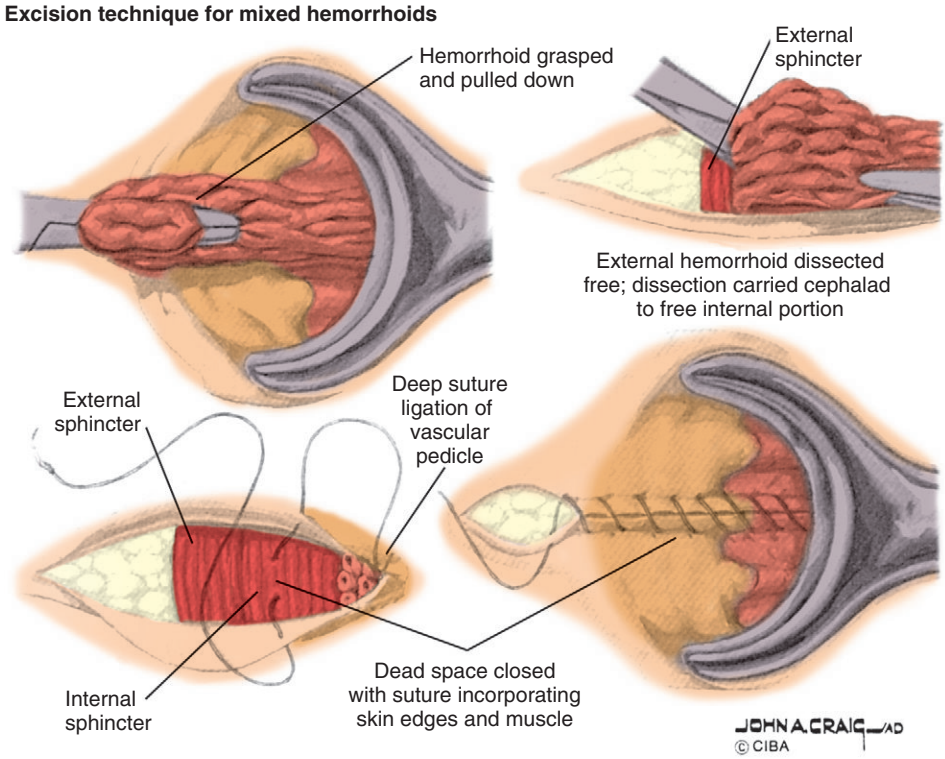


FIGURE 7 Ferguson hemorrhoidectomy (closed hemorrhoidectomy).

performed in the prone jackknife (preferred) or lithotomy position under local, regional, or general anesthesia, with the gluteal folds retracted with tape. Antibiotics are not administered routinely. A Hill-Ferguson retractor is placed in the anal canal and the hemorrhoid grasped at the perianal skin, the mucocutaneous junction, and the apex of the hemorrhoid. Dilute epinephrine solution is injected to reduce bleeding during dissection and to spare the superficial external sphincter. A diamond-shaped incision (scalpel/electrocautery) is made from the perianal skin into the anal canal and tapered toward the apex of the hemorrhoid. It is important to dissect superficial to the fibers of the internal sphincter, which is readily recognized due to its white muscle fibers. The apex of the hemorrhoid is clamped and suture ligated with 2-0 absorbable suture and the wound closed with accurate mucosa to mucosa approximation. The mucosa is fixed to the underlying sphincter muscle to recreate a new dentate line. The suture line continues into the perianal skin. The tail of the apical suture is left long for identification of the pedicle in case of postoperative hemorrhage. The same procedure is repeated at other major hemorrhoidal pedicles. Dibucaine-impregnated Gelfoam is placed in the anal canal. Patients are discharged the same day with narcotic and NSAID pain medications, Sitz baths, and stool softeners and are seen 10 days after surgery. They are instructed to keep dry gauze in between the buttocks and change it two or three times a day. The advantage of this technique is faster healing, but it also has the disadvantage of occasional wound infection and fistula formation. The success rate of this technique in the long-term follow-up period exceeds 90%.

The use of energy devices such as Harmonic Scalpel or Ligasure has been reported. There is no real advantage in using energy devices. It does increase the cost of the operation, and if the surgeon is not careful, excessive excision of the anoderm with subsequent fibrosis and scarring may lead to an anal stricture that is difficult to correct.

Park's Submucosal Excision

Park's submucosal excision is an attempt to remove the hemorrhoid and maintain the integrity of the overlying mucosa and anoderm. However, the operation is tedious to perform and often associated with breakdown of the suture line and infection or fistulas. This procedure, despite its intended design, has not gained popularity.

The most common complication after excisional hemorrhoidectomy is urinary retention, followed by bleeding. Urinary retention occurs in 6% to 10% of patients and can be minimized by restricting fluid intake (IV or oral) for 4 to 6 hours postoperatively. Adequate pain control, relief of pelvic spasm with a warm bath, upright posture, privacy, and the sound of running water will often allow a patient to void without a Foley in the recovery room. Early bleeding is the result of a technical error, but bleeding occurring 5 to 7 days later is caused by slough of the suture line. If bleeding is severe and continues, the patient must be taken back to the operating room for resuturing of all hemorrhoidectomy suture lines.

Anal stenosis is a serious late complication from overaggressive excision of the anoderm. Treatment involves dilations or resection with flap anoplasty. Minor incontinence usually resolves over 3 months and can be minimized by preventing overzealous sphincter retraction. Major incontinence is very rare and indicates underlying sphincter damage.

Fixation Procedures

Stapled Hemorrhoidopexy

Stapled hemorrhoidectomy or procedures for prolapsed hemorrhoids (PPH) were popularized by Longo as a less painful alternative to excisional hemorrhoidectomy. It involves circular resection and anastomosis of a 1- to 2-cm ring of anorectal mucosa and submucosa at the top apex of the hemorrhoidal plexus. The operation (1) interrupts the superior hemorrhoidal vascular pedicles, (2) resuspends the prolapsing tissue at the anorectal ring, (3) preserves the vascular cushions (important for continence), and (4) avoids painful perianal wounds.

Patients are instructed to take an 8-oz. phosphosoda enema on the morning of the operation. Operations are performed under local,

spinal, or general anesthesia in the prone jackknife (preferred) or lithotomy position. Preoperative antibiotics are not routinely administered.

The anal canal is dilated with a circular anal dilator. The circular anal dilator and obturator are inserted into the rectum. The obturator is removed, and the anal dilator is sutured to the perianal skin. The purse-string suture anoscope is inserted through the dilating anoscope to facilitate the placement of a circumferential purse-string suture.

Purse-string suture placement is the crucial part of this procedure. A 2 0 Prolene (polypropylene) purse-string suture is placed approximately 2 cm proximal to the apex of the hemorrhoids and 4 cm above the dentate line (Figure 8, *A*). This positions the purse-string suture approximately 4 cm proximal to the dentate line and the final staple line 2 cm above the dentate line. Care is taken to include only mucosa and submucosa at the same level circumferentially and to avoid gaps in the purse-string suture. In female patients the surgeon inserts a finger into the vagina, while placing the sutures in the anterior wall of the rectum to ensure that the suture is not accidentally placed too deep. Once completed, the purse-string suture is gently tightened to draw the redundant mucosa into the lumen of the rectum. The purse-string suture is deemed adequate if the rectum can be completely occluded with tension on the suture. The anvil of the stapler is inserted into the rectum and can be completely occluded with tension on the suture. The anvil of the stapler is inserted into the rectal lumen through the purse-string suture, which is then tied over the shaft of the stapler. The stapler is then closed slowly until it is fully tightened and the 4-cm mark on the head of the stapler is at the anal verge. In female patients the vagina is examined again to confirm that the posterior vaginal wall was not drawn into the head of the stapler. The stapler is held closed for 1 minute to assist in hemostasis, and then fired and removed.

The specimen retrieved from the stapler is inspected to verify that a complete "doughnut" of the tissue was excised. A digital examination confirms that the staple line is circumferential. The purse-string anoscope or a large Hill-Ferguson retractor is then inserted into the anus to examine the staple line and the sew areas for any bleeding.

A small role of Gelfoam (Pharmacia and Upjohn, Kalamazoo, MI) coated with anesthetic ointment is placed into the rectum. Patients are usually discharged home with oral analgesics and stool softeners.

PPH has been extensively studied. Several large randomized trials and systemic reviews have reached similar conclusions, and a representative systemic review is presented. In a review of 25 randomized controlled trials of 1918 patients with 1 to 62 months follow-up comparing conventional hemorrhoidectomy to stapled hemorrhoidopexy, PPH was associated with less operating rime (weighted mean difference: 11 minutes, $P = 0.006$); appeared to be less painful (37% reduction in analgesic requirement); required less time off work (weighted mean difference, j8.45 days; $P < 0.00001$); enabled an earlier return to normal activities (weighted mean difference, j15.85 days; $P = 0.03$); and had better wound healing (odds ratio, 0.1; $P = 0.00006$). The patient satisfaction was significantly higher with stapled hemorrhoidopexy than conventional hemorrhoidectomy (odds radio, 2.33; $P = 0.003$). Although there was an increase in the recurrence of hemorrhoids at 1 year or more after the stapled procedure (5.7% vs 1%; odds ratio, 3.48; $P = 0.02$), the overall complication rate did not differ significantly from that of the conventional procedure (stapled vs conventional: 20.2% vs 25.2%; $P = 0.06$). Stapled hemorrhoidopexy had less postoperative bleeding (odds ratio, 0.52; $P = 0.001$), wound complications (odds radio, 0.05; $P = 0.005$), constipation (odds ratio, 0.45; $P = 0.02$), and pruritus (odds ratio, 0.19; $P = 0.02$). The overall need for surgical (odds ratio, 1.27; $P = 0.4$) and nonsurgical (odds ratio, 1.07; $P = 0.82$) reintervention after the two procedures was similar.

Unexplained persistent postoperative pain and major pelvic septic complications (pelvic sepsis, pneumoperitoneum, intra-abdominal sepsis, Fournier gangrene, rectovaginal fistula, and rectal perforation) have not been noted in any randomized trials. Most of these complications are probably related to technical errors, such as inappropriate placement of purse-string sutures that were too deep or too cephaled or distal in the rectum.

The ideal patient has circumferential Grade II/III internal hemorrhoids without significant external disease intra-abdominal (see Figure 8, *B* and *C*). Care should be taken in patients with narrow anal canals or previous sphincter injury. Additionally, Grade IV hemorrhoids treated with PPH have an increased risk of early recurrence. It is advisable that surgeons experienced in colon and rectal surgery perform this procedure.

Suture Hemorrhoidopexy

Pakravan and colleagues described open suture hemorrhoidopexy in 2009. This is a simple and inexpensive variation of stapled hemorrhoidopexy. An absorbable 3/0 suture (e.g., Vicryl) is placed above the dentate line horizontally and again in the same direction at the apex of hemorrhoid (Z stitch) 3 cm above the distal suture. A 1-cm window of rectal mucosa is excised in between the horizontal suture lines to allow adherence, scarring, and fixation. The suture is then tied. The same procedure is repeated in all quadrants when a prolapse is present. When all sutures are tied, the entire prolapsing complex of hemorrhoids and distal rectal mucosa is elevated and fixed at the anorectal ring. This is a cost-effective procedure most suitable for third-degree and very symptomatic second-degree hemorrhoids. The advantage of this operation is that it is simple and requires no special instrumentation and may be done again for additional hemorrhoids or future recurrences.

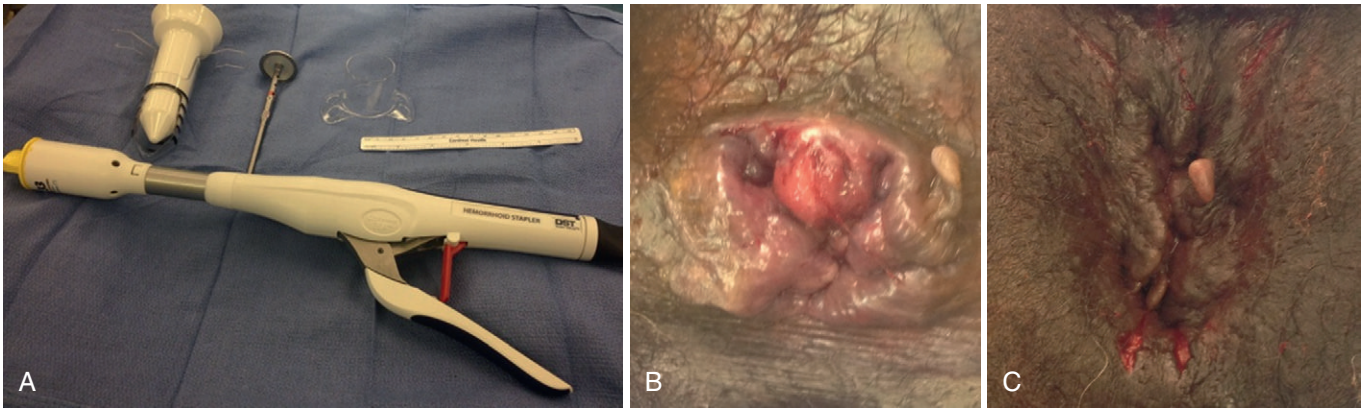

FIGURE 8 **A,** PPH—placement of purse-string 4 cm above the dentate line and resection and stapling of ring of rectal mucosa/submucosa. **B,** Preoperative view with prolapsed circumferential hemorrhoids. **C,** Postoperative result after application of the stapler.

Partial Stapled Hemorrhoidopexy

A recent variant of the stapled technique involves 1-3 quadrant resection and fixation using a special slotted stapler. Preliminary results promise decreased postoperative morbidity with equivalent efficacy.

Doppler Guided Transanal Hemorrhoidal Ligation

Hemorrhoidal artery ligation uses a special Doppler probe anoscope to identify and suture ligate the terminal branches of the superior hemorrhoidal artery, which feeds the major and minor hemorrhoidal plexus (Figure 9). Figure of eight absorbable suture ligation of an average of six pedicles is performed resulting in the reduction in the vascularity and size of the hemorrhoids.

In a systematic review of 150 patients in 3 randomized control trials (RCT) comparing PPH to transanal hemorrhoid ligation (THD), both procedures had similar efficacy with reduced postoperative pain in the THD group. The overall recurrence at 1 year is 11%, 10%, and 9% for prolapse, bleeding, and pain, respectively.

A recent modification of rectro-anal-repair (RAR) in conjunction with DGTHL is currently under investigation. RAR involves restoration of prolapsed tissue to their anatomic location with longitudinal absorbable sutures placed through a special slotted anoscope.

SPECIAL SITUATIONS

Strangulated Hemorrhoids

Incarceration of third- and fourth-degree hemorrhoids leads to edema, thrombosis, necrosis, and ulceration. Emergent hemorrhoidectomy in the operating room is safe provided all necrotic hemorrhoidal tissue is excised individually and care is taken to preserve viable anoderm. Injection of dilute epinephrine together with 150 to 200 IU of hyaluronidase aids in reducing the edema and facilitating the operation. Alternatively, massage/reduction of internal hemorrhoids with multiple rubber band ligations and external thrombectomies can provide immediate relief. Future hemorrhoidectomy is seldom needed. A randomized trial comparing excisional hemorrhoidectomy to incision and ligation showed both techniques to be safe with slightly improved early recovery after incision/ligation.

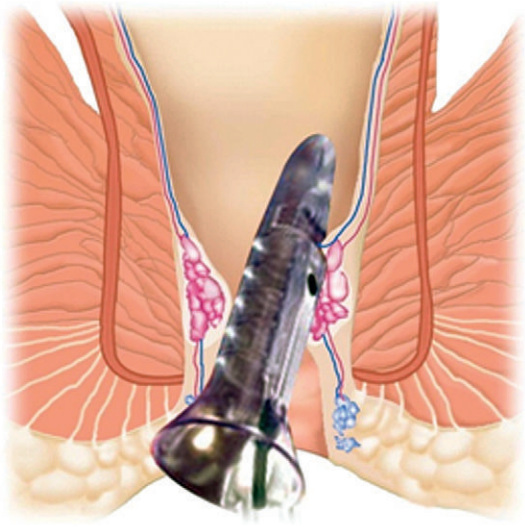

FIGURE 9 Doppler guided hemorrhoid artery ligation.

Hemorrhoids in Pregnancy

Constipation, lax sphincters, increased blood volume, and straining often result in exacerbation of hemorrhoids during the third trimester and postpartum and often resolve spontaneously after delivery. Generally the approach is conservative with Sitz baths, fiber, and stool softeners. The rare patient with acutely thrombosed prolapsed hemorrhoidal disease is operated on under local anesthesia in the left lateral position.

Hemorrhoids in Inflammatory Bowel Disease

Hemorrhoidectomy in patients with active anorectal Crohn's disease should not be performed because of an increased risk of nonhealing, local complications, major incontinence, and subsequent need for proctectomy. Patients with quiescent ileal or colonic disease undergoing conservative hemorrhoid surgery have a 90% healing rate at 2 months.

Hemorrhoids in the Immunocompromised

Anorectal complications are common in patients with HIV/AIDS. Infectious etiology and malignancy need to be ruled out using cultures, endoscopy, and biopsies. Many patients suffer from episodic or chronic diarrhea and incontinence. In selected patients with HIV infection under good control, excisional and nonexcisional therapies for proven symptomatic hemorrhoid disease can be safely accomplished with minimal complications. Surgery in patients with hematologic malignancies should only be offered as a last resort to relieve pain and sepsis.

Hemorrhoid Varices and Portal Hypertension

Contrary to popular belief, the incidence of hemorrhoidal disease is no greater in patients with portal hypertension than in the general population. Anorectal varices are seen in up to 80% of patients with portal hypertension but are implicated in less than 1% of massive gastrointestinal bleeding. Procedures used in the control of bleeding anorectal varices are direct suture ligation; stapled anopexy; transjugular portosystemic shunt; and mesocaval, mesorenal, and sigmoid to ovarian vein shunts.

Anal Fissure

Susan L. Gearhart, MD, FACS, FASCAS

Anal fissure, or a longitudinal anal tear or ischemic ulcer, is a common cause of anal pain and bleeding in both infancy and adulthood. Symptoms associated with anal fissure usually occur following defecation. The pain can be short-lived or last several hours, and the bleeding is usually observed on the toilet tissue. Often patients will complain of hemorrhoids or anal tags because of the swelling around the anal fissure that occurs when the fissure is irritated. A history of constipation increases the likelihood for an anal fissure nearly threefold.

The cause of an anal fissure is believed to be related to trauma occurring to the anal canal with the passage of a hard stool. Fissures may also occur following a course of diarrhea. It has been demonstrated with anal manometric evaluation that trauma to the mucosa overlying the internal sphincter leads to a sustained increase in resting pressure within the anal canal. Furthermore, there is evidence to suggest an inverse relationship between anal resting tone and perfusion to the anoderm. A decrease in perfusion associated with increase in anal resting tone leads to poor tissue healing. Since the vascular supply to the anal canal enters laterally, posterior and anterior trauma to the anal canal will exhibit the slowest healing; this is due to increased relative ischemia. Currently, methods for treating anal fissures focus on decreasing anal resting pressure and therefore increasing perfusion of the anoderm.

Anal fissures occur up to 90% of the time in the posterior midline; however, fissures in women occur 25% of the time in the anterior midline. Acute fissures or fissures that have been present for less than 6 weeks have the appearance of a simple tear or ulcer in the anoderm, which starts at the dentate line. Chronic anal fissures, defined by symptoms present for more than 6 to 8 weeks, can be further characterized by the presence of an anal tag or "sentinel pile" at the distal end of the fissure and a hypertrophied anal papilla at the proximal end near the dentate line. Often the internal sphincter muscle is easily visualized in the fissure bed (Figure 1). Diagnosis of an acute or chronic fissure is made easily by the patient's history and physical exam findings. The physical exam is performed by gently spreading the buttocks with opposing thumbs while the patient is in the prone jackknife position. The typical anal fissure can be identified easily in the anterior or posterior position. Once a fissure has been identified, it would be prudent to avoid any further evaluation of the anal canal, which may worsen the patient's symptoms.

Anal fissures are frequently misdiagnosed. The most common diagnosis confused with anal fissures is hemorrhoids. Other diagnoses in the differential include a fistula in anorectal and perirectal abscess, inflammatory bowel disease, sexually transmitted diseases, and anal cancer. For this reason, all fissures that fail to heal with appropriate treatment should be biopsied. Atypical fissures are fissures not found in the midline and can be multiple, painless, and nonhealing (Figure 2). The associated diagnoses with lateral fissures include inflammatory bowel disease, syphilis, tuberculosis, leukemia, cancer, and human immunodeficiency virus (HIV). All atypical fissures should be biopsied or excised to rule out additional pathology.

TREATMENT

Acute Anal Fissure

The management of an acute posterior or anterior anal fissure that has been symptomatic less than 6 weeks is for the patient to improve bowel habits by increasing fiber supplements. The normal requirement for fiber consumption per day is 40 g. This amount may be obtained more easily by the addition of over-the-counter fiber supplements such as Metamucil or Fibercon. Patients can find dietary information about fiber from various websites. In addition, warm sitz baths after bowel movements and the addition of stool softeners if needed may aid in promoting healing.

Medical Therapy for Chronic Anal Fissure

For chronic anal fissure, there are several nonsurgical therapies. Most nonsurgical therapies are aimed at smooth muscle (internal sphincter) relaxation, antiinflammatory therapy, and pain control (Table 1). When evaluating the outcomes of different medical therapies, it is important to keep in mind that the natural history of anal fissures is a waxing and waning of symptoms. Furthermore, long-term follow-up of these patients is necessary to determine the success of these treatments. Therapies aimed at relaxation of the smooth muscle are designed to improve healing through improving blood flow to the anal canal. The role of antiinflammatory medication and topical anesthetics are to decrease pain that is due to inflammation and promote healing. The objective of these therapies is to provide quick relief through a short course of treatment. However, with diet modification and improvement in stool quality, in combination with antiinflammatory therapy, prolonged healing can occur.

Currently, several therapies are available that are effective at smooth muscle relaxation. Nitroglycerine, or glyceryl trinitrate (GTN), is a dimer of nitric oxide thought to locally release nitric oxide. Nitric oxide will then, in turn, bind to 3′,5′-cyclic guanosine monophosphate (cGMP), which results in a cascade of intracellular interactions ultimately leading to smooth muscle relaxation. In a similar fashion, L-arginine, an amino acid that is known to donate nitric oxide, leads to smooth muscle relaxation. The use of phosphodiesterase (PDE) inhibitors has been postulated to be an effective treatment for anal fissures. PDE is an enzyme important in the degradation of cGMP, which then, along a similar pathway as above, leads to smooth muscle relaxation (Figure 3).

Cytoplasmic calcium is important for smooth muscle contraction. By inhibition of calcium channel, smooth muscle relaxation occurs. The use of calcium channel antagonists first became popular in the treatment of esophageal spasm in conditions such as achalasia. Their use has also gained popularity in the treatment of anal fissures through this same mechanism. Botulinum toxin (Botox) prevents the release of acetylcholine from presynaptic nerve terminal and thus inhibits neuromuscular transmission in striated muscles such as the external anal sphincter. The exact mechanism that leads to induced relaxation of the internal anal sphincter from Botox is not known, but it is believed that relaxation of the external anal sphincter may bring about internal sphincter relaxation.

Nelson and colleagues (2012) evaluated 75 studies in which 5031 participants were randomized to a nonsurgical therapy for anal fissure. All atypical fissures, including inflammatory bowel disease, anal cancer, and infection, were excluded. The results of this review show that GTN was significantly better than placebo in healing anal fissure (49% vs 36%; $P < 0.0009$). However, the dose was listed as either 0.2% or 0.4%, 2 or 3 times a day, for 6 to 8 weeks; 30% of patients suffered from headaches; and recurrence occurred over time in 50% of patients. Botox and calcium channel antagonists were equivalent to GTN in efficacy but did not result in as many adverse events. However, Botox dosing was variable with anywhere from 10 to 100 units given intramuscularly in the external anal sphincter, internal anal sphincter, or the intersphincteric space (Figure 4). One author recommended Botox always be placed anteriorly even if the fissure is posterior. The studies evaluating calcium channel antagonists did not include long-term follow-up, and no study evaluated

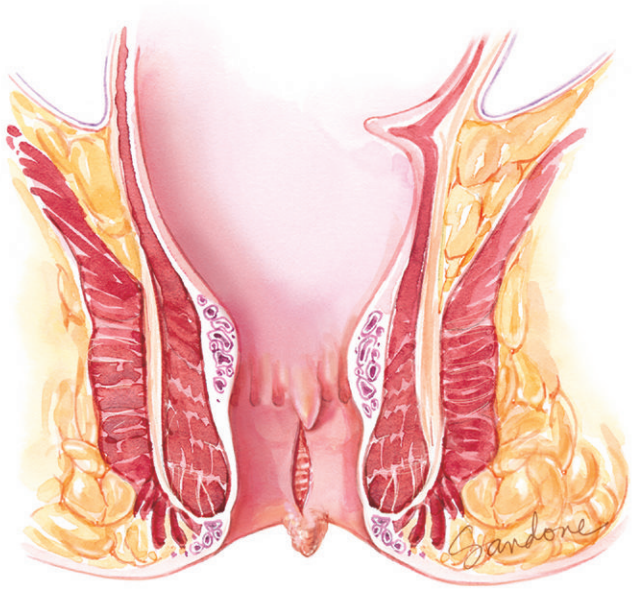

FIGURE 1 Chronic anal fissure exhibiting a sentinel pile and hypertrophied anal papilla. The internal sphincter muscle is seen within the bed of the fissure.

any patient past 1 year. Finally, no medical therapy came close to the efficacy of surgical sphincterotomy. However, none of the medical therapies in the randomized studies were associated with the risk of fecal incontinence.

Studies evaluating treatment for atypical anal fissures and anal fissures associated with inflammatory bowel disease are limited. It is important to emphasize the need for a biopsy, usually incisional or full thickness. If this is negative for infection, granuloma, or cancer, alternative therapies include fissurectomy or treatment with a local injection of steroid (Kenalog, Bristol-Myers Squibb, Princeton, NJ). Some authors have tried medical therapy aimed at reducing the anal resting tone. However, caution must be exercised in the use of medical therapy for the atypical fissure, since the pathophysiology of this fissure is unclear. Close follow-up is also recommended.

Surgical Therapy for Chronic Anal Fissure

The goal of the surgical approach to treatment of a chronic anal fissure is the relief of spasm of the internal anal sphincter. There are several operative techniques currently available to heal a chronic anal fissure by injuring the internal sphincter muscle. Historically, spasm of the internal anal sphincter muscle has been reduced with anal dilation. Because of the uncontrolled nature of this procedure, it has largely been replaced by the lateral internal sphincterotomy, which can be performed using an open or closed approach. In the open approach, a small incision is made in the intersphincteric groove (Figure 5). The internal sphincter muscle is identified and dissected

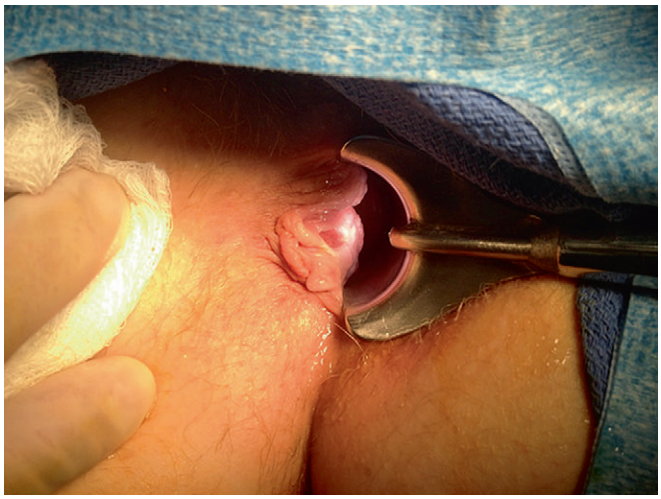

FIGURE 2 An exam under anesthesia reveals a prominent atypical lateral anal fissure or ulcer.

Smooth muscle relaxation	Antiinflammatory	Pain control
Nitroglycerine ointment/patch	Topical hydrocortisone (Analpram-HC)	Topical anesthetic (Lidocaine)
Calcium channel antagonists (diltiazem, nifedipine)	Injectable steroid (Kenalog)	Clove oil
Phosphodiesterase inhibitors (sildenafil, minoxidil)		
α-Adrenoceptor antagonist (indoramin)		
Botulinum toxin injection		
Anal dilators		
L-Arginine		
Sitz baths		

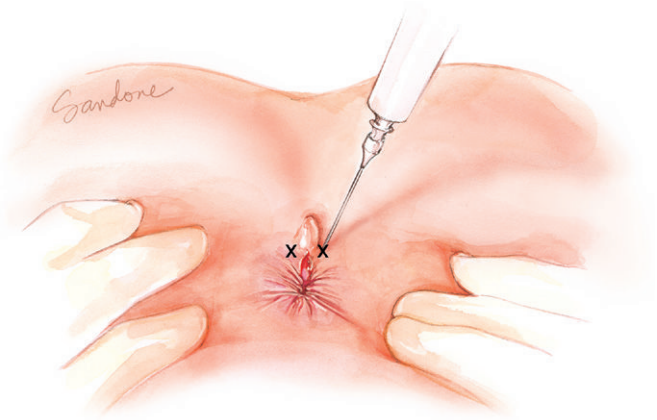

FIGURE 4 Botulinum toxin used in the treatment of a chronic anal fissure is injected here into the internal anal sphincter at both lateral edges of the fissure.

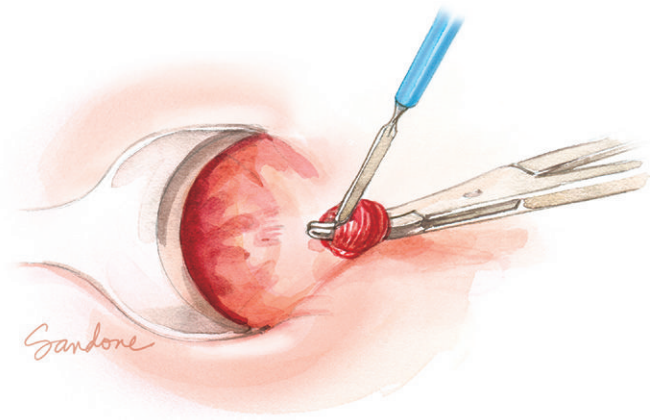

FIGURE 6 The hypertrophied internal sphincter is identified and elevated out of the wound. The sphincter is then divided using electrocautery.

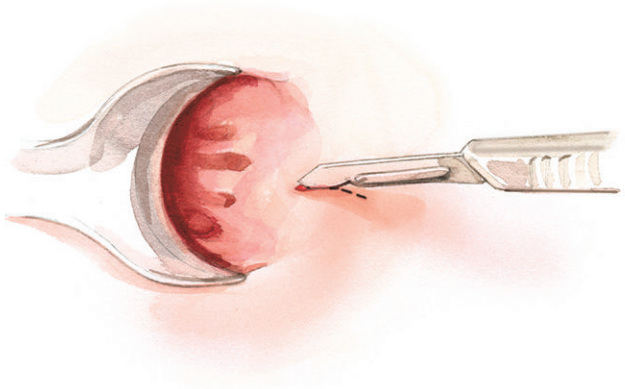

FIGURE 5 With the patient in the prone position, an incision is made in the intersphincteric grove on the right because less hemorrhoidal disease is found on the right side of the anus in the lateral position than on the left side.

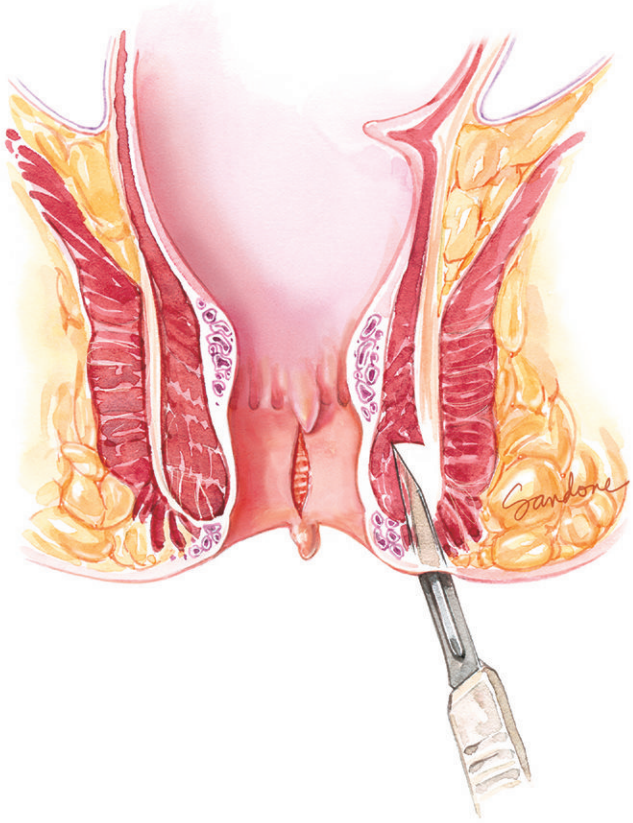

FIGURE 7 The closed lateral internal sphincterotomy is performed using an 11 blade scalpel along with gentle palpation of the anal sphincter complex.

free from the surrounding tissue and divided under direct vision with electrocautery (Figure 6). The wound is irrigated and closed with an absorbable suture. The closed technique has the same treatment goal; however, the procedure is performed with a scalpel blade, which is guided by palpation of the internal sphincter muscle (Figure 7). In both procedures, the sphincter muscle that is divided should at least include the muscle that is hypertrophied. It has been recommended by several investigators that the sphincter division should start at the dentate line. This procedure is associated with healing rates of greater than 90% and therefore remains the treatment of choice for those patients failing medical therapy.

The major drawback from surgical cutting or injury to the internal anal sphincter muscle is the risk of fecal incontinence. Recently, several reports have indicated that the rate of incontinence can be greater than 20%. However, it has recently been pointed out by a Cochrane review of surgery for anal fissure that although incontinence rates were reportedly higher, especially to flatus, that after fissure healing occurred, quality of life remained good despite the incontinence. Recently, a procedure introduced largely in Europe, the fissurectomy with or without advancement flap closure, has gained popularity because there is no direct injury that occurs to the anal sphincter muscles. In this procedure, the fissure is excised using a scalpel or scissors. If the wound edges are healthy, the anoderm is advanced downward or the skin is advanced upward to cover the sphincter complex. No internal sphincter muscle is cut; however, in some series, Botox was injected at the end of the procedure. The rate of incontinence associated with this procedure is less than 10%.

Treatment Algorithm

Once an anal fissure is diagnosed, it is important to determine the length of time it has been present. For any fissure that has been present for less than 6 weeks (acute), the treatment of choice is warm

sitz baths, increased intake of dietary fiber, and stool softeners. Regardless of length of time, all patients with fissures should be educated on the benefits of a high fiber diet. If no healing of the anal fissure occurs, medical therapy with calcium channel antagonists for 6 weeks is the author's first choice. If a patient presents initially with a chronic anal fissure and has not tried medical therapy, medical therapy for a 6-week trial is initially attempted. If pain improves, then no further treatment is necessary. If pain recurs in less than 6 weeks, surgery should be considered. Otherwise, a repeat trial of medical therapy can be offered. The author favors medical approaches in female patients because of the increased risk of fecal incontinence. The surgical treatment of choice is lateral internal sphincterotomy. In this procedure, at a minimum, the hypertrophied portion of the internal anal sphincter should be divided. If the risk of incontinence is high, fissurectomy with advancement flap should be considered.

ACKNOWLEDGMENT

The author would like to acknowledge Corrine Sandone for her help in preparing the figures.

Anorectal Abscess and Fistula

Jennifer Blumetti, MD, FACS, and Jose R. Cintron, MD, FACS

INTRODUCTION

Anorectal abscesses and anal fistulas are very common, affecting thousands of patients annually, and were described in the literature as early as 400 BC by Hippocrates. The most common etiology is cryptoglandular, blockage of the anal crypts that leads to infection of the anal glands and results in suppuration. Abscesses result in anal fistula in 40% to 60% of cases, and the two entities may be considered a progression of the same disease, with abscess the acute state and fistula the chronic state. The treatment of abscesses has remained largely unchanged over time. Wide drainage remains the mainstay of treatment. The treatment of anal fistula has changed dramatically over the years. Fistulotomy with or without seton drainage has traditionally been the treatment for anal fistula. More recently, noncutting or sphincter-sparing techniques have been developed as a result of concerns for varying degrees of incontinence arising from division of the anal sphincter. Approaches to the patient with anorectal abscess and fistula are presented.

ABSCESS

Anorectal abscesses arise from cryptoglandular infection in up to 90% of patients, although other causes such as Crohn's disease or the downward progression of pelvic sepsis, such as diverticulitis or appendicitis, can also occur. Other uncommon causes of abscess are trauma and atypical infections such as tuberculosis. Abscesses are most commonly classified on the basis of location as perianal, ischiorectal, intermuscular, intersphincteric, submucosal, or supralevator (Figure 1). Abscesses that originate in the deep postanal space may track to the ischiorectal fossa either unilaterally or bilaterally, resulting in a horseshoe abscess (Figure 2, *A*).

Diagnosis

Diagnosis of abscess is typically clinical, although imaging may be useful in selected cases. Patients typically report anal pain. Swelling and fever are also common symptoms. A thorough physical examination is necessary to rule out other causes of anal pain, such as fissure or thrombosed hemorrhoid. Erythema, palpable swelling, and tenderness are typically seen with perianal or ischiorectal abscesses. Fullness on digital rectal examination in the posterior anal canal is indicative of a deep postanal space abscess, and exquisite tenderness on digital examination without any external signs may be indicative of an intersphincteric abscess. If abscess is suspected but examination cannot be completed because of patient discomfort, then examination with anesthesia should be performed. Patients with systemic symptoms such as fever, tachycardia, and elevation of white blood cell count with few physical findings may have a supralevator abscess and could benefit from computed tomographic (CT) scan imaging to aid in diagnosis. Necrotizing soft tissue infection should be suspected if the patient has systemic signs combined with erythema, crepitus, induration, blistering, "dishwater" drainage, or overt gangrene of the tissue (Figure 3, *A*).

Treatment

The mainstay of treatment is adequate drainage of the abscess. Antibiotics alone do not play a role, although they may be indicated as an adjunct in patients with significant cellulitis, diabetes, or immunosuppression (patients with acquired immune deficiency syndrome (AIDS), chemotherapy, or transplant). Surgical drainage of simple perianal or superficial ischiorectal abscesses may be performed in the office or emergency room setting with a local anesthetic. Instillation of lidocaine with epinephrine is performed around the area to be drained. An elliptic incision is then made over the area of fluctuance

to drain the abscess (Figure 4). Packing is typically not necessary for smaller abscesses. Some practitioners prefer to place a small mushroom catheter in the cavity to allow for drainage.

Larger ischiorectal abscesses and suspected intersphincteric abscesses should be drained in the operating room with regional or general anesthesia. Intersphincteric abscesses should be unroofed. Large ischiorectal abscesses should not be unroofed over the length of the abscess; rather, multiple counter incisions should be made and Penrose drains placed between the incisions to allow for drainage. This prevents a large defect and allows for better wound healing. A horseshoe or hemihorseshoe abscess involving the deep postanal space should be managed with opening of the deep postanal space and counter incisions made over the lateral aspects of the abscess. This is done through a radial incision made in the posterior midline between the anus and the coccyx. The external sphincter and the anococcygeal ligament are spread in the midline, which allows for drainage of the deep postanal space. The responsible anal gland is drained by dividing the distal aspect of the internal sphincter in the posterior midline. Counter incisions are then made and connected to the deep postanal space with Penrose drains to fully drain the abscess. If a fistula is present, a seton should also be placed (see Figure 2, *B* to *D*).

Necrotizing infections are managed with broad-spectrum antibiotics to cover gram-positive, gram-negative, and anaerobic organisms. Prompt wide surgical débridement to healthy tissue should then be performed. Several reexaminations in the operating room may be necessary to adequately treat this aggressive disease (see Figure 3, *B*).

FISTULAS

Anal fistulas occur in almost half of the patients with anorectal abscess. They are most commonly cryptoglandular in origin with internal openings located at the level of the dentate line, but they can also occur with Crohn's disease, obstetric injuries, or trauma. Fistulas are typically classified by anatomic location as described by Parks in 1976 (Figure 5). Intersphincteric fistulas involve only partial amounts of the internal sphincter muscle, and transsphincteric fistulas involve varying amounts of both internal and external sphincter muscle. Transsphincteric fistulas can also be classified as low or high depending on the amount of sphincter muscle involved, with low transsphincteric fistulas involving the distal one third of the external sphincter and high transsphincteric fistulas involving more than half

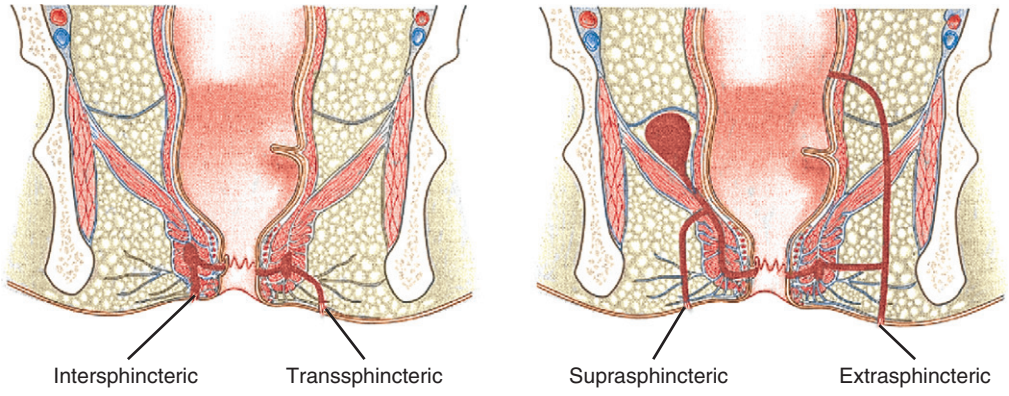

FIGURE 5 Park's classification of anal fistula.

of the external sphincter muscle. The less common suprasphincteric fistulas involve the entire external sphincter. Extrasphincteric fistulas are rare; they are typically not cryptoglandular in origin but may result from trauma, perforation of the rectum from foreign body, or Crohn's disease or can be iatrogenic.

Diagnosis

The diagnosis of anal fistula should be suspected in patients with a history of anorectal abscess that does not heal. A patient typically reports pain or purulent or bloody discharge and gives a history of a surgically or spontaneously drained abscess. Systemic signs are typically absent unless an undrained abscess is present. A history of prior anorectal surgery should be elicited, and the patient's continence should also be assessed before any intervention. On examination, an external fistula opening is easily identified. A thorough examination should be made to evaluate for the number and location of the openings in relation to the sphincter complex. A palpable cord from the external opening toward the anal canal may be present. Internal examination with anoscopy should reveal the internal opening, although this may need to be performed with anesthesia because of patient discomfort. A history of a change in bowel habits, multiple external fistula openings, internal openings at a location other than the dentate line, or multiple internal openings should alert the examiner to the possibility of atypical causes of fistula such as Crohn's disease, human immunodeficiency virus (HIV), or malignancy.

Goodsall's rule (Figure 6) predicts the location of the internal opening based on the location of the external opening and is accurate in most cases. External fistula openings located posteriorly typically have internal openings in the posterior midline and a curved tract.

Anteriorly based fistulas typically have a radial course to the internal opening. Exceptions to Goodsall's rule may occur when the external fistula openings are located greater than 3 cm from the anal verge anteriorly. These likely have internal openings in the posterior midline.

Examination with anesthesia is an essential part of the diagnosis of suspected anal fistula. The accurate location and number of internal openings and their relationship to the sphincter muscles should be clearly delineated. Placement of a probe from the external opening to the internal opening should be performed, but with caution because aggressive probing may result in iatrogenic injury and creation of false tracts. The instillation of hydrogen peroxide into the external opening may help with identification of internal fistula openings. Endoanal ultrasound scan and fistulography may also aid in identification of internal openings in the operating room. Magnetic resonance imaging (MRI) can also be used if no internal opening can be identified in the operating room.

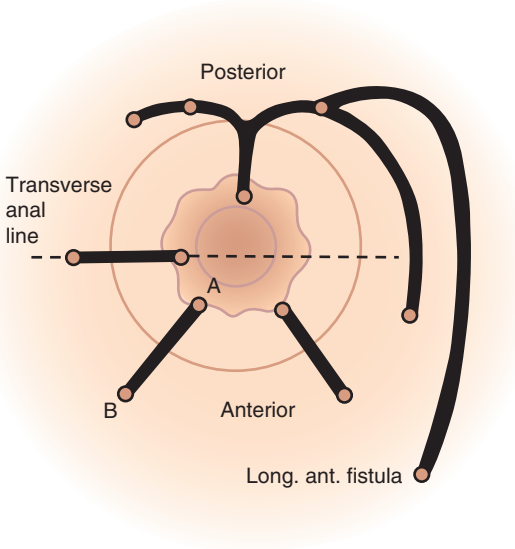

FIGURE 6 Goodsall's rule. A line is drawn transversely *(A)*. External openings anterior to this line track to the anus in a radial fashion *(B)*, and external openings posterior to this line track in a curvilinear fashion to the posterior midline. *(From Townsend CM, Beauchamp RD, Evers BM, et al, editors:* Sabiston textbook of surgery, *ed 19, Philadelphia, 2012, Elsevier Saunders, Fig 53-20.)*

Treatment

The treatment of anal fistula can be divided into cutting or noncutting (sphincter-sparing) procedures. Cutting procedures include simple fistulotomy or staged fistulotomy. Sphincter-sparing procedures include seton placement, endorectal or dermal advancement flap, fibrin sealant, anal fistula plug, and ligation of the intersphincteric fistula tract (LIFT). The choice of treatment is based on location of the fistula tract in relation to the sphincter muscles, the status of the patient's continence, and the number and type of prior anal procedures. These procedures are typically performed with regional or general anesthesia and with the patient in the prone jackknife position.

PRIMARY FISTULOTOMY

Fistulotomy has been considered the gold standard in the treatment of anal fistulas. Simple or primary fistulotomy can be safely performed in superficial fistulas (i.e., fissure fistulas), intersphincteric fistulas, and low transsphincteric fistulas (1/3 or less external sphincter muscle involved). Populations in which primary fistulotomy should not be performed are women with anterior fistulas, patients with disturbed continence, and patients with Crohn's disease or advanced HIV disease because incontinence rates can be high with this procedure. Fistulotomy is performed by placing a probe through the fistula tract and then unroofing the tract along its length (Figure 7). The wound can then be marsupialized by suturing the edges of the wound to the base of the tract with absorbable suture, which decreases the time for wound healing. Fistulotomy can be performed at the time of abscess drainage if the internal opening is readily visualized, such as in intersphincteric abscess or fistulas.

SETONS

A seton is commonly used in anal fistulas that cannot be treated with primary fistulotomy alone. High transphincteric fistulas, suprasphincteric fistulas, and anterior fistulas in women and in patients with HIV or Crohn's disease typically have a seton placed as part of the treatment. A seton can be used in one of three ways. First, setons can be used to drain sepsis and allow for identification of the tract at a subsequent operation. These setons are typically loosely tied, heavy-duty, nonabsorbable braided sutures that promote fibrosis and

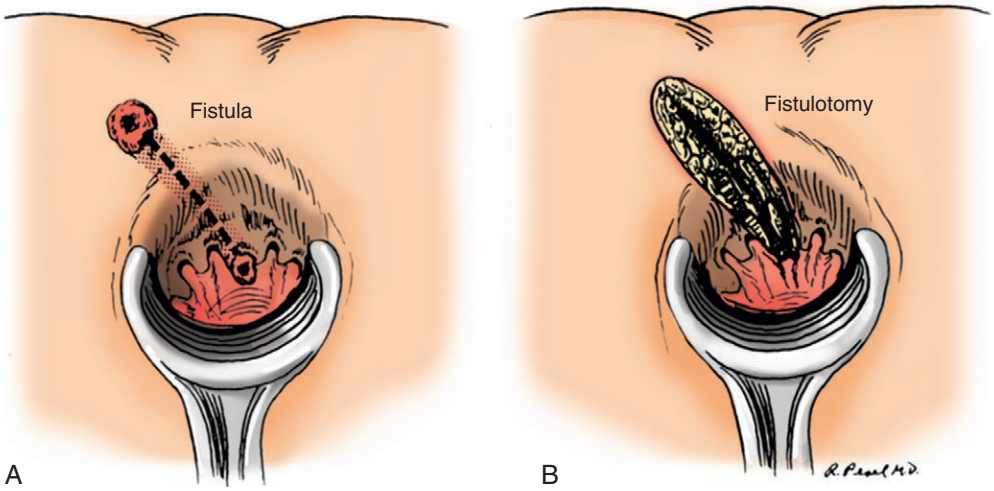

FIGURE 7 Primary fistulotomy. **A,** The fistula tract is identified. **B,** The tract is opened along its length. *(Original illustration provided by Dr. Russell Pearl.)*

FIGURE 8 Setons in place. The seton in the posterior midline is a nonabsorbable braided suture. The seton on the right is a vessel loop. *(Photograph provided by Dr. Jose Cintron.)*

maturation of the tract before a definitive operation, either fistulotomy or a sphincter-sparing procedure (Figure 8). This may be performed in conjunction with a partial fistulotomy in which the distal part of the internal sphincter is divided and the seton placed in the remaining tract. The fistulotomy is then completed 8 to 12 weeks later once the first stage has healed. The second use of the seton is for patients in whom the seton may be the definitive procedure or in whom fibrosis is not desired (e.g., because of Crohn's disease or advanced HIV). In these patients, a vessel loop may be used as a seton to allow for drainage and prevent recurrent abscess formation (see Figure 8). The third technique is the use of a cutting seton. In this procedure, the skin overlying the fistula tract is opened, and a heavy braided suture, vessel loop, or rubber band is placed into the fistula tract and tied snugly. This is then tightened every 1 to 2 weeks with suture or rubber band placed via a hemorrhoid ligature, allowing for pressure necrosis to slowly cut through the sphincter muscles. This technique can result in significant incontinence rates and is used infrequently.

ADVANCEMENT FLAPS

Endorectal advancement flaps were originally described in 1912 by Elting and are used as an alternative to cutting procedures. Endorectal advancement flaps are commonly performed in high transphincteric fistulas, in low transsphincteric fistulas in women, and in Crohn's fistulas if the patient has normal rectal mucosa. Endorectal flaps can be performed as a primary procedure or subsequent to seton drainage (Figure 9). The fistula tract should be curetted, and

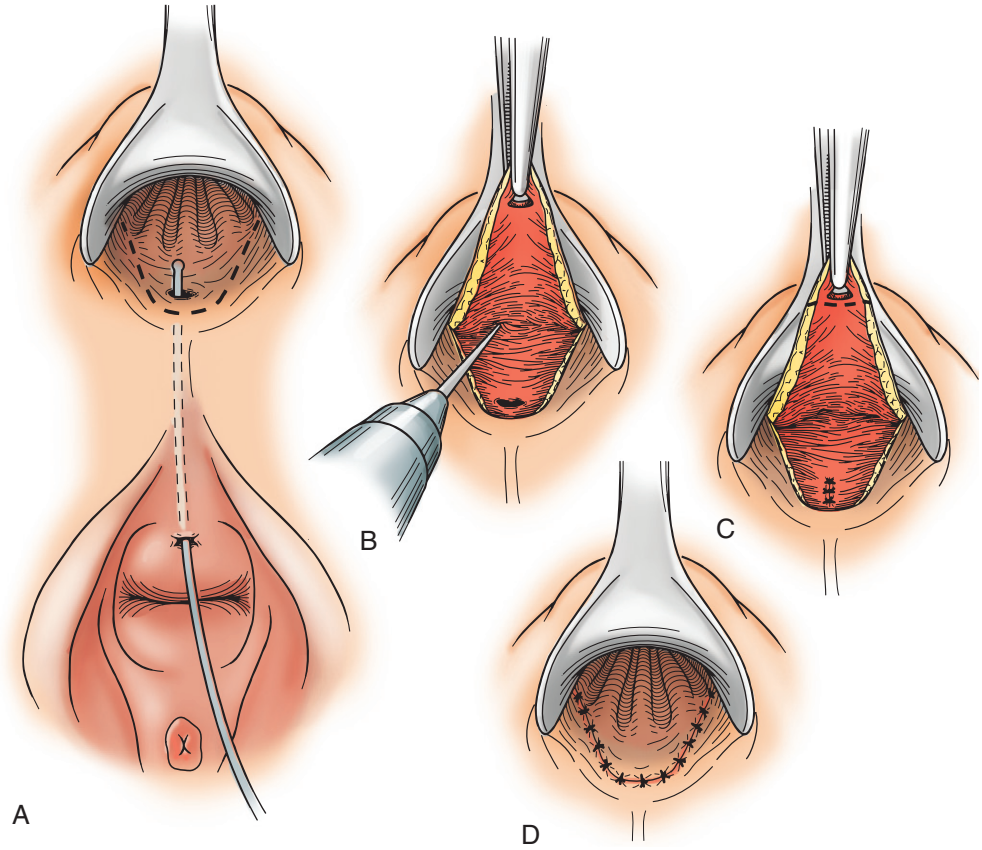

FIGURE 9 Endorectal advancement flap. **A,** A probe is placed through the tract. The flap extends distally to the internal opening. **B,** The flap is raised 4 to 6 cm. **C,** The distal aspect of the flap is excised, and the internal opening in the muscle is sutured. **D,** The flap is then sutured into place with interrupted suture. *(From Hyman N: Endoanal advancement flap repair for complex anorectal fistulas,* Am J Surg *178:337–340, 1999.)*

the internal opening is then excised. A flap of mucosa, submucosa, and superficial circular muscle is created, extended 4 to 6 cm proximal to the internal opening to allow for a tension-free closure. The base of the flap provides the blood supply to the flap and should be twice the width of the apex of the flap. The internal opening is then closed with absorbable suture, and the flap then advanced and sutured to the dentate line. The external opening is widened to allow for drainage. This procedure is not appropriate for fistulas with internal openings that are distal to the dentate line. If the flap is sutured too distal, then the result is a mucosal ectropion. Success rates for this procedure range from 75% to 98%.

Dermal advancement flaps were originally used for mucosal ectropion and anal stenosis but were modified to treat anal fistulas. This technique involves creation of a pear-shaped incision that extends from just proximal to the internal opening and then to the external opening (Figure 10). The full-thickness flap is raised by deepening the incision lateral to the external sphincter muscle. Care is taken not to undermine the incision because the blood supply to the flap could become compromised. The internal opening is then excised and closed with absorbable suture. The flap is then advanced into the anal canal and sutured just proximal to the internal opening with interrupted absorbable suture. The donor site is left open to heal by secondary intention. This type of flap reduces the risk of mucosal ectropion and has a success rate of 77%.

FIBRIN SEALANT

The use of fibrin sealant is appealing because it has a low morbidity and no risk of incontinence and can be repeated if necessary. This technique is beneficial in longer rather than shorter fistula tracts. Typically, the patient has had a seton placed before the procedure to allow drainage of any infection. The fistula tract is then curetted. The commercially prepared product, such as Tisseel (Baxter Healthcare, Deerfield, Ill), is used. The two components of the sealant are injected through a dual-lumen catheter that has been inserted into the external opening and advanced to the internal opening. The catheter is slowly withdrawn during injection until a "pearly" coagulant is seen at the internal opening. Success rates with this procedure range from 14% to 40% (Figure 11).

FISTULA PLUG

The anal fistula plug is also a noncutting, sphincter-sparing technique and, similar to fibrin glue, has low morbidity and can be repeated if necessary. The ideal candidate for this procedure is one with a transsphincteric fistula who has had prior drainage with a

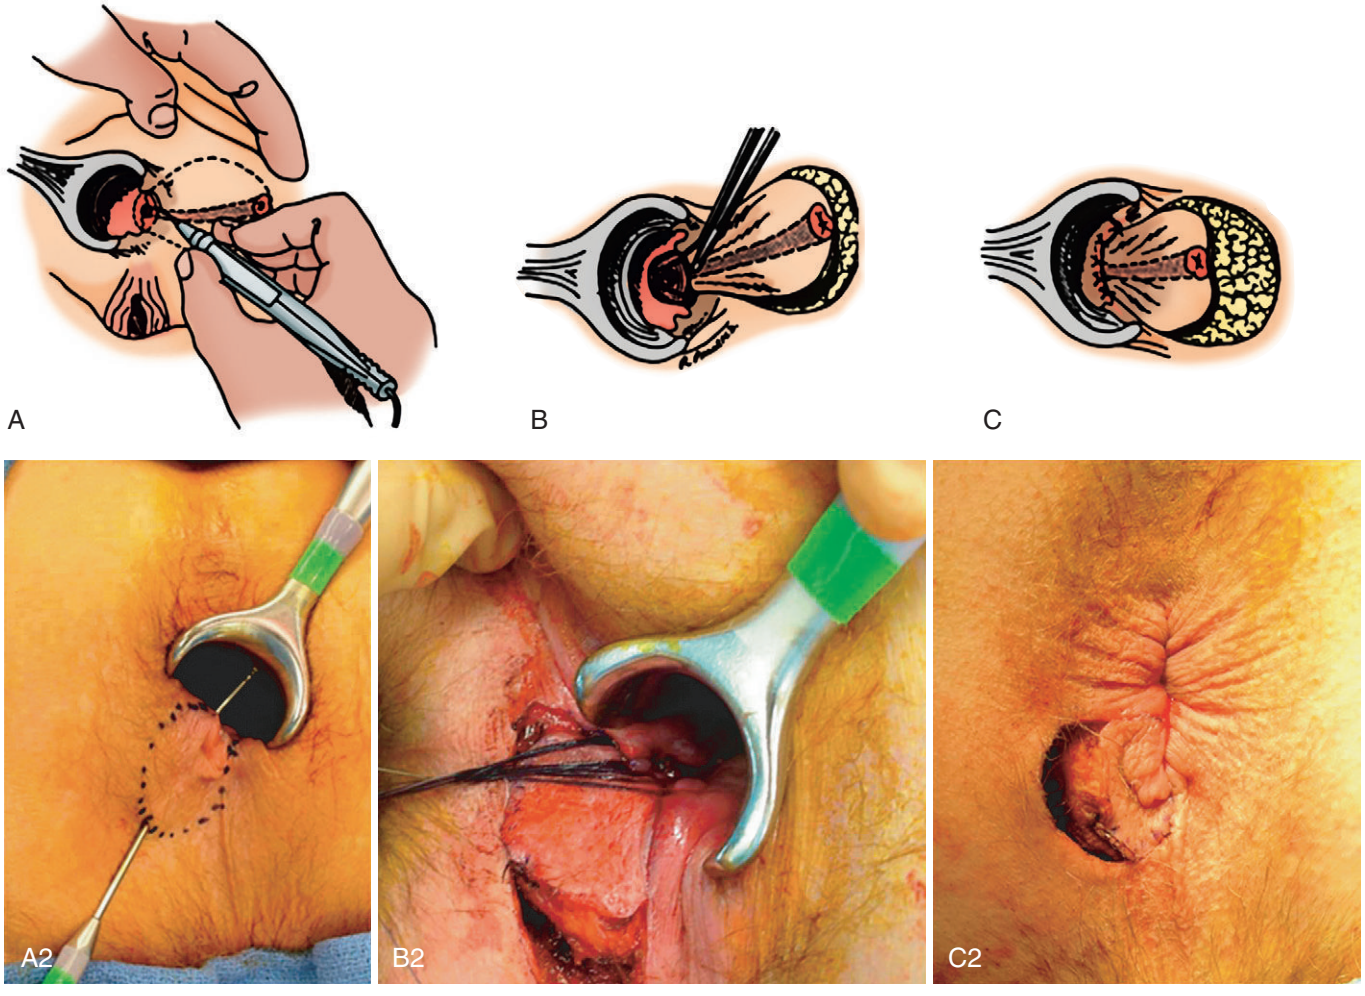

FIGURE 10 Dermal advancement flap. **A,** The U-shaped flap is created to encompass the external opening. **B,** The internal opening is excised, and the full-thickness flap is raised, advanced into the anal canal, and sutured into place. **C,** The final appearance of the flap. *(Illustrations from Nelson RL, Cintron J, Abcarian H: Dermal island-flap anoplasty for transsphincteric fistula-in-ano: assessment of treatment failures,* Dis Colon Rectum *43:681–684, 2000. Photographs provided by Dr. Jose Cintron.)*

seton for 6 to 12 weeks before placement of the plug. Plugs may be made of treated porcine submucosa (Cook Biodesign; Cook Medical, Bloomington, Ind) or synthetic bioabsorbable polymer (Gore Bio-A; W. L. Gore and Associates, Flagstaff, Ariz; Figure 12) The fistula tract should be curetted, and the external opening débrided. The plug is then advanced from the internal opening to the external opening, until the base of the plug is seated at the internal opening. The plug is then sutured to the internal opening with absorbable suture to close the internal opening over the plug. The excess plug at the external opening is trimmed, and the external opening left open. Success rates have been reported primarily for the porcine submucosa plug and range from 43% to 87%.

LIGATION OF INTERSPHINCTERIC FISTULA TRACT

One of the more recently developed procedures for anal fistula, the ligation of the LIFT, was originally described by Rojanasakul in 2007. The procedure is ideal for transsphincteric fistulas with mature tracts, and most patients have had seton drainage before this procedure. A curvilinear incision is made just lateral to the intersphincteric groove. The internal and external sphincter muscles are separated in the intersphincteric space; no sphincter muscle is divided. A probe is placed within the fistula tract, and the tract is isolated circumferentially within the intersphincteric groove. It is then ligated proximally and distally with absorbable sutures after the probe is removed. The tract is then divided, or alternately a segment is excised. The incision is then closed with absorbable suture, and the external opening is widened to allow for drainage (Figure 13). Early success rates have ranged from 57% to 89%.

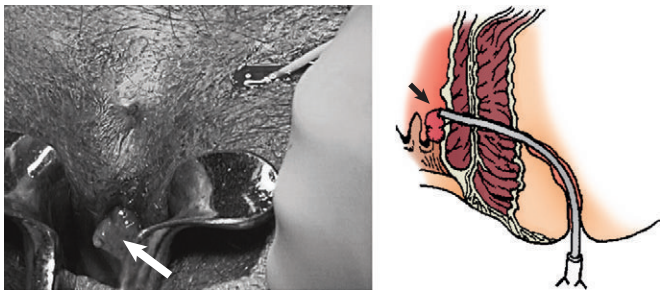

FIGURE 11 Fibrin sealant. The sealant is injected via a long catheter through the external opening and into the internal opening. The *arrow* shows the sealant at the internal opening. *(From Singer M, Cintron J: New techniques in the treatment of common perianal diseases: stapled hemorrhoidopexy, botulinum toxin and fibrin sealant,* Surg Clin North Am *86(4):937–967, 2006, Fig. 2.)*

CHOICE OF PROCEDURE

A proposed treatment algorithm for anal fistula can be seen in Figure 14. Simple low-lying fistulas can almost always be treated with primary fistulotomy with high success rates and low incontinence rates, except in patients with Crohn's disease or HIV, in women with anterior fistulas, or in patients who have undergone sphincter division in the past. Fistulas with a significant amount of sphincter involvement and an associated abscess should first undergo drainage of the abscess and placement of a loosely tied seton, with a plan to return to the operating room for definitive surgery in 6 to 12 weeks. If there is a well-defined tract at reoperation, then a LIFT procedure is appropriate. Longer tracts may be amenable to fibrin sealant or fistula plug, which can be repeated if the fistula recurs. Endorectal flaps should be performed in fistulas with internal openings at the dentate line. Those with internal openings distal to the dentate line may be candidates for dermal flaps.

CONCLUSION

Anorectal abscesses and fistulas are very common diseases that result from infection of the anal crypts and glands. Wide drainage continues to be the mainstay of abscess treatment. Surgical procedures for anal fistula are trending toward more sphincter-sparing procedures and away from fistulotomy as the sole treatment. The surgeon should understand the various techniques used in the treatment of anal fistula so that treatment can be tailored to the individual patient.

Anorectal Stricture

Bard C. Cosman, MD, MPH, and Yarah M. Haidar, MD

DEFINITION

A *rectal stricture* is a nondistensible narrowing of the rectum that may interfere with free flow of the fecal stream. An *anal stricture* is a nondistensible narrowing of the anal canal that may interfere with defecation. The term *anorectal stricture* covers both conditions, although an individual patient typically has either one or the other and not both. Both conditions have been defined functionally as either the inability to pass a 12-mm diameter sigmoidoscope through the narrowed area or the inability to pass stool without pain because of partial obstruction of the lumen. Older sources describe benign and malignant stricture, but it is now customary to discuss only benign conditions under the heading of stricture; obstructing rectal and anal cancers are discussed under those headings. The term *stenosis*, synonymous with stricture, is most commonly applied to the muscle spasm that accompanies anal fissure—a functional rather than structural stenosis that is discussed under the heading of anal fissure. Congenital strictures are almost never seen in the adult patient, and they are covered in pediatric surgical texts as anorectal malformations or under the general heading "imperforate anus."

CAUSES

Benign, acquired anorectal strictures are caused by fibrosis, a nonspecific response to inflammation.

Rectal stricture may follow proctitis arising in inflammatory bowel disease (IBD), tuberculous or amebic proctitis, proctitis from venereal infections (syphilis, gonorrhea, *Chlamydia trachomatis*, *Herpes simplex),* radiation proctitis from prostate or cervical cancer treatment, and trauma from instrumentation. Suppositories, especially those that contain ergotamine or nonsteroidal antiinflammatory drugs, have been implicated. Probably the most common cause for rectal stricture in developed countries is iatrogenic, from a strictured surgical anastomosis.

Anal stricture may follow any inflammatory condition, including anal fistula, burns, and radiation injury from anal cancer treatment. Ulcerating anal infections such as chancroids and *H. simplex* may cause stricture, especially when they are chronic or recurrent. The most common cause for anal stricture is again iatrogenic, from

excision of anoderm during anal operations for hemorrhoids, warts, and fistula.

CLINICAL PRESENTATION

Because of the extreme variability of fecal consistency and bowel habits, little correlation is found between the severity of anorectal stricture and the severity of symptoms. Symptoms may include pain, constipation, decreased stool caliber, difficulty in defecation, tenesmus, bleeding, diarrhea, urgency, and fecal incontinence. Pain is the most common symptom, followed by difficult defecation, followed by bleeding. Like stricture anywhere in the colon, rectal stricture may cause large bowel obstruction. Anal stricture almost never causes frank obstruction because patients seek treatment long before.

DIAGNOSIS

Rectal stricture may present insidiously because most processes that cause it are slow and chronic and the stricture may not be within reach of an examining finger. Anal stricture is always accessible to digital examination and is usually identified in the course of treatment for the causative condition. On the basis of digital anal and distal rectal examination, one can call a stricture mild, moderate, or severe. A *mild stricture* allows the passage of an index finger but feels abnormally tight to the examiner. A *moderate stricture* necessitates forceful and painful digital examination, prompting the examiner to refrain and consider examination with sedation or anesthesia. A *severe stricture* prohibits digital examination, mandating examination with anesthesia.

NONOPERATIVE MANAGEMENT

Medical Treatment

Many patients after anal operations such as hemorrhoidectomy have what amount to transient inflammatory strictures. Like a postoperative patient, anyone with an anorectal stricture may be helped with hydration, fiber, and stool softeners. Patients with IBD strictures should receive disease-specific medical treatment, which can help the inflammatory component but does not affect fibrosis. Infections should be identified and suppressed with antibiotics or antiviral medication.

Mechanical Dilation

Rectal strictures may be dilated in the endoscopy suite, the operating room, or even the office, depending on the location of the stricture and how painful it is to dilate. Tools for dilation include bougies, Hegar dilators, end-to-end anastomosis (EEA) sizers, and the rigid proctoscope. Today's version of the age-old "divulsion" treatment is balloon dilation, which can be done through a flexible sigmoidoscope.

Anal strictures can be dilated digitally, with the serial introduction of fingers. Severe anal strictures may respond to Hegar dilators of increasing diameter, followed by a finger. For many patients, defecation can be a form of autodilation, as long as the stool is solid; this argues for fiber rather than stool softeners for long-term use.

Stricture dilation is beneficial up to the point of injury that causes more fibrosis. In the words of the old-time "ambulant proctologist" Blanchard, "One cicatrix cannot be mended by the formation of another, any more than two wrongs make one right."

OPERATIVE MANAGEMENT

Stricturotomy and Stricturectomy for Rectal Stricture

These operations and their attendant controversies were the subject of whole books and monographs before the antibiotic era. As a measure of its prominence in the 19th century, the section on rectal (not anal) stricture comprises 15% of Allingham's anorectal surgical text. Today the rare stricture that does not respond to dilation is typically removed via anterior resection, a form of stricturectomy. Stricturotomy lives on in methods of fixing the rare membranous or short-segment stricture. These can be divided endoscopically with cautery or laser, and they can also be cored out with a circular stapler—something between stricturotomy and stricturectomy. The combination of effective treatment of underlying causes and endoscopic balloon dilation has made rectal stricture operations very rare today.

Anoplasty for Anal Stricture

Anoplasty is done for patients with moderate or severe stricture, or any symptomatic stricture refractory to dilation. The goal is to divide the stricture and correct the resulting defect. Anoplasty can be divided into three categories: transverse closure, simple random flaps, and full-thickness advancement flap.

1. *Transverse closure.* As in small bowel strictureplasty, the stricture is divided longitudinally, then sutured transversely. If there is substantial tension in bringing the edges together, as there often is, a flap repair is selected instead.
2. *Simple random flaps.* These receive their blood supply via a skin bridge. Examples include mucosal advancement, Y-V, and rotational S flaps.
 a. *Mucosal advancement flap.* A transverse incision is made at the dentate line, extending into the anal verge. The scar is excised, and the mucosa is sutured to the distal border of the internal sphincter at the anal verge. The external part of the wound is left open. This method is suitable for mid or high anal canal strictures.
 b. *Y-V advancement flap:* The initial incision is made radially at the level of the stricture, making the vertical limb of the Y. The bifurcation of the Y is located distally on the perianal skin. This flap is suitable for anal verge (low) strictures *(*Figure 1, *A)*.
 c. *Rotational S flap:* In an S flap, the abnormal tissue is removed and replaced with skin, fixing the mucocutaneous junction at the normal position. The skin coverage is provided by a double-rotational flap, outlined by a large S, with the anal canal at the center. This more extensive flap is suitable for patients with recurrent strictures, high strictures, or strictures with mucosal ectropion *(*Figure 1, *B)*.
3. *Full-thickness advancement flaps:* These receive their blood supply through the subcutaneous fat from the underlying muscle. Examples include the diamond, house, and V-Y flap. All three of these flaps are used in long strictures, high strictures above the dentate line, or strictures with mucosal ectropion.
 a. *Diamond flap:* Excision of scarred skin and anoderm leaves a roughly diamond-shaped defect. This is covered by a diamond-shaped flap that is advanced from distal to proximal, to the intraanal portion of the defect.
 b. *House flap:* A longitudinal incision extends from the dentate line to the distal end of the stricture. This incision corresponds to the walls of the house-shaped flap. It is

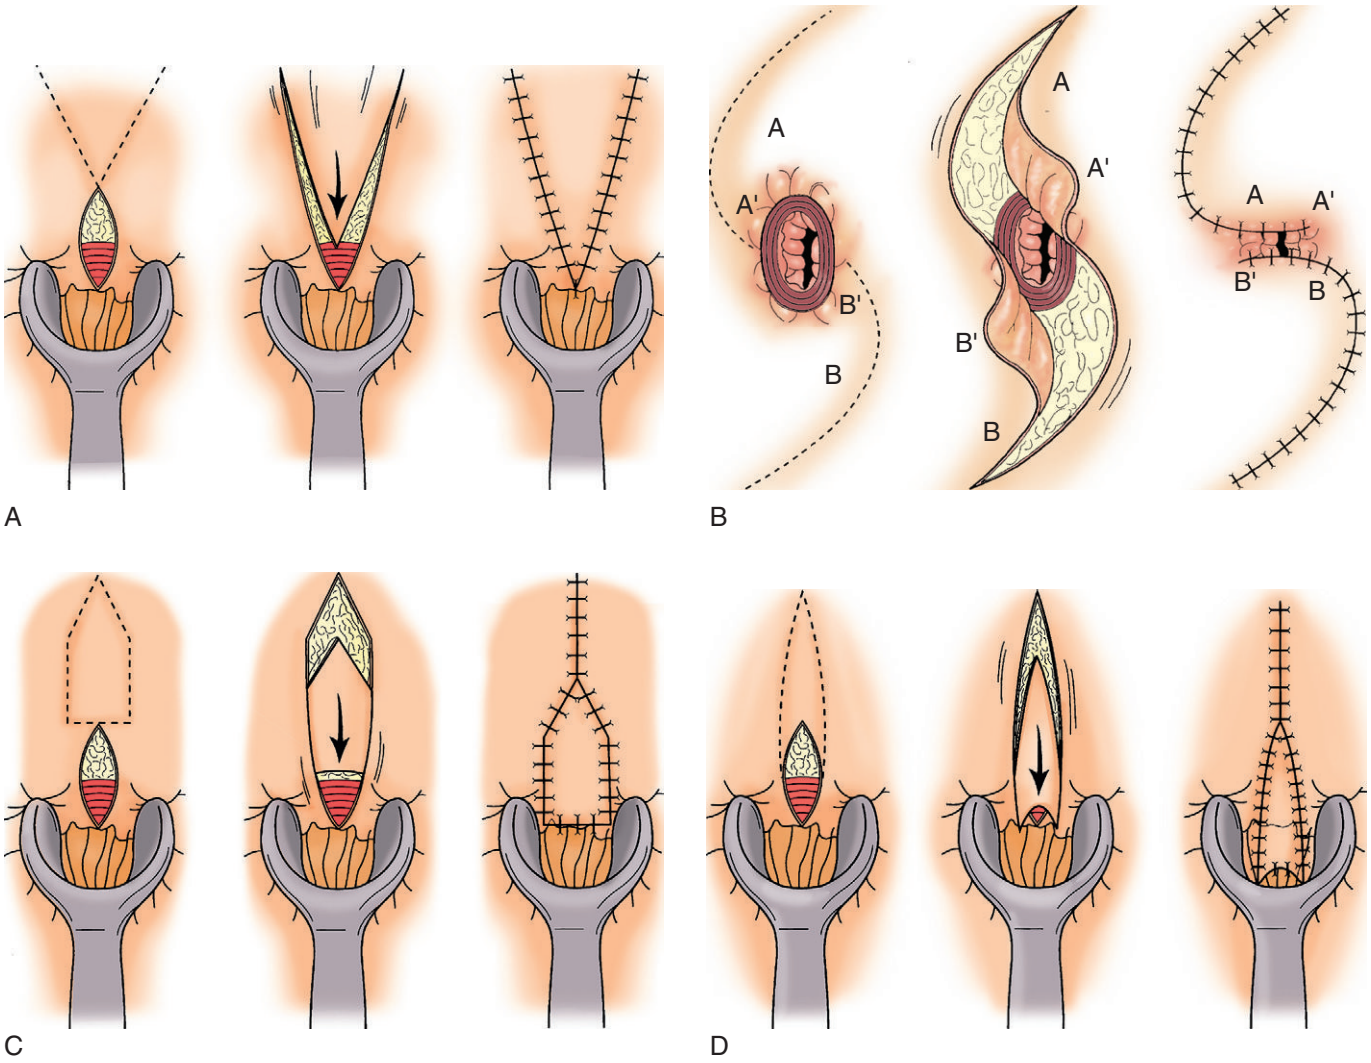

FIGURE 1 **A,** Y-V flap. **B,** S flap. **C,** House-shaped flap. **D,** V-Y flap. *(From Liberman H, Thorson AG: How I do it: anal stenosis,* Am J Surg *179(4):325-329, 2000.)*

advanced proximally to line the entire length of the anal canal *(Figure 1, C)*.

c. *V-Y advancement flap.* The strictured segment is excised radially, and then a V-shaped flap is advanced to the dentate line. Like the house flap, the V-Y's broad proximal edge can correct large deficiencies of anoderm *(Figure 1, D)*.

SUMMARY

Anorectal strictures can develop from any cause of fibrosis, the most common of which is iatrogenic from previous anorectal surgery. Digital examination is used to categorize reachable strictures as mild, moderate, or severe. Symptoms do not correlate well with these categories. Treatment is based first on relieving symptoms, which commonly include pain, difficult defecation, and bleeding. Patients with mild symptoms can be treated with dietary modification, medication for the underlying condition (in the case of IBD or infection), and possibly dilation. Patients with severe symptoms and those with failed dilation may benefit from surgical treatment. For rectal stricture, this is primarily stricturectomy, although stricturotomy remains an option in rare cases. For anal stricture, various anoplasty options aim to incise the stricture and place distensible tissue in the resulting defect.

The Management of Pruritus Ani

Mantaj S. Brar, MD, FRCSC, and
Anthony R. MacLean, MD, FRCSC, FACS

INTRODUCTION

Pruritus ani refers to the symptoms of itching and burning of the perianal skin. Patients often delay seeking medical attention, and their unsupervised attempts at treatment, including aggressive repetitive cleaning and the use of over-the-counter creams or ointments, typically only worsen symptoms. Although the estimated incidence rate of pruritus ani in the general population is 1% to 5%, it presents less often in clinical practice because many patients do not seek medical attention. This condition affects males more often than females, with a ratio of 4:1, and although also seen in children, most patients present in the fourth to seventh decades of life. Pruritus ani may be localized or diffuse in the perianal region. The onset of symptoms is typically gradual and is often worse at night or in warm, moist climates.

ETIOLOGY

Pruritus ani is classified as either idiopathic pruritus ani or secondary pruritus ani. The many secondary causes of pruritus ani include anorectal, infectious, and dermatologic and several systemic illnesses (Box 1). The diagnosis of idiopathic pruritus ani is only made after a thorough patient evaluation and exclusion of secondary causes. Although the authors' experience suggests that an overwhelming majority of pruritus ani is idiopathic, the proportion of patients with a secondary cause varies from 20% to 75% in the published literature.

Idiopathic Pruritus Ani

Several factors have been implicated in idiopathic pruritus ani, including local irritants, excess moisture, repeated trauma from wiping, and medications (Box 2). Fecal contamination is implicated as a local irritant in many cases, the presence of which may not be evident to the patient. Feces contain bacterial endopeptidases, allergens, and bacteria, which are capable of causing skin irritation. In addition, evidence from skin patch testing has shown that the perianal skin is particularly sensitive to irritation and pruritus from exposure to feces compared with skin at other areas of the body. Fecal contamination itself can be the result of poor hygiene, incontinence, chronic diarrhea, or loose stools and is also the mechanism by which several anorectal pathologies cause symptoms. Interestingly, physiologic studies in patients with idiopathic pruritus ani have shown a lower threshold for internal anal sphincter relaxation and lower retention capacity than in control subjects, suggesting that a functional abnormality may contribute to idiopathic pruritus ani. Several medications have been associated with idiopathic pruritus ani and cause symptoms either by causing diarrhea or loose stools, by inducing a histamine release, or by an idiopathic mechanism. The most commonly associated medications include colchicine, quinidine, tetracycline, erythromycin, and stool softeners (see Box 2). In addition, certain foods have also been associated with idiopathic pruritus ani, including coffee, cola, tea, chocolate, spicy foods, and citrus foods (see Box 2). Several proposed mechanisms include alteration of the pH of stool by citrus or spicy foods that cause local irritation, by histamine release, and by caffeinated foods that cause a transient inappropriate relaxation of the internal anal sphincter. Excess fluid intake may also cause pruritus ani by causing loose stools or diarrhea and subsequent fecal contamination and frequent wiping.

Secondary Pruritus Ani

Anorectal Conditions

A variety of anorectal conditions have been associated with pruritus ani, including prolapsing internal hemorrhoids, external hemorrhoids, anal fissures, fistula-in-ano, and neoplasms. Fistula-in-ano causes chronic irritation of the perianal skin from chronic drainage of fluid and a small amount of fecal debris. Prolapsing hemorrhoids and rectal prolapse lead to a chronic drainage of mucus at the level of the perianal skin and fecal contamination, which leads to irritation of the skin. In addition, prolapsed internal hemorrhoids, external hemorrhoids, and skin tags may impair good hygiene and result in feces left in the folds of the perianal skin after defecation, causing irritation. Other conditions that impair sphincter function, cause diarrhea, or decrease stool bulk may lead to fecal soiling and cause pruritus. Pruritus ani may be the presenting symptom of Paget's disease or Bowen's disease, and these neoplasms, although rare, should be considered in the differential diagnosis. Classically, the symptoms of pruritus are more severe and persistent in the setting of an underlying neoplasm.

Infectious Conditions

Infectious agents that cause pruritus ani include bacteria, viruses, fungi, and parasites. Bacterial infections most commonly associated with pruritus ani include *Corynebacterium minutissimum* (erythrasma), beta-hemolytic *Streptococcus* sp., and *Staphylococcus aureus*. Several sexually transmitted infections *(Gonococcus, Chlamydia,* and *Syphilis)* have also been implicated, although these pathogens are rarely responsible for chronic symptoms. Viral infections such as herpes simplex and human papillomavirus (HPV) can cause pruritus ani. With condylomata acuminata, functional changes of the anal sphincter may lead to fecal leakage and pruritus. Fungal infections with *Candida,* although usually a commensal organism in the perianal region, can lead to pruritus, particularly in patients with diabetes and immunosuppression and after treatment with antibiotics or steroids. However, the presence of dermatophytes in the perianal region is always considered pathologic in the setting of pruritus ani. The most common parasitic infection causing pruritus ani is *Enterobius vermicularis,* or pinworms; it usually affects children with nocturnal symptoms.

Dermatologic Conditions

The most common dermatologic causes of secondary pruritus ani are contact dermatitis, allergic dermatitis, lichen sclerosus, lichen planus, and psoriasis. Contact or allergic dermatitis may be the result of a number of possible irritants or allergens including soaps, deodorants, perfumes, topical medications, and foods. Patients with allergic dermatitis commonly have a history of asthma, hay fever, or eczema and may also have a family history. They present with dry scaly lesions that typically involve the face, neck, dorsum of the hands, and popliteal and antecubital fossa, and symptoms are usually worse with dry cold weather and stress. The etiology of lichen sclerosus and lichen planus are poorly understood but may be related to altered cell-mediated immunity. Lichen sclerosus commonly affects perimenopausal women, with involvement of the vulva and vagina in

60% of patients. Although the symptoms are adequately treated with topical steroids, patients should be warned that the appearance of the skin may not change. In addition, the risk of squamous cell carcinoma in chronic nonresponders is reported to be 5%, and therefore, these patients should be followed closely and biopsies should be performed, particularly if symptoms of pruritus persist. Lichen planus is associated with ulcerative colitis, lichen sclerosus, myasthenia gravis, and several hepatic diseases, namely hepatitis C, chronic active hepatitis, and primary biliary cirrhosis. Lesions usually begin on the volar aspects of the wrists and forearms, and involvement of the genitalia and mucous membranes is common. Lichen planus is characteristically a self-limiting disease that resolves over 8 to 12 months. Psoriasis commonly involves the scalp and the flexor surfaces of the elbows and knees and may also involve the perianal skin, but rarely exclusively.

Systemic Conditions

Several systemic diseases may be associated with pruritus ani, although it is uncommon as the sole presenting symptom. These diseases include diabetes mellitus, hepatic disease or jaundice, leukemia, lymphoma, aplastic anemia, renal failure, and hyperthyroidism (see Box 1).

PATIENT EVALUATION

A thorough history is imperative in the assessment of a patient with pruritus ani and should include details regarding location, frequency, and duration of symptoms; aggravating and alleviating factors; a dietary history, including fluid, coffee, and alcohol consumption; medication history; stool patterns, including frequency, stool consistency, and rectal bleeding; symptoms of incontinence; perianal hygiene patterns; history of skin lesions or dermatologic conditions; a medical history; and a review of any allergies.

Physical examination should include careful inspection of the perianal skin and genitalia, palpation of inguinal lymph nodes, a digital rectal examination, and a complete skin examination.

The appearance of the perianal skin can be classified with the Washington Hospital criteria: stage I consists of skin that is red and inflamed; stage II consists of white, lichenified skin; and stage III involves lichenified skin coincident with coarse ridges of skin and ulceration (Figure 1).

In addition, all patients should be evaluated with anoscopy and sigmoidoscopy. Colonoscopy should be considered in patients older than 40 years, with changes in bowel habits, with symptoms of gastrointestinal bleeding, or with a family history of colorectal cancer.

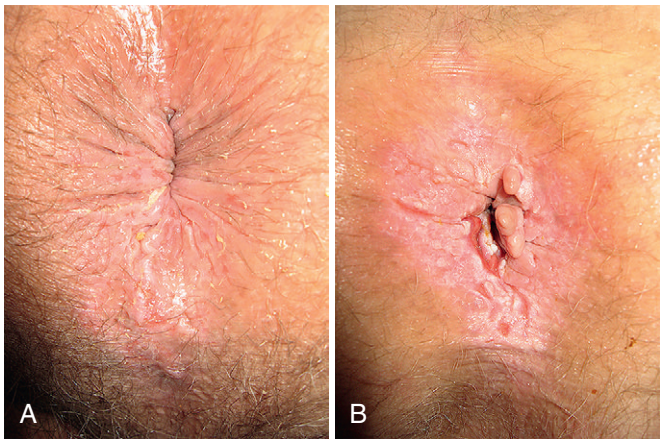

FIGURE 1 **A,** Washington stage II pruritus ani with white, lichenified skin. **B,** Washington stage III pruritus ani shows lichenified skin with ridges and ulcerations. *(From Markell KW, Billingham RP: Pruritus ani: etiology and management,* Surg Clin North Am *90(1):125–135, 2010. Courtesy of C. Os Finne, St. Paul, Minn.)*

Any suspicious lesions should be biopsied with a simple punch biopsy and should include both the lesion and the normal perianal skin if possible. If Bowen's disease is suspected, 3% acetic acid may be applied to the perianal region, causing whitening of the affected skin and mucosa, and may assist in demarcating the lesion and directing biopsies.

If infectious pathogens are suspected, aerobic, anaerobic, and fungal cultures should be taken, ideally before digital rectal examination because lubricants may have bactericidal activity. Infections caused by beta-hemolytic *Streptococcus* sp. present with a moist, bright, erythematous rash with distinct borders and can be confirmed with a rapid *Streptococcus* antigen test. Erythrasma appears as scaly patches of red to brown lesions, and if suspected, a Wood's lamp may be used to examine the groins, thighs, toe web spaces, and perianal region to confirm the diagnosis with the presence of coral-red fluorescence. False-negative results may result from recent washing, and if clinical suspicion is high, patients should return for reassessment and after refraining from washing for 48 hours. Herpes simplex is characterized by the presence of small, painful vesicles during an active eruption, and the diagnosis is confirmed with polymerase chain reaction (PCR) assay of vesicular fluid or serologic tests. The diagnosis of *Candida* infections may be difficult because they usually present with bright erythema commonly without the characteristic satellite lesions, and positive cultures may be misleading because *Candida* can be a commensal organism in the perineum. If pinworms are suspected, the diagnosis is confirmed with microscopic evaluation of cellophane tape applied to the perianal region in the early morning.

The diagnosis of dermatologic conditions may be difficult because of the atypical appearance of these conditions when involving the perianal skin and the absence of significant clinical exposure to these diagnoses. Contact dermatitis presents with extreme erythema with vesicles and scaly, macerated skin. If suspected, allergic dermatitis may be confirmed with skin patch testing. Psoriasis involving the perianal region has a so-called "inverse-psoriasis" appearance with a poorly demarcated, asymmetric, nonscaly lesion. Lichen sclerosus presents initially as a painful pruritic erythematous reaction and progresses into a thickened, indurated, raised, macular reaction and ultimately in sclerosis and atrophy of the affected skin. It classically appears in the figure-of-eight distribution around the vulva and anus. Lichen planus presents as shiny, pigmented, flat-topped papules and usually involves the volar aspects of the wrists and forearms.

For images of common dermatologic causes of pruritus ani, refer to the review by Zuccati and colleagues. If a dermatologic condition is suspected, consultation with a dermatologist should be obtained.

TREATMENT

Idiopathic Pruritus Ani

Idiopathic pruritus ani can be a difficult and frustrating condition for patient and physician alike. Patients commonly have chronic symptoms and social embarrassment and have had several unsuccessful attempts at self treatment. However, most patients respond to conservative measures, and patient reassurance about the benign nature and expected resolution of symptoms can be extremely helpful in alleviating the anxiety associated with the condition. In the authors' experience, patients with grade II or III skin changes generally need a longer course of conservative treatment for symptom resolution; these patients should be counseled accordingly.

Treatment begins with eliminating possible irritating factors, improving stool bulk, and educating the patient on perianal hygiene (Figure 2). Patients are instructed to discontinue all topical medications and any implicated oral medications if possible (see Box 2). Although no evidence exists for diet modification, all possible irritants from the diet should be eliminated (see Box 2), and a diary documenting dietary intake and symptoms should be instituted. Individual foods can then gradually be reintroduced after 2 weeks, one at a time, to identify foods that may aggravate symptoms. Patients should also be advised to wash undergarments with nonperfumed, hypoallergenic detergent. A high-fiber diet or fiber supplementation should be encouraged to increase stool bulk and help maintain regular bowel movements, which may minimize fecal soiling. In the setting of diarrhea or loose stools, antimotility agents, such as loperamide, may be considered and used judiciously to decrease stool frequency and reduce fecal contamination. In addition, if soiling is significant, tap-water enemas after bowel movements may be helpful in evacuating any residual feces in the distal rectum and anus and may further reduce contamination. Appropriate perianal hygiene and minimization of trauma and irritation to the perianal skin are paramount for effective conservative treatment. Whenever possible, patients should bathe after bowel movements. If bathing is not possible, patients should gently clean the perianal with premoistened wipes. The perianal skin should be dried after cleansing with a hair dryer at a low setting or, alternatively, gently patted dry with a soft towel. Vigorous rubbing or wiping should be strictly avoided. Patients should be instructed to keep the perianal skin as dry as possible, and strategies may include wearing loose-fitting cotton underwear, placing a cotton ball in the underwear, and using talcum powder on the perianal skin. Lastly, patients who have difficulty controlling nocturnal scratching should consider wearing a pair of soft cotton gloves at night.

Adjuncts to initial conservative management include use of topical steroids or antipruritic medications. The evidence of the efficacy of topical steroids is conflicting; a small cohort study showed no benefit when compared with a mild-cleansing agent, but a small randomized controlled trial (RCT) showed significant reduction in symptoms when compared with placebo. In the setting of local inflammation especially, 1% topical hydrocortisone cream applied twice daily may help relieve symptoms and promote healing. However, the use of topical steroids should be limited to 2 to 4 weeks because prolonged use may cause thinning and atrophy of the skin. Topical antipruritic medication may be applied at bedtime to prevent nocturnal itching and scratching, but topical "-caine" anesthetics should be avoided because they may worsen symptoms. In addition, oral antihistamines at bedtime may also be effective in reducing nocturnal symptoms.

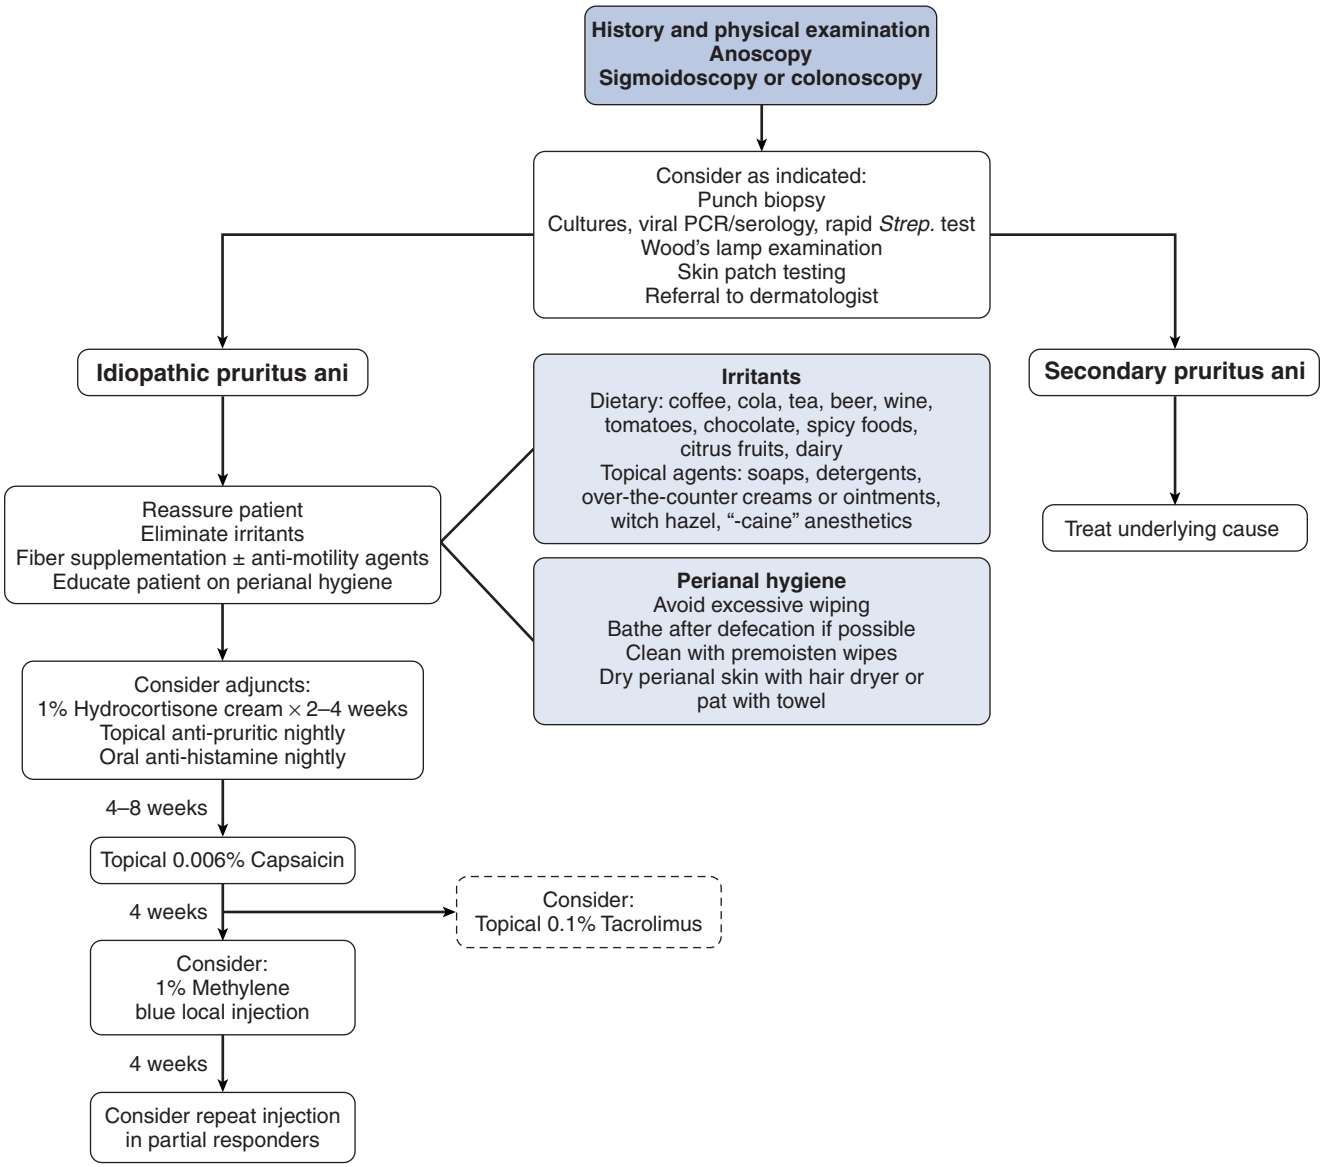

FIGURE 2 Management algorithm for pruritus ani. *PCR*, Polymerase chain reaction.

Patients with persistent symptoms despite conservative measures should be reevaluated at 4 to 8 weeks (see Figure 2). Secondary causes of pruritus ani should again be considered and excluded. This may include obtaining cultures if infectious etiologies are suspected, referral for patch testing to exclude an occult allergy, or punch biopsy of any persistent lesions, although the diagnostic yield of these investigations has been found to be extremely low.

Treatment options for refractory idiopathic pruritus ani include topical capsaicin, topical tacrolimus, and local injection of methylene blue. The use of topical agents before methylene blue injection is recommended for the ease of use and lower risk of adverse events. The use of 0.006% topical capsaicin has been shown in a recent small RCT to be effective at relieving symptoms when applied in a thin layer three times daily for 4 weeks. In patients with response to treatment, symptomatic relief occurred within 3 days, and after the treatment period, patients continued to use the preparation on an as-needed basis for long-term relief. The proposed mechanism of action of capsaicin is the inhibition of synthesis, release, and storage of the neuropeptide substance P, which mediates pain and itching impulses from peripheral sensory neurons. Patients should be warned that application of the cream causes a burning sensation and side effects may include moderate to severe burning and urticaria. Alternatively, the use of 0.1% topical tacrolimus ointment applied daily for 4 weeks showed a significant reduction in symptom intensity and frequency in one small RCT, although long-term effectiveness was not reported. Side effects of topical tacrolimus include a minor burning sensation with application.

When topical therapies are ineffective for refractory cases, local injection of methylene blue may be considered. The exact mechanism of action in unknown, but it is postulated that methylene blue may be directly toxic to nerves supplying the perianal skin, a finding supported with electron microscopy. Several techniques have been described in the literature; the authors use a technique described by Mentes and associates. The symptomatic area is marked, patients are placed in prone jackknife position with the buttocks taped to retract them laterally, and then the perianal area is prepped. Fourteen to 20 mL of an equal parts solution of 2% methylene blue and 0.5% lidocaine is prepared and then injected with a 22-gauge needle intracutaneously targeting the dermoepidermal junction. Repeat injection may be performed at 4 weeks for partial response. Patients should be warned about the blue appearance of the perineum, which may last up to 6 weeks after injection, and numbness in the perianal skin,

which may be persistent. Other possible side effects include a transient change in continence, cellulitis, and a small risk of skin necrosis requiring surgical débridement, which may be related to larger volume or superficial injections.

Secondary Pruritus Ani

The treatment of secondary pruritus ani is directed at the underlying anorectal, dermatologic, infectious, or systemic condition. For anorectal conditions (see Box 1), correction of the anorectal pathology, and the subsequent reduction of fecal contamination and moisture of the perianal skin, usually leads to resolution of symptoms. Local topical treatment or resection of Paget's and Bowen's disease alleviates symptoms, although the optimal treatment and follow-up of these lesions remains controversial (see Tumors of the Anal Canal chapter).

Bacterial infections are generally treated with appropriate oral antibiotics; however, longer courses may be necessary for successful eradication and symptom relief. For patients with erythrasma, the addition of topical betamethasone to the perianal skin and half-strength Whitfield's ointment to other involved areas may be helpful. Treatment of herpes simplex with oral acyclovir is usually effective, and condylomata are treated with topical podophyllin, topical 5-fluorocuracil, cryotherapy, fulguration, or surgical excision. Fungal infections with *Candida* or dermatophytes are successfully treated with topical imidazole, and in the setting of a moist rash, the addition of an antifungal powder may assist in keeping the perianal skin dry. In cases of suspected or confirmed pinworms, patients and all their household members are treated with 2 doses of oral mebendazole given 2 weeks apart to prevent reinfection.

If a dermatologic condition is suspected based on the appearance of perianal skin or the presence of other skin lesions, treatment should be initiated in consultation with a dermatologist. If contact or allergic dermatitis is suspected, the avoidance of the irritant or allergen is the most important intervention, in addition to reinforcing appropriate perianal hygiene (as in idiopathic pruritus ani). The addition of topical 1% hydrocortisone cream may also be helpful in contact dermatitis.

SUMMARY

Pruritus ani is a common condition that can often be successfully diagnosed and treated with a careful and thorough approach. Management of this condition consists of identifying and addressing the cause, minimizing further injury to the perianal skin, and maintaining close follow-up with the patient to ensure healing and relief of symptoms.

Surgical Treatment of Fecal Incontinence

Liliana Bordeianou, MD, MPH

Fecal incontinence is a sometimes devastating medical disorder that affects as many as 25% of elderly women; it may also be seen in younger women, particularly those who have experienced traumatic or obstetric injuries, and (more rarely) in males. Although it is not life threatening, fecal incontinence may have a profound effect on quality of life, leading to depression, anxiety, and agoraphobia. For the elderly, involuntary loss of feces is a common cause of entry into assisted living facilities and nursing homes.

The cause of fecal incontinence is frequently multifactorial and requires thoughtful etiologic evaluation. As part of this evaluation, after assessment of the severity of leakage, physicians commonly perform a physical examination, anorectal physiology testing, endoanal ultrasound scan, and, on occasion, defecography to exclude internal intussusception or rectal prolapse. Treatment for the condition, before any surgical intervention, may involve fiber supplementation to increase stool consistency, loperamide to decrease stool frequency, and amitriptyline to increase rectal sensory thresholds to fecal stimulation. These medical manipulations can also be combined with biofeedback, a series of specialized monitored exercises aimed at increasing anal sphincter strength and decreasing urgency through sensitivity retraining. Ultimately, most patients with mild fecal incontinence respond to these medical and biofeedback therapies. However, patients with severe leakage of solid and liquid stool frequently need further treatment, and fortunately, they can be offered several treatment options.

OVERLAPPING SPHINCTEROPLASTY

A leading cause of fecal incontinence is occult sphincter injury, which is experienced by nearly 10% of women who give birth vaginally. (Even higher rates are reported in women who experienced a difficult childbirth, requiring forceps or vacuum assistance, and in those who had episiotomies at delivery.) Some of these women have fecal incontinence develop immediately. In others, the clinical sequelae of injury only emerge with age. Therefore, the author recommends that all women with fecal incontinence and a history of vaginal delivery be evaluated for possible obstetric injury. The condition can sometimes be diagnosed by means of a regular physical examination but more often requires endoanal ultrasound scan, which provides a 360-degree image of the anal canal and permits one to clearly visualize both the internal and the external anal sphincter (Figure 1).

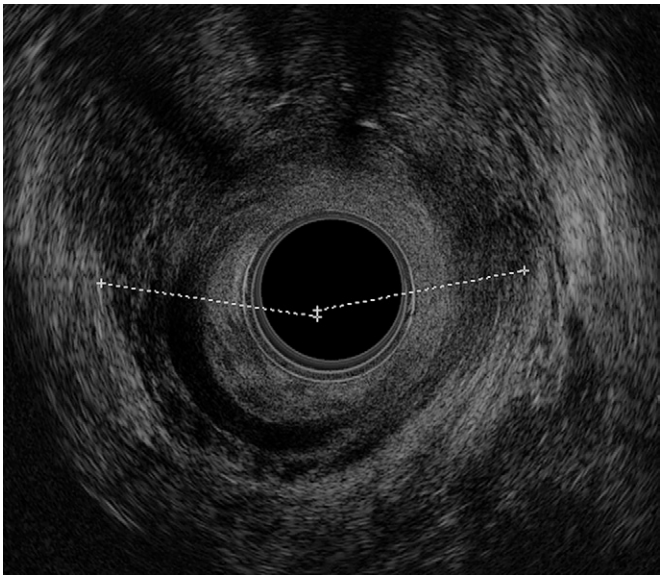

FIGURE 1 Obstetric injury with internal and external sphincter disruption. The external sphincter injury is marked.

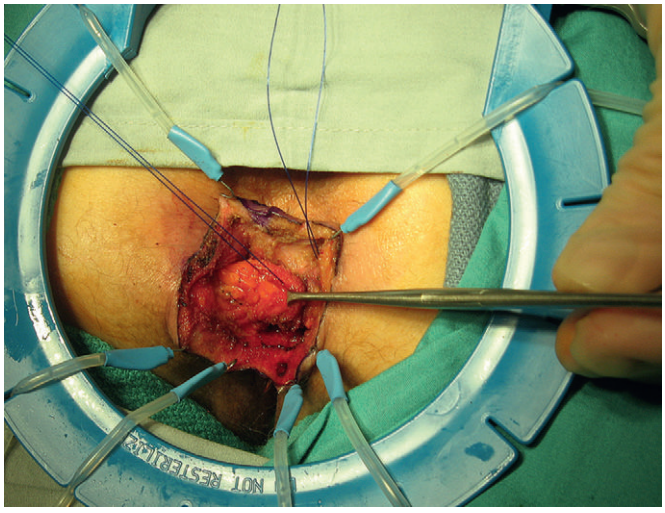

FIGURE 2 Overlapping external sphincteroplasty to correct obstetric injury.

In an appropriately selected patient, sphincter repairs (sphincteroplasty) can ameliorate or cure fecal incontinence. Nonetheless, sphincteroplasty is not appropriate for all patients who have been diagnosed with sphincter injury. The overall sphincter repair success rate is approximately 60%; it is lower in patients who have delayed pudendal nerve terminal motor latencies (which suggest a neurogenic cause of incontinence) and in patients with preserved anal sphincter pressures (which suggest an extrasphincteric cause). Careful evaluation is required to determine those patients for whom sphincteroplasty is a viable option and those for whom it may not be.

If sphincteroplasty is elected, the preparation includes bowel cleansing. The operation is best performed in the jackknife prone position. The surgeon makes an elliptic incision on the perineal body and separates the rectum from the vagina all the way to the levators. The surgeon then identifies and frees the snapped edges of the external anal sphincter to allow for an overlap of the edges. The scar tissue on the anterior aspect of the sphincter is not removed; instead, the scar is overlapped till the viable edges of the muscle are approximated. Interrupted mattress sutures of 2-0 polypropylene are then used to approximate the scar and the muscle in this overlapped position (Figure 2). Finally, the repair is covered with interrupted subcutaneous sutures, and the skin is loosely closed on top to allow drainage, which decreases the chance of a wound infection.

Patients are generally instructed to self administer a tap-water enema as part of the immediate postoperative course, to irrigate the rectum and stimulate a daily bowel movement. These patients are also placed on a bowel regimen aimed at decreasing the risk of postoperative constipation, which could lead to fecal impaction and eventually to wound dehiscence.

SACRAL NERVE STIMULATION

An alternative means of treatment for fecal incontinence, recently approved by the U.S. Food and Drug Administration (FDA), is sacral nerve stimulation (SNS). Its mechanism of action is unknown. The author generally offers SNS treatment to all patients who do not have a large sphincter injury that may be amenable to a simpler sphincter repair and who report full bowel movement loss more than twice a week.

The procedure is performed in two steps. At first, a small-tined lead is placed into the S3 foramen with fluoroscopic guidance. The wire is tunneled under the skin and connected to an external neurostimulator for a 2-week trial period. The patient is then asked to keep a bowel diary. Success is defined as a 50% reduction in the frequency of fecal incontinence episodes; if this rate is achieved, a permanent stimulator is connected to the previously tunneled lead and placed in the subcutaneous fat of the buttock.

The stimulator insertion procedure is simple, has low complication rates (aside from occasional infections of the wound and the device), and can be performed with light sedation. The device appears to ameliorate incontinence in at least 80% of the patients in whom it is implanted, with 40% reporting a return to full continence. At this time, the principal drawback of the procedure is the high price of the device, which is not covered by all insurance carriers, and the fact that its battery runs out in about 3 to 5 years, requiring further surgery to replace it.

INJECTABLES

Solesta (Salix Pharmaceuticals Inc., Raleigh, NC) is an FDA–approved, gel-like injectable dextranomer stabilized in hyaluronic acid. Studies comparing it with placebo treatment have found that Solesta, when injected into the anal submucosa, slightly reduces the number of fecal incontinence episodes and improves quality of life with minimal complications. However, the role and efficacy of this treatment remains open to debate. An argument can be made that the gel should be used before attempting a more expensive SNS implantation. However, the gel should not be used in those with severe incontinence who are being considered for an artificial bowel sphincter (see subsequent discussion) because the coexistent implants could potentially increase the rate of artificial bowel sphincter erosion and infection.

ARTIFICIAL BOWEL SPHINCTER

For patients with moderate to severe incontinence who do not respond to less intrusive approaches, an artificial bowel sphincter is sometimes considered. This device, which was approved by the FDA more than a decade ago, involves a fluid-filled cuff, which is placed around the anal sphincter and connected through tubing to a reservoir (usually placed in the space of Retzius). When filled with fluid,

the cuff occludes the anus. When patients want to defecate, they squeeze a pump (generally hidden in the labia majora in the woman or the scrotum in the male) to temporarily transfer the fluid from the cuff to the reservoir. After the patient defecates, the cuff reinflates slowly to again pinch closed the anal canal.

Although the device is very effective, it presents risks as a result of its capacity to break or erode. This can lead to infection and even, on occasion, severe necrotizing infections. The author generally does not recommend the artificial bowel sphincter for any patients who have other added risk for perineal infections, such as prior radiation, obesity, or diabetes. Active research efforts are currently underway to modify and simplify the device and improve its durability.

OTHER

In some cases, fecal incontinence can be caused by full-thickness rectal prolapse or internal intussusception. The surgical approaches to these disorders are discussed in a separate chapter.

The Management of Rectovaginal Fistula

Ashwin L. deSouza, MS, MRCSEd, DNB, FCPS, MNAMS, and Herand Abcarian, MD

INTRODUCTION

Rectovaginal fistulae constitute one of the most frustrating conditions to treat. Although not life-threatening, they are associated with significant morbidity that greatly influences social well-being, sexual activity, and overall quality of life. With a limited number of surgeons conversant in its management, patients with rectovaginal fistulae often present to tertiary referral centers after multiple failed procedures.

Almost all reported literature on the management of rectovaginal fistula is made up of individual case series, each with a small number of patients. It is therefore difficult to objectively compare the results of the different treatment options available. The diverse etiology, numerous treatment options, and lack of randomized trials make it difficult to formulate evidence-based guidelines to optimally manage this condition.

This chapter emphasizes the surgical management of rectovaginal fistula and presents broad treatment guidelines based on current reported literature.

CAUSES

Obstetric injury is the most common cause of rectovaginal fistula. Approximately 2% of all vaginal deliveries are associated with third- and fourth-degree perineal tears, and 3% of these patients will subsequently develop a rectovaginal fistula. Fistulae arising from obstetric injury are often associated with anterior defects in the anal sphincter, leading to some degree of fecal incontinence.

Crohn's disease follows closely as the second most common cause, with 20% to 40% of patients developing either an anorectal or rectovaginal fistula. Rectovaginal fistulas are more likely to be associated with large bowel than with small bowel involvement and can occur in up to 10% of women with Crohn's disease. Rectovaginal fistulae associated with Crohn's disease have a high recurrence rate and often require multiple procedures before healing can be achieved.

Surgical trauma, anorectal infection, vaginal or anal neoplasm, and radiation therapy for malignancy constitute the other less common causes (Table 1).

CLINICAL MANIFESTATION

Patients usually present with symptoms of passage of gas or feces through the vagina, although this is often misinterpreted as anal incontinence. Sometimes the clinical presentation may be less obvious, with complaints of a persistent vaginal discharge, dyspareunia, or repeated urinary tract infections.

Because the majority of rectovaginal fistulae are below the level of the sphincter complex, digital examination can often locate the indurated fistulous tract. Meticulous examination with an anoscope or speculum usually reveals the granulation tissue around the opening of the fistula, which can be gently probed to delineate the tract. However, not all rectovaginal fistulas are evident on an initial clinical examination. If a high degree of clinical suspicion exists, a thorough examination with the patient under anesthesia is justified, especially in patients with Crohn's disease, in whom the activity of disease in the rectum can also be evaluated. On occasion, injection of dilute methylene blue in hydrogen peroxide into the primary opening of a fistula may aid in defining the secondary opening.

The goals of preoperative evaluation are to identify the fistula, determine the etiology, and evaluate the extent of the causative pathology and surrounding injuries. Endoanal ultrasonography (EAUS) is an important diagnostic tool to determine defects in the anal sphincter complex, and it can also serve to delineate additional occult collections in complex fistula tracts. Hydrogen peroxide–enhanced transanal ultrasonography has also been advocated to map complex fistulas. Pelvic magnetic resonance imaging (MRI) and endorectal MRI are useful diagnostic modalities that are especially popular in European countries.

Tests to determine the functional status of the pelvic floor and anal sphincter are indicated if there is a history of sphincter injury or any degree of incontinence. Anorectal manometry to determine

TABLE 1: Rectovaginal fistula etiology

Obstetric injury	Forceps delivery, episiotomy (posterior midline), prolonged labor, third- and fourth-degree perineal lacerations
Inflammatory bowel disease	Crohn's disease
Postsurgical	Anorectal surgery (fistulotomy) Vaginal surgery (hysterectomy, rectocele repair) Abdominal surgery (hysterectomy, low anterior resection, pouch procedure)
Infectious	Cryptoglandular abscess, diverticulitis, tuberculosis
Neoplastic	Anal canal, rectum, vagina, cervix
Radiation induced	External beam radiotherapy, brachytherapy

sphincter dysfunction and measurement of pudendal nerve terminal motor latency to detect nerve damage are two useful tests to evaluate the function of the pelvic floor. Undiagnosed sphincter injury or pudendal nerve damage could compromise an otherwise successful repair.

After complete workup of the perineum, an evaluation of the entire colon in cases of rectal malignancy, and of the small bowel in cases of Crohn's disease, is mandatory. Thus additional workup could include a small bowel series, colonoscopy, barium enema study, and a computed tomographic scan.

CLASSIFICATION OF RECTOVAGINAL FISTULAE

Rectovaginal fistulae may be classified according their relation to the sphincter complex as *high* (above the sphincter complex) or *low* (at or below the level of the sphincters, also known as *anovaginal*). The low fistula is almost always caused by obstetric trauma and is often associated with sphincter disruption.

Rectovaginal fistulae have also been classified as *simple* or *complex.* Simple fistulae are located in the middle or lower portion of the rectovaginal septum, are less than 2.5 cm in diameter, and are caused by local trauma or sepsis. A complex fistula, on the other hand, is usually greater that 2.5 cm, is located in the upper portion of the rectovaginal septum, and is secondary to causes other than trauma and infection, such as neoplasia, diverticulitis, or inflammatory bowel disease.

PREOPERATIVE PREPARATION

The type of preoperative preparation is largely subjective but usually varies with the type of procedure planned for the repair. For simple advancement flaps, a phosphate enema on the morning of the procedure is usually adequate. For more extensive repairs, such as an overlapping sphincteroplasty or an interposition flap, a full mechanical bowel preparation is preferred. Perioperative antibiotics and deep venous thrombosis prophylaxis can be administered as per institutional protocol.

TABLE 2: Surgical options

Surgical approach	Procedures
Transanal	Fistulotomy Endorectal advancement flap Rectal sleeve advancement Fibrin glue Bioprosthetics
Transvaginal	Vaginal advancement flap
Transperineal	Episioproctotomy plus layered closure Overlapping sphincteroplasty Interposition flaps
Transabdominal	Primary repair plus omental flap Rectal resection plus coloanal anastomosis and omental flap

SURGICAL MANAGEMENT

With fistulas due to obstetric injury, which occur in the immediate postpartum period, at least 3 months elapse before the acute inflammation subsides and fibrosis develops. In the interim, symptoms can be improved with stool-bulking agents or with induced mild constipation with loperamide or other antidiarrheals. Once inflammation subsides, a thorough evaluation of the sphincter mechanism should be undertaken to delineate the extent of sphincter disruption.

The presence of sepsis is an absolute contraindication to any attempt at surgical repair; thus drainage of abscesses and collections is the first step in management. A loose noncutting seton is usually placed through the fistula tract and kept in place until the infection subsides; this may take as long as 3 months and even longer in patients with Crohn's disease.

There are four surgical approaches to repair a rectovaginal fistula: *transanal, transabdominal, transvaginal,* and *transperineal.* Table 2 lists the various surgical options of each approach.

Transanal Approach

Fistulotomy

A fistulotomy involves laying open the fistula tract, which may or may not be excised. This is often performed as a two-stage procedure, in which a noncutting seton is first placed through the fistula to allow for drainage and fibrosis. In the second stage, the seton is removed by dividing the remaining tissue to lay open the tract.

Although a fistulotomy results in successful healing, it involves division of varying thicknesses of the external sphincter muscles. This causes a keyhole deformity, which almost always results in some degree of incontinence, often permanent. Hence a fistulotomy, although indicated only for superficial fistulas, is rarely used.

Endorectal Advancement Flap

Endorectal advancement flap forms the mainstay of treatment for low rectovaginal fistulas and is best suited for patients who do not have disruption of the sphincter muscles. The procedure is usually performed in the outpatient setting and with the patient in prone position, which offers excellent exposure of the anterior rectal wall. Both the anus and vagina are prepared, and a probe is inserted through the fistula from the vagina into the rectum. A trapezoid flap is then outlined with the base cephalad and twice the width of the apex. The flap consists of the rectal mucosa, submucosa, and a

portion of the underlying internal sphincter, including the fistula opening at the apex; this is raised in cephalad manner with the use of needle-tip electrocautery. A sufficient length of flap should be mobilized 3 to 4 cm proximal to the fistula opening to ensure a tension-free closure after excision of the fistula. Injection of a dilute epinephrine solution facilitates dissection and minimizes blood loss.

After the flap is elevated, the fistula tract is curetted to remove all granulation tissue, and the defect in the remaining muscle layer (internal sphincter) is closed with a few interrupted absorbable sutures. The tip of the flap is then excised to remove the fistula opening, and the flap is advanced caudad and sutured in place with 3-0 interrupted absorbable sutures to close the wound. The vaginal opening is left open to facilitate drainage. Postoperative care includes a high-fiber diet, sitz baths, and stool softeners to avoid fecal impaction.

The endorectal advancement flap offers the advantages of performing the repair from the high-pressure side of the fistula and of preserving sphincter integrity. Short-term success rates for rectal advancement flaps alone vary from 42% to 68%, although higher success rates have been reported with the addition of a sphincteroplasty, if a sphincter defect exists.

Rectal Sleeve Advancement

In the presence of limited circumferential or stricturing disease in the distal rectum (e.g., Crohn's disease), a rectal sleeve advancement can be attempted. The procedure involves mobilization of the proximal rectum, resection of the involved distal portion, and restoration of continuity with an anorectal anastomosis.

Kraske Approach

The patient is placed in a semiprone jackknife position, and an incision is made just to the left of the midline, extending from the sacrococcygeal joint to the external anal sphincter. The incision is deepened, and the distal portion of the coccyx is excised. The pelvic floor muscles are then divided in the midline down to the rectum, which is circumferentially mobilized superiorly as far as possible and distally up to the anal canal. The rectum is then transected at the level of the pelvic floor. A circumferential mucosectomy is then performed from the level of the dentate line up to the level of rectal transection. The fistulous tract is completely excised, and the defect in the rectovaginal septum is closed with a few interrupted absorbable sutures. The vaginal defect may be left open for drainage. The mobilized rectum is then advanced to the dentate line and sutured in a single layer with interrupted sutures.

Fibrin Glue

Fibrin glue attempts to seal the fistula tract with a fibrin plug, which allows for ingrowth of fibrous tissue that permanently closes the fistula with minimal dissection and no sphincter disruption. However, experience with fibrin glue in rectovaginal fistulae has been very limited because of disappointing results. Extrusion of the fibrin plug as a result of the short length of the fistula tract is the predominant cause of failure.

Bioprosthetics

Two bioprosthetics have been used for rectovaginal fistulae: the bioprosthetic mesh (Surgisis ES; Cook Surgical, Bloomington, Ind) and the Rectovaginal Fistula Plug (RVP; Cook Surgical, Bloomington, Ind). Both products are made from lyophilized porcine intestinal submucosa, which provides a matrix for ingrowth of host connective tissue.

The bioprosthetic mesh is used as an interposition graft. The rectovaginal septum is dissected through a perineal incision, and the fistula is excised. After closure of the rectal and vaginal openings, the rehydrated mesh is placed between the rectum and vagina with an adequate overlap over the rectal and vaginal closures; it is sutured in position with a few interrupted absorbable sutures, with the mesh kept as taut as possible.

The bioprosthetic rectovaginal fistula plug is tapered at one end to facilitate insertion. A fistula probe is introduced from the vaginal to the rectal opening, and the tapered end of the plug is tied to the probe with a suture. The probe is then withdrawn, the plug is pulled with it, and the button is lodged at the broader end at the rectal opening. The excess plug at the rectal end is then excised, and the plug is sutured in position with absorbable sutures, which closes the rectal mucosa over the plug. The vaginal opening is left open, and the excess plug is trimmed at this level. The short length of the fistula tract poses the same problem with the plug as with fibrin glue, which makes the plug suitable only for rectovaginal fistulas that are well over 1 cm in length.

The experience with bioprosthetics as a whole in rectovaginal fistulas is very small. Success rates of fistula closure by interposition techniques have been reported to be from 66% to 86%.

Transvaginal Approach

Vaginal Advancement Flap

In a technique similar to the rectal advancement flap, a flap of vaginal mucosa is raised, and the fistula tract is excised. The rectal mucosa is closed separately, over which the defect in the rectovaginal septum is approximated with interrupted absorbable sutures. The apex of the flap is then trimmed to excise the fistula opening and is sutured into position to close the wound.

The primary advantage of a vaginal flap is the use of healthy, pliable, and well-vascularized vaginal tissue, even though the repair is on the low-pressure side of the fistula. A vaginal flap is easier to mobilize than a rectal flap, especially in the presence of anorectal stenosis. In a comparative analysis of 11 studies, no difference was found in the closure rates between a rectal and vaginal advancement flap in rectovaginal fistulas due to Crohn's disease.

Transperineal Approach

Episioproctotomy and Layered Closure

This repair converts the fistula into a fourth-degree perineal tear by dividing all the tissue between the rectum and vagina through the perineal body. A layered closure is then performed to close the rectal mucosa, the rectal and vaginal muscular walls, and finally the vaginal mucosa. The greatest disadvantage of this procedure is the creation of a full-thickness defect in the anal sphincter. If the repair should fail, the patient will be fully incontinent. For this reason, this procedure should be attempted in only patients with documented existing sphincter disruption and incontinence.

Overlapping Sphincteroplasty

This technique is ideal for patients with concomitant sphincter injury. The detailed technique of an overlapping sphincteroplasty is described elsewhere in this text but essentially involves dissection and mobilization of the external sphincter through a transperineal approach. Very often the sphincter is so attenuated at the site of injury that the healthy ends of the sphincter can be overlapped and sutured into position without the need to divide or excise any tissue. This technique has the advantage of not worsening the degree of incontinence should the repair fail while still achieving the same end result. In the presence of sphincter injury, the addition of an overlapping sphincteroplasty to a rectal advancement flap has been reported to greatly increase the success rates.

Interposition Flaps

Patients with multiple failed attempts at repair usually have relative ischemia in the surrounding tissues. The interposition of healthy, vascularized tissue in the rectovaginal septum can theoretically increase the chance of successful closure but with a potential risk of de novo dyspareunia. The gracilis and bulbocavernosus flaps are the two most described pedicled flaps for rectovaginal fistula. Although not mandatory, fecal diversion is usually recommended, either before or at the time of the flap procedure.

The approach is usually via a perineal incision between the posterior fourchette of the vagina and the anal verge. The incision is deepened to expose the rectovaginal septum, which is then dissected proximal to the level of the fistula by about 2 cm. The fistula is then completely excised, and the rectal and vaginal defects are closed primarily.

The gracilis muscle has only vestigial function, and a reliable vascular pedicle enters the muscle laterally in its upper third. The muscle of either leg can be used and is harvested through an incision in the medial aspect of the thigh. The harvested muscle is then tunneled through the subcutaneous tissue at the groin and brought out at the perineal incision. This is then placed between the rectum and vagina and held in position with a few interrupted absorbable sutures. The success rate of the gracilis muscle flap has been reported to be as high as 75%.

A Martius flap, in which the bulbocavernosus muscle is used with the overlying fat in the labia majora, is based on the perineal branch of the pudendal artery and is placed in the rectovaginal septum in similar fashion. As with all interposition flaps, this repair has the potential risk for increased postoperative dyspareunia, but there are usually no complaints related to labial function or cosmesis. The success rate with this procedure has been reported to vary from 50% to 93.8%.

Transabdominal Approach

Rectal Sleeve Advancement

The patient is placed in the lithotomy position, and the rectum is mobilized anteriorly and posteriorly in standard fashion, right down to the pelvic floor, and the lateral vascular supply is kept intact. The rectum is then transected at the pelvic floor, which completes the abdominal part of the procedure. The transanal exposure and anastomosis is as described in the Kraske approach.

A rectal sleeve advancement can be offered only if the proximal rectum is normal and is most appropriate in patients with limited, circumferential disease in the distal rectum. Closure rates of 54% to 87% have been described for a rectal sleeve advancement flap in studies with a follow-up greater than 2 years.

Omental Interposition

This transabdominal approach is best suited to repair high rectovaginal fistulas, which are usually a complication of anterior resection, hysterectomy, or diverticulitis. The rectum is dissected down to the level of the fistula, which is then divided to expose the rectal and vaginal openings. If the rectal wall is healthy and pliable, the fistula opening can be débrided and closed primarily. However, if the surrounding rectum is unhealthy, a resection with primary coloanal anastomosis may be considered. The vaginal opening is then closed, and a pedicled omental flap is placed between the two closures and held in position with a few interrupted sutures.

Sometimes, a low rectovaginal fistula may require a transabdominal approach. After the failure of multiple local procedures, further attempts at repair with manipulation of local tissues have a very slim chance of success. A transabdominal approach in this setting has the advantages of resecting all ischemic tissue and bringing down well-vascularized tissues to the anal canal.

The procedure entails mobilization of the rectum and separation of the rectovaginal septum down to the pelvic floor. The fistula openings in the rectum and vagina are then débrided and closed perineally with interrupted absorbable sutures. An omental flap, based on either the left or right gastroepiploic artery, is prepared and placed in the pelvis. From the perineum, the lower rectovaginal septum is dissected free. The omental flap is then brought down into the rectovaginal septum and sutured to the subcutaneous tissue of the perineum. Additional sutures are placed to anchor the omentum to the levator ani along the lateral pelvic walls for tension-free interposition (Figure 1). Although this is a major surgical procedure, it brings vascularized omentum into the rectovaginal septum between the rectal and vaginal closures and may be the only option for successful closure in patients with multiple failed procedures.

TREATMENT GUIDELINES

Fecal Diversion

There is no consensus on the indications of proximal fecal diversion in rectovaginal fistulas, as it has been shown that a stoma does not necessarily ensure the success of a repair. However, after two failed attempts, surgeons are more inclined to place a diverting stoma prior to or at the time the third procedure is attempted. Repairs using interposition pedicle flaps are also more likely to be protected with a proximal stoma.

Choice of Repair

Considering the diverse etiology, the large number of surgical options, and the lack of randomized evidence, deciding on a line of treatment is often a daunting task. The choice of procedure is largely governed by the type of fistula (low or high, simple or complex), the etiology, the status of the sphincter mechanism, the number of prior failed attempts, and the functional status of the patient.

The results reported for each procedure vary greatly, and no procedure yields consistent results. It should be appreciated that almost any procedure for rectovaginal fistula is going to fail in a significant number of patients. This is why irreversible steps, such as full-thickness sphincter division, which might make the condition worse if the repair fails, are best avoided.

Probably the first point to consider in deciding on a line of treatment is the status of the sphincter mechanism. Documented defects in the anal sphincter with associated incontinence require an overlapping sphincteroplasty. This procedure is often combined with a rectal advancement flap and is the most commonly used first-line option in low fistulas resulting from obstetric trauma.

In the absence of sphincter injury, either a rectal or vaginal advancement flap can be considered as first-line options. Although the results for both procedures are more or less similar, a rectal advancement flap puts the repair on the high-pressure (rectal) side of the fistula and is often preferred over the vaginal flap. However, a rectal flap necessitates the presence of a healthy rectum and is best avoided in the presence of poorly controlled Crohn's proctitis or in the presence of rectal disease involving strictures.

If a rectal flap fails as the first procedure, it would probably be better to try the vaginal flap at the second attempt rather than to repeat the rectal flap. After failure of both a rectal and vaginal flap, the surgeon has the option of repeating a flap procedure or of considering an interposition pedicle flap. If the local tissues are still healthy and pliable, a repeat flap can be attempted. However, it should be appreciated that at every subsequent procedure, the success

rate decreases further. Multiple failed attempts (more than three) render the rectovaginal septum and surrounding tissue ischemic, and further attempts at local repair are less likely to succeed. Interposition flaps should then be considered with appropriate counseling in view of the potential for de novo dyspareunia. Either a gracilis or Martius flap is an acceptable alternative.

Because experience with bioprosthetics is limited, definitive recommendation for their use is impossible. However, because bioprosthetics rely on tissue ingrowth from surrounding tissue, an ischemic rectovaginal septum would probably not be the best environment for a bioprosthetic mesh. If the proximal rectum is healthy, a distal proctectomy with a coloanal anastomosis will resect the diseased distal rectum, bring healthy proximal rectum to the anal canal, and also provide the opportunity to place a pedicled omental flap in the ischemic rectovaginal septum.

SPECIAL CONSIDERATIONS

Radiation-Induced Fistulae

With the increased use of both brachytherapy and external-beam radiation in the treatment of pelvic malignancies, radiation-induced complications are likely to increase. The first step in management of radiation-induced rectovaginal fistulas is to rule out the presence of residual or recurrent malignancy. This requires detailed imaging and an examination with the patient under anesthesia with multiple biopsies of areas of irregularity or random biopsies if no irregularity exists. Once the presence of malignancy has been ruled out, the condition of the rectum, vagina, and surrounding perineal tissues needs to be evaluated.

It is mandatory to wait at least 6 months after the completion of radiation treatment before any repair is attempted. This allows for the full effect of radiation to be realized and for the surrounding tissue to recover. If the local tissues are healthy, a rectal or vaginal advancement flap can be attempted. However, it should be appreciated that because the repair is being performed with radiated tissue, it is less likely to succeed. If one attempt at local repair fails, subsequent attempts will most likely be futile. Interposition flaps with nonradiated tissue (e.g., gracilis flap) or a resection of the involved rectum with a coloanal anastomosis and omental interposition then remains the best available option and is preferable to the classic Bricker procedure.

Crohn's Disease

Almost every patient with Crohn's proctitis and a rectovaginal fistula will require an examination under anesthesia and drainage with a noncutting seton until the infection and inflammation subsides. This is also essential to optimize medical therapy. After quiescence of the acute episode, definitive therapy for the rectovaginal fistula can be pursued.

Local repair is the initial choice in most cases of Crohn's disease–associated rectovaginal fistulae. If the rectum is relatively free from disease, and the rectal wall is pliable, a rectal advancement flap can be attempted. However, in the presence of rectal scarring, this procedure is best avoided. The alternatives include an anocutaneous flap, rectal sleeve advancement, or vaginal flap. An anocutaneous flap can be done only if the anal skin is soft and supple, which is often not the case in patients with Crohn's disease, although a success rate of 70% has been reported for this procedure. The vaginal advancement flap is another alternative for which good healing rates have been reported, especially when a portion of the levator ani muscle is interposed between the rectal and vaginal walls below the flap of vaginal mucosa. Closure rates with this technique have been reported to be as high as 92.3%; however, a 40% to 60% success rate is probably more realistic in Crohn's disease.

Crohn's disease–associated rectovaginal fistulae have an overall poor prognosis, with a recurrence rate that varies from 25% to 50%. It is therefore very important to elaborately counsel patients and set realistic treatment goals. In patients with poorly controlled proctitis, surgical options are very limited. Quite often patients are symptomatic from the abscesses associated with the repeated flare-ups of Crohn's proctitis. Prolonged seton drainage for 12 to 18 months epithelializes the fistula tract and limits further episodes of abscess. Very often, patients with multiple failed procedures prefer prolonged seton drainage to a total proctocolectomy and permanent ileostomy, which is the procedure of last resort.

Malignancy

The only definitive treatment of malignant rectovaginal fistulae is an en block surgical extirpation of the fistulous tract with the mass and any contiguous organs involved in the malignant process. This often requires a posterior or total pelvic exenteration. A diverting stoma is often placed to decrease symptoms, while the patient receives neoadjuvant therapy. The patient should then be reevaluated after adjuvant treatment to determine the extent of response and fitness for a major surgical procedure. In patients of good performance status with a satisfactory response to adjuvant therapy, a pelvic exenteration may be considered. However, very few patients fit this description, and treatment remains palliative in most cases.

The Management of Condyloma Acuminata

Charles B. Whitlow, MD, and
David A. Margolin, MD

Human papilloma virus (HPV) is a DNA papovavirus that requires differentiating squamous epithelium for viral replication and is the most common sexually transmitted disease in the United States. The Centers for Disease Control (CDC) estimates that more than 20 million Americans are infected with HPV and that more than 6 million new cases will be reported each year as the prevalence approaches 50% in sexually active adults. Currently, more than 100 subtypes of HPV exist as determined by DNA typing. Although HPV infections are most commonly located in the cervix, vagina, vulva, perineum, penis, and anus, the infection can affect any part of the body. Most HPV infections go unrecognized, but roughly one third of the HPV subtypes are associated with anogenital warts, accounting for about 10% of all HPV infections. Despite its indolent nature, HPV is responsible for a spectrum of perianal disease from asymptomatic infection, benign warts, and anal intraepithelial dysplasia to invasive anal squamous cell cancer.

Although one third of HPV subtypes are associated with anogenital warts, DNA subtypes 6 and 11 are the most common and are considered to be low-risk types with regards to malignant degeneration. Subtypes 16, 18, 31, and 35, although also seen in anogenital warts, are considered high risk because of their association with anal dysplasia and anal cancer. Because of the histologic similarities between the cervix and anus, a transition zone from columnar to squamous epithelium, the role of HPV in the development of anal dysplasia (AIN) and anal canal cancer is similar to the well-established role of HPV in the development cervical dysplasia and cervical cancer.

PRESENTATION AND EVALUATION

Morphologically, benign warty anogenital HPV infections or condyloma acuminata are the characteristic gray or pink, fleshy, cauliflower-like growths appearing on partially keratinized epithelium (Figure 1). However, HPV can also appear as small papules or as thick keratotic warts similar to common skin warts. They can be sessile or pedunculated and may range in size from several millimeters to giant Buschke-Löwenstein lesions. As condylomas enlarge and increase in number, they can encircle the anal margin and become confluent, sometimes making visualization of the anus difficult. Lesions may also be present in the anal canal and extend above the dentate line.

Most patients report a growth or growths in the perianal region. Like most types of anal pathology, a self diagnosis of hemorrhoids is common. Other frequent symptoms include pruritus, bleeding, chronic moisture or drainage, difficulty with hygiene, and pain. Physical examination must include inspection of the genitalia, groin folds, perineum, and perianal region. Anoscopy is needed to detect anal canal lesions and also allows for inspection of the distal rectal mucosa. Because of a higher incidence in patients with HPV, additional evaluation for other sexually transmitted diseases should be performed. Female patients should undergo vaginal speculum examination and Pap smear. Because condyloma acuminata, intraepithelial dysplasia, and anal squamous cell cancer are more common in patients with immunocompromise, a thorough history of high-risk behavior is mandatory and human immunodeficiency virus (HIV) testing should be considered. This chapter focuses on condyloma of the perianal skin and anal canal because these are the affected areas treated by general and colorectal surgeons.

THERAPY

Although spontaneous resolution of condyloma is reported, most patients need treatment. The goal of that treatment should be complete destruction of all condyloma; however, the underlying viral infection may persist. Patients should be counseled in advance that recurrence is common and generally occurs during the first 3 months. Many therapeutic options can be divided broadly into two categories: provider-administered ablative/cytodestructive therapies (including cryotherapy, laser ablation, and trichloroacetic acid [TCA]) and patient-administered topical therapies (such as podophyllotoxin, sinecatechins, and imiquimod). Other options such as interferon, topical 5-fluorouracil (5-FU), vaccines, and cidofovir are less well established.

FIGURE 1 Perianal condyloma.

Topical Therapies

The mainstay of topical treatment for condyloma in the authors' practice is imiquimod (Zyclara, 3M Health Care, Loughborough, England). Imiquimod is an imidazoquinoline heterocyclic amine that functions as an immune response modifier. Imiquimod directly activates innate immune cells through Toll-like receptor 7, resulting in increased cytokine production, specifically increased interleukin-1 and tumor necrosis factor–alpha, and production of type I interferons (IFNs; IFN-alpha and IFN-beta). Indirectly, imiquimod enhances antigen-specific cell-mediated immunity. Imiquimod, an ointment, is applied at bedtime 3 times a week, left in place for 6 to 8 hours, and washed off in the morning. Treatment may take up to 16 weeks. A number of randomized controlled studies have shown that 5% imiquimod achieved a 50% complete response rate with a recurrence rate of 11%. The side effects of imiquimod are mostly local in nature and include burning, erythema, pain, and itching. However, these side effects are generally mild. Currently, imiquimod is not approved for use in the anal canal because of the possibility of significant ulceration and bleeding. The authors currently use imiquimod as their primary treatment modality. For patients with extensive warty disease, they use an 8-week to 10-week course before surgical treatment. Because of the high risk of recurrence in these patients, treatment for another 6 weeks is often continued after the surgical wounds are healed.

Podophyllin and Podophilox

Podophyllin is an amitotic agent obtained from the *Podophyllum* plant. It is an impure resin, generally suspended in tincture of benzoin in concentrations of 20% to 25%, and is applied to external warts by a provider on a weekly basis. The resin should be washed off 4 to 6 hours after application. Concerns about the use of podophyllin include local and systemic toxicity, teratogenicity, and mutagenicity. It is contraindicated in larger lesions and pregnancy. Clearance rates of most studies of podophyllin range from 40% to 60%, with recurrence rates as high as 60%.

Podofilox (podophyllotoxin) is the purified and standardized active component of podophyllin. It is available as a 0.5% topical gel or solution, which is applied by the patient twice a day for 3 days followed by 4 days with no treatment. This cycle is then repeated for 1 month, although at least one study shows safety for use up to 8 weeks. Local side effects include a burning sensation, pruritus, tenderness, and erythema but rarely are severe enough to require cessation of treatment. Total area of tissue treated should be less than 10 cm^2. Clearance rates in the 70% to 80% range are commonly reported, with recurrence rates of 10% to 20%. Podofilox has not been approved for anal canal or perianal condyloma; however, the gel has been studied in perianal warts with only 3% of patients discontinuing usage because of side effects.

Trichloroacetic acid

TCA is a corrosive chemical that denatures and precipitates protein. It is applied on a weekly basis directly to condyloma with an applicator. Because it destroys any tissue it contacts, normal adjacent skin should be protected with petrolatum. TCA is useful for small anal canal lesions; however, complete drying after application is important to protect unaffected anoderm. Few clinical trials exist that assess effectiveness, despite its fairly widespread use, but reported resolution rates range from 20% to 70%. It is ineffective for bulky disease, and the authors use it only for small lesions (<5 mm), few in number, in the anal canal.

Cryotherapy

Cryotherapy with liquid nitrogen is an appropriate technique for treatment of small perianal condyloma. This technique can be done

in the office without anesthesia. Liquid nitrogen is applied with cotton-tipped applicator. The applicator is applied for 15 to 30 seconds. Care must be taken to limit the zone of injury because the application can cause significant pain. In an attempt to minimize local skin injury and pain, multiple smaller applications may be needed to achieve complete wart clearance. A specific advantage of cryotherapy compared with other modes of therapy is that it may be applied in the anal canal. A disadvantage to cryotherapy aside from local skin irritation is that intraanal applications may cause ulceration and significant rectal bleeding. The other drawback to office-based cryotherapy is maintenance of a ready supply of liquid nitrogen. The recurrence rate with cryotherapy is 20%.

5-Fluorouracil

5-Fluorouracil cream has been used as a topical treatment for anogenital condyloma. 5-FU is a pyrimidine antagonist that blocks the methylation of deoxyuridylic acid to thymidylic acid, interrupting DNA synthesis in the s-phase. Because of its mutagenic potential, 5-FU is contraindicated during pregnancy and should not be used by women of child-bearing age. No randomized controlled studies have evaluated its efficacy. Case studies have shown a 10% to 30% condyloma clearance rate. However, little data are available concerning recurrence.

Miscellaneous Treatments

The literature is filled with various other medical treatments for condyloma, including interferon, autologous vaccine, cidofovir, and many others. These have not proven to be effective in prospective trials, nor have they gained any widespread acceptance or usage.

Surgery

The goal of surgical treatment of condyloma is eradication of visible lesions with minimized destruction of normal adjacent tissue. This is accomplished through one of several techniques: tangential excision, electrocautery excision or fulguration, curettage, and laser excision. All of these techniques require some form of anesthesia and postoperative analgesics. These techniques are superior to the topical preparations listed previously for initial resolution of condyloma with cure rate of 60% to 90%. Recurrence rates of 20% to 30% are commonly reported.

Tangential excision with a scalpel or scissors can be performed as an office procedure and is especially useful for patients with smaller lesions that are few in number. The patient is placed in the lateral or prone jackknife position, and local anesthetic (lidocaine or bupivacaine with epinephrine) is injected subcutaneously or submucosally. Excision is performed at the level of the dermis, and hemostasis obtained with direct pressure or cauterization with silver nitrate. Cleansing with soap and water daily and after each bowel movement is all that is necessary for wound care.

Excision and fulguration with electrocautery is the optimal treatment for many anal condyloma. Smaller lesions can be treated with infiltration of local anesthesia; for larger lesions, outpatient general or spinal anesthesia is usually required. The patient is placed in lateral or prone jackknife position and then prepped and draped in the sterile manner. The superficial-most layer of the lesion is fulgurated with the electrocautery tip to a gray-white appearance that is then wiped with a dry gauze or a curette. This process of fulguration and tissue removal is repeated until the condyloma is completely removed without burning into the deep dermis or subcutaneous fat. Larger pedunculated warts are transected at the junction of the stalk with normal skin with a scalpel or electrocautery. In those patients with flat lesions, recurrent lesions, and those that do not have a benign appearance (ulcerated, friable, or hypervascular) and in patients who are HIV positive, removed specimens should be sent for histopathologic evaluation. Postoperative care includes adequate oral analgesics and cleansing as described previously. An application of topical 5% lidocaine may be helpful for pain control. Because fulguration causes significant eschar formation, increasing pain and erythema may be a sign of bacterial infection. These infections are treated with either silver sulfadiazine or mupirocin. Full-thickness excision is discouraged for lesions than can be treated with the previous techniques. However, it may be necessary in larger flat lesions and especially in giant Buschke-Löwenstein tumors.

Surgical treatment of condyloma acuminata with the laser has been described. There is no benefit to the laser with regards to postoperative pain or clearance rates. Studies have shown higher recurrence in those patients treated with laser compared with electrocautery. Aside from the cost, the disadvantages of laser treatment include the need for special training and the exposure of operating room personnel to smaller viral particles in the laser plume compared with electrocautery smoke.

Treatment Recommendations

The goal of treatment for condyloma acuminata is eradication of visible disease with minimal morbidity and a low recurrence rate. Several factors should be considered in determining appropriate treatment. These include patient age, pain tolerance, compliance, and the size, number, and location of lesions to be treated.

For small lesions (<5 mm), regardless of the number, topical therapy should be the initial treatment. For a patient with a small number of lesions (<5), any topical preparation can be used. The authors currently use TCA in these cases. For patients with more extensive disease not involving the anal canal, imiquimod is the first-line therapy because intraanal application of imiquimod can cause severe mucosal ulceration. Small intraanal lesions can be treated with TCA or cryotherapy. Patients with intraanal lesions, those who are noncompliant with imiquimod, and those with failure of imiquimod therapy are offered excision and fulguration.

For more extensive disease, especially large multilobulated, cauliflower-like condyloma, surgery is the mainstay of treatment. The authors' preference for surgical treatment is excision and fulguration with the electrocautery as described previously. In these patients, after epithelial healing, imiquimod is used for treatment of any residual or recurrent disease. Although this is the authors' standard treatment, its efficacy in prevention of recurrence is still under investigation.

The treatment of anal condyloma and the prevention of anal canal cancer is an area of continued evolution. Currently, specific subtypes 16, 18, 31, and 35 are recognized to have an increased oncogenic potential; the histologic similarity between the anal transition zone and the cervical transition zone is also recognized. These are areas where immature metaplastic tissue susceptible to HPV infection can be found. It is important to recognize that oncogenic subtypes morphologically do not cause warty disease. Finally, some specific patient populations (individuals with immunocompromise [HIV, transplant] and men who have sex with men [MSM]) have been shown to have an increase in the rate of dysplastic lesions and anal canal cancer.

Currently, in conjunction with infectious disease colleagues, the authors screen and treat these patients aggressively. Individuals with HIV and immunocompromise undergo anal cytologic testing or Pap smear yearly. A key point to remember here is that this should be done with cotton-tipped swab, not polyethylene terephthalate swab, because of cellular adherence. Also, this should be done before a digital rectal examination because the lubricant used for the examination decreases cytologic results. Anal cytologic results can range from atypical cells of undetermined significance to low-grade squamous intraepithelial lesions (LSIL) to high-grade intraepithelial lesions (HSIL) to squamous cell cancer.

Once a cytologic diagnosis of HSIL is made, the patient then undergoes high-resolution anoscopy with biopsy and focal destruction of dysplastic lesions (Figures 2 to 4). Aside from treatment of normal warty tissue, this procedure allows for identification and treatment of potentially premalignant areas of AIN. This procedure involves high-resolution anoscopy with an operating microscope, acetowhitening with 3% acetic acid of the anal canal, and counter staining of the region with Lugol's solution. With direct vision, the anal canal is inspected for areas that do not stain brown with Lugol's solution. The authors also look closely for cellular changes that would be seen on colposcopy, cellular mosaics and abnormal corkscrewing vessels. The areas are biopsied for confirmation and focal destruction. Biopsy allows for better quantification of the histologic diagnosis of anal intraepithelial neoplasia (AIN I, II, or III). These stained areas are then ablated with electrocautery. Although postoperative pain is a problem in roughly 50% of patients, there is a low chance of other significant morbidities. With use of high-resolution anoscopy and directed ablation, as opposed to radical excision, one can effectively eliminate AIN in individuals with HIV. The recurrence rate is high in patients with HIV (approximately 50%), but retreatment is safe and well tolerated (Figure 5).

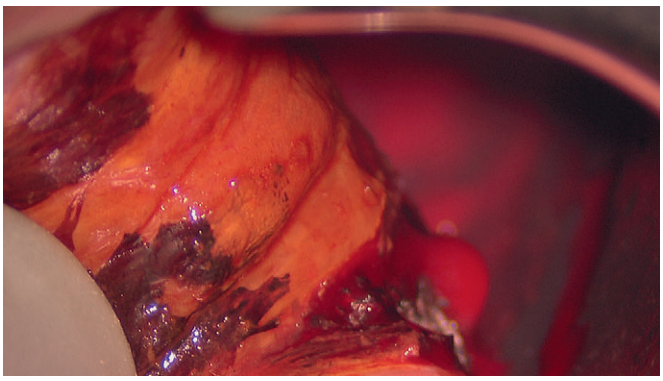

FIGURE 3 High-grade dysplastic lesion after aceto-whitening and Lugol's staining on high-resolution anoscopy (HRA).

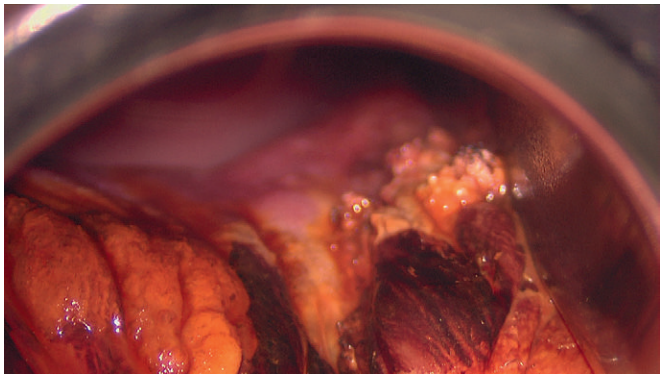

FIGURE 4 High-grade dysplastic lesion after focal destruction.

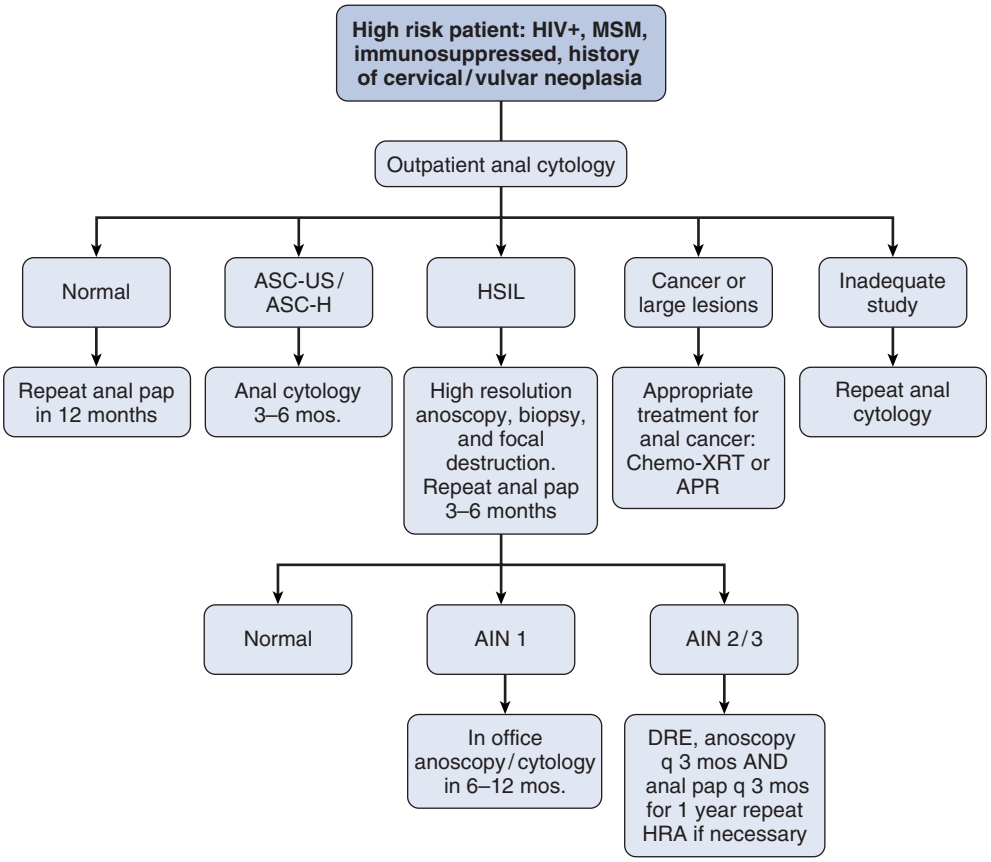
Human Papilloma Virus Vaccine



The quadrivalent HPV vaccine has been shown to be effective at preventing cervical infection and high-grade cervical neoplasia associated with HPV 6, 11, 16, and 18. CDC guidelines as of December 2011 recommend routine vaccination of males ages 11 and 12 years, vaccination of males ages 13 to 21 years not previously vaccinated, and vaccination for males ages 22 to 26 years based on increased risk factors such as HIV or anal-receptive intercourse. This vaccination showed reduced rates of anal intraepithelial neoplasia in homosexual males ages 16 to 26 years compared with placebo. The group studied did not have preexisting HSIL or warts, and the effect on vaccination in patients with existing disease is not known.

GIANT CONDYLOMA ACUMINATA

First described by Buschke and Löwenstein in 1925, giant condyloma acuminata (GCA) have been recognized as potentially malignant lesions. These large slow-growing painful cauliflower-like lesions located on the perineum and penis are sexually transmitted and associated with HPV types 6 and 11. These lesions were initially thought to be similar to ordinary condyloma because of their histologic similarity (benign histology, vacuolization of the cells of the superficial layer of the epidermis, parakeratosis, and infrequent mitotic figures). However, significant differences have been noted. GCA has marked papillomatosis, thickened rete ridges, increased acanthosis, and increased mitotic activity compared with ordinary condyloma. GCA also has shown infiltration of the surrounding tissues. This fact combined with GCA's histologic appearance can make it difficult to distinguish GCA from verrucous carcinoma. GCA has also been found to harbor areas of invasive squamous cell carcinoma, leading to the speculation that GCA represents part of the continuum from condyloma to invasive squamous cell cancer.

The mainstay of treatment for GCA involves surgical excision. Ideally, wide local excision with a 1-cm margin is treatment of choice. This may require flap coverage or skin grafting to repair the defect. Rarely should this require fecal diversion for wound care and healing purposes (Figures 5 and 6). In lesions that involve the anal sphincters, abdominal-perineal resection is a viable option. In their review of the published literature, Trombetta and Place identified 45 patients in whom surgery was the primary therapy. This included simple excision, wide local excision, and abdominal-perineal resection. A 45% recurrence rate was seen with surgical treatment. This was a significant improvement from the 71% recurrence rate seen in those patients initially treated with nonsurgical therapy (podophyllin, intralesional interferon, and 5-FU).

The role of chemoradiation is an option in the treatment of extensive GCA in poor surgical candidates or where clear surgical margins are impossible. This is reasonable considering the relationship between HPV, GCA, and invasive non-GCA squamous cell-carcinoma. Similar to the treatment of anal canal cancer with 5-FU, mitomycin C and external beam radiation (XRT) has been shown to cause complete regression in cases of GCA (Figure 7).

MSM – male having sex with male
HRA – high resolution anoscopy
ASC-US – atypical squamous cells of unknown significance
ASC-H – atypical squamous cells cannot rule out high-grade lesion
LSIL – low grade squamous intraepithelial lesion
HSIL – high grade squamous intraepithelial lesion
AIN 1 – low grade anal intraepithelial neoplasia
AIN 2/3 – high grade anal intraepithelial neoplasia
DRE – digital rectal exam
Chemo-XRT – combined modality chemo/radiation
APR – abdominoperineal resection

The Management of Pilonidal Disease

Jeffrey A. Sternberg, MD, FACS, FASCRS

PILONIDAL DISEASE: COMMON AND CHALLENGING

Pilonidal disease is a common, acquired chronic infection of the skin and subcutaneous tissue overlying the sacrum and coccyx with an incidence of approximately 25 per 100,000. It typically affects people in their teens, 20s, and 30s. The disease rarely first becomes symptomatic after age 40. Men are affected at rates two to three times more frequent than those of women. The disease can manifest acutely, or individuals can live with intermittent symptoms for many years. In its most severe form, pilonidal disease can be severely debilitating, causing daily discomfort and limiting activity. Because pilonidal disease affects people in their most productive years, the socioeconomic effect of the disease is great because affected patients spend significant time away from school or work.

Pilonidal disease was originally described by Herbert Mayo in 1833 and initially thought to be of congenital origin. Unacceptably high recurrences despite seemingly adequate surgical interventions however, support the acquired as opposed to the congenital theory of etiology.

Pilonidal disease first gained public attention during World War II when more than 78,000 soldiers with this condition were admitted to U.S. Army hospitals for an average of 55 days. Surgical outcomes were so poor on these individuals that the U.S. military essentially banned further surgical procedures for this disease.

Pilonidal disease continues to be greatly misunderstood, and rates of recurrence and morbidity from traditional surgical approaches are unacceptably high. Because of this, the surgical treatment of pilonidal disease must change. Nonoperative treatment has gained popularity, but there is little evidence that nonsurgical treatments can cure significant pilonidal disease. More contemporary operations involving flaps and off-midline closure are gaining popularity among surgeons willing to move beyond surgical tradition. These more complex procedures may be performed in an outpatient setting, require minimal absence of patients from work or athletics, and have much lower recurrence rates than do conventional excisional procedures. Because many general and colon and rectal surgeons have limited experience with reconstructive procedures involving flaps, few have performed these rigorous but arguably superior operations. Asymmetric flap procedures should become the new norm for the treatment of advanced or recurrent pilonidal disease.

Because most recommendations regarding the treatment of this disease are derived from expert opinion or case report studies, the best treatment of pilonidal disease remains controversial.

ETIOLOGY AND CHARACTERISTICS

The Name

Pilonidal disease is an acquired condition of the natal cleft (Figure 1). There are two important ingredients in the development of pilonidal disease: a deep cleft and hair. The term *pilonidal* comes from the Latin *pilus,* meaning "hair," and *nidus,* meaning "nest." Most pilonidal abscesses contain hairs. Hairs that are shed from the scalp or back fall into and become lodged in an unusually deep cleft near the tailbone. The hairs in pilonidal abscesses are not ingrown. Hairs and debris are secondary invaders and not the cause of the condition. The shed hairs insert from their root end because barbs prevent them from inserting from their external apex. Local hair removal or eradication is therefore not preventive or curative.

Causes

Pilonidal disease most commonly occurs in hirsute individuals with deep natal clefts. The environment inherent in a deep natal cleft is the true cause of pilonidal disease. The cycle begins when an individual with a deep cleft sits. The stretch of the sitting motion ruptures hair follicles in the midline, and they become plugged with keratin. This follicular occlusive process is similar to what occurs in hidradenitis suppurativa. A subcutaneous abscess then develops. The moist, anaerobic nature of the cleft prevents healing, and a dilated pore or pit opens in the midline (Figure 2). Further sitting motions cause the skin of the cleft to tighten and lift off the sacrococcygeal fascia, which creates a suction force that pulls hair and debris through the holes, causing enlargement of the subcutaneous abscess. A foreign body reaction develops and contributes to the formation of pus and inflammation.

In the body's attempt to expel the infection, a secondary sinus may track to the cephalad aspect of the natal cleft (Figure 3). Such a secondary external opening is the result and not the cause of the disease, even though it may seem more impressive than the more anally located dilated pores. These pores, termed the *primary openings,* are the true source of pilonidal disease. The condition is less often observed in people with shallow natal clefts.

Not a Congenital Condition

Pilonidal disease is not caused by an infected congenital cyst. The abscess cavity in pilonidal disease does not have an epithelial lining

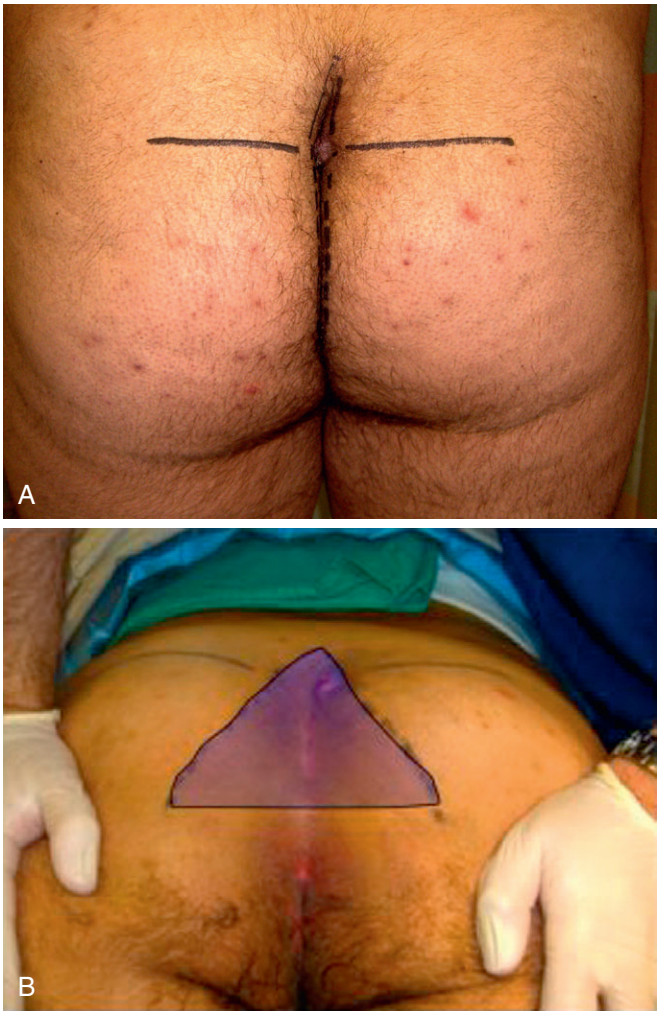

FIGURE 1 **A,** In a patient lying down, the edges of the buttock cheeks that touch when the person is standing are marked. The horizontal line is the contact point with the chair when the patient is seated. **B,** The buttock cheeks are spread to reveal the natal cleft, a 5- to 9-cm region bounded by the midsacrum and the perineum. The lateral borders are formed by the edges of the buttock cheeks that touch when the person is standing.

and is therefore not a cyst. Therefore, the term *pilonidal cyst* is a misnomer. The condition is simply a subcutaneous abscess filled with purulent material and debris, most often hair.

Implications of Anatomy on Surgical Approach

Failure to recognize that the depth of the cleft is the causative factor in this disease leads to misdirected surgical procedures. Wide excisions that attempt to remove a nonexistent cyst leave large midline wounds in persistently deep clefts that may not heal because of the anaerobic environment and repetitive shear forces (Figure 4). Such procedures often result in a larger wound that is even more difficult to treat than the original abscess. Even when such wounds heal, individuals remain at risk for recurrence of pilonidal abscess because the original cleft conditions remain hostile: the cleft remains deep.

FIGURE 2 Five midline dilated pits in pilonidal disease.

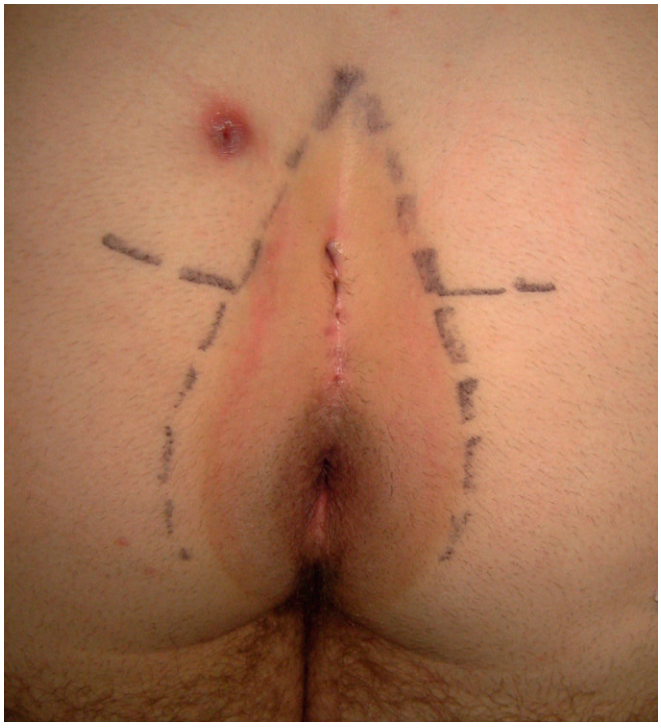

FIGURE 3 Chronic pilonidal sinus. Note four midline pits (the upper three contain protruding hairs) and left draining sinus tract cephalad to pits.

Making the Diagnosis

Pilonidal disease can exist for months or years before it causes symptoms. The disease may manifest as an acute painful abscess or as a chronic draining sinus. To make the diagnosis, the clinician must recognize the dilated pits in the midline of the natal cleft with or

FIGURE 4 Large unhealed wound 6 months after wide excision and attempted midline closure in a 19-year-old male.

without an associated secondary sinus. Shed hairs are often seen protruding from these midline pits. Patients may report trauma to the coccygeal area before the development of symptoms. Trauma can cause an abscess to become inflamed or otherwise bring the patient's attention to the area. Pilonidal abscesses are not thought to be the direct result of acute trauma.

A CHANGING PARADIGM

Despite the currently accepted notion that pilonidal disease is a condition that is acquired rather than congenital, many surgeons continue to perform wide excisions in the midline deep cleft in an attempt to remove the nonexistent congenital cyst. Surgical procedures for pilonidal disease will continue to be unsuccessful until surgeons realize that the depth of the natal cleft in affected individuals is the cause of the disease. Therefore, for procedures to be routinely effective, the natal cleft must be made shallower. Traditional operations for pilonidal disease typically involve the unnecessary extensive excision of tissue down to the sacrum. Wounds are then left open to heal by secondary intention in the midline or closed in the midline in a residual deep cleft. Most midline incisions in a deep anaerobic environment will open because of trapped dead space and the hostile conditions in the cleft. Marsupialized wounds may heal but do so over a long period of time, and daily packing may be required. Many individuals with open sacral wounds are unable to sit, which results in significant morbidity that interferes with work, attending classes, or group living in school dormitories. A surgeon should not undertake an operation for pilonidal disease unless she or he is confident that the outcome is highly likely to be better than living with the disease itself. Often, overly aggressive surgical procedures make this condition worse and result in a more complex pilonidal condition or one or more large unhealed wounds that are more challenging to correct than the original problem (see Figure 4).

The Difficult Environment of the Cleft

Wounds in deep natal clefts are very resistant to healing. The reasons for this are not fully understood. Contributing factors include anaerobic conditions, a location and anatomy that challenge good hygiene, shear forces from movement, and mechanical forces from the natural contour and gluteal muscle tension. Aggressive débridement, cautery, and dressing changes are rarely successful in healing chronic wounds in this region. Even negative-pressure wound therapy is typically unsuccessful. The best corrective therapy is asymmetric flap closure of these wounds that make the natal cleft shallow and leave operative incisions off the midline, where they are in the open air and can heal. Surgeons should be aware of the potential danger of creating midline wounds in the natal cleft, inasmuch as they often do not heal. Significant pilonidal disease or recurrent pilonidal disease necessitates a definitive surgical procedure to reduce the depth of the natal cleft to render it well aerated, dry, and shallow, so that hair and debris cannot be trapped.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Recognition of midline pits with or without a chronic draining sinus clinches the diagnosis of pilonidal disease. On occasion, the sinus opening, if present, can be contained within the natal cleft, but typically it lies outside the boundaries of the natal cleft and above it on the right or left side. This location of the secondary opening probably results from the body's attempt to expel infection to the outside world (the "closed" nature of the cleft may be perceived as internal). With acute abscesses, edema can obscure the midline pits, and these pits may be visible only once the abscess has been adequately drained and the swelling subsides. If it is difficult to see the primary openings; placing upward traction on the natal cleft skin often reveals these pits because their deep apices are often tethered to the underlying abscess cavity.

Pilonidal disease must be distinguished from other processes such as perianal abscess, perianal fistula, hidradenitis suppurativa, or unusual skin infections. If the abscess extends down the natal cleft and approaches the anus, the condition can be difficult to differentiate from a perianal abscess. Draining openings in the lower part of the natal cleft without the dilated midline pits can be the result of a perianal fistula. Sometimes perianal fistulas do occur in individuals with quiescent pilonidal disease, in which case the focus of treatment should be on the symptomatic perianal fistula rather than the quiescent pilonidal disease. Pits off the midline sometimes indicate a different disease process such as hidradenitis suppurativa or unusual skin infections such as syphilis, tuberculosis, or actinomycosis.

Classification schemes exist for pilonidal disease, but they are not commonly referenced and are therefore not of significant clinical utility.

Imaging

Imaging is generally not required to evaluate or confirm the diagnosis of pilonidal disease. Only in rare circumstances during which chronically ill patients are suspected of harboring osteomyelitis of the sacrum should imaging such as magnetic resonance imaging (MRI) be employed. Findings on fistulograms and sinograms rarely change surgical therapy. In circumstances in which an anal fistula must be ruled out as a cause of a low-lying natal cleft pit, MRI or endoanal ultrasonography with hydrogen peroxide injected in the external opening of the suspected fistula may be helpful.

ACUTE PILONIDAL ABSCESS MANAGEMENT

Pilonidal disease may initially manifest as an acute abscess. The primary treatment of an acute pilonidal abscess is incision and drainage. Drainage should be performed 1 to 2 cm off the midline to avoid a large midline wound. A cruciate incision or an elliptical incision is

needed to provide adequate drainage and prevent early closure of the draining incision. In such difficult-to-reach areas, packing is not recommended or required. Such procedures are usually safely performed in an office setting with local anesthesia and very rarely require an operating room setting. Antibiotics are usually not needed unless there is significant cellulitis or the individual is immunosuppressed or diabetic.

The flora of such wounds is usually represented by skin organisms, anaerobes, or both. These wounds do not typically contain resistant staphylococci unless they are recurrent.

After drainage, patients are instructed to soak in a warm tub several times a day for several days and to keep the area clean. Showering is permitted. They are asked to return in 3 weeks, at which time the primary openings are often seen.

Individuals who develop an acute abscess only once or who develop infrequent abscesses that necessitate only minor office-based drainage procedures are typically not advised to undergo surgical intervention. Over time, however, such conditions may progress to a chronic abscess with multiple dilated pits and chronic induration in the cleft without a drainable abscess. Patients with recurrent acute abscesses, those with a chronic abscess, and those who have a preference for definitive therapy should be evaluated or referred for surgical intervention.

CHRONIC PILONIDAL SINUS

A pilonidal sinus may develop after several acute abscess flares, or it may be initial presentation of the disease. Affected individuals have multiple dilated midline pits (some of which may be epithelialized as a result of their chronicity) and a chronic draining sinus that typically opens to the cephalad right or left aspect of the natal cleft.

Of importance is that the draining sinus at the top of the natal cleft is a secondary opening and that surgical treatment directed solely at this opening will fail to cure the condition because the more anally located primary pits are the source of the disease. Some individuals can live with a chronic pilonidal sinus with minimal symptoms and never require surgical intervention. However, in many cases, these sinuses are accompanied by annoying drainage and chronic pain, and therefore many patients desire definitive surgical therapy.

NONSURGICAL APPROACHES

Patients who have no symptoms despite the appearance of their pilonidal condition and those with minimal symptoms can be managed by observation. The best conservative approach involves doing nothing. There is little evidence that local shaving or hair removal is effective at preventing recurrent disease once primary openings have appeared. Some surgeons have advocated injecting phenol into sinus tracts to destroy them. This is quite painful and often has to be performed while the patient is under regional or general anesthesia, with a several-day hospitalization for postoperative pain control. The rationale for this treatment is that phenol destroys tissue and causes scarring. Because the scar tracts remain in the deep natal cleft, these individuals remain at risk for developing recurrent pilonidal disease. Few data support use of phenol in pilonidal disease.

SURGICAL APPROACHES

Indications for surgical intervention include recurrent acute abscesses, symptomatic chronic pilonidal sinuses, and patients' preference. Because of the demanding educational and employment activities of young individuals affected by the disease, many opt for surgery to try to eliminate the uncertainty of recurrent disease.

For early disease with several upper natal cleft pits and a short draining sinus, conservative surgical intervention consists of unroofing or pit-picking techniques.

Unroofing

In unroofing, a fistula probe is delivered through the lowest pit and out through either the highest pit or sinus if it is present (Figure 5). Electrocautery is used to perform a minimal elliptical incision over the probe and unroof the skin, connecting the midline pits and the sinus. The underlying abscess cavity is curetted to remove debris. The edges of the wound are best marsupialized. Packing can be performed but is cumbersome unless the patient has daily assistance. For short tracts, some patients can undergo these procedures under local anesthesia in an office setting, but procedures involving longer tracts necessitate regional or general anesthesia in an operating room. Wide excisions are unnecessary because the abscess cavities are rarely complex unless prior surgical procedures have been performed in this region. Injecting methylene blue is unnecessary because granulation tissue enables easy identification of the tract. Complete healing may take 6 weeks, but patients are permitted to be active during the healing period. Occasional silver nitrate treatments in the physician's office are useful in preventing the development of exuberant granulation tissue. The overall success rate of this procedure is unknown.

Pit Picking

Minimal excision of midline pits with débridement of the abscess cavity, often through a lateral wound as described by Bascom and Bascom, is a potentially curative procedure for early disease (Figure 6). Patients with several midline pits and perhaps a minor short tract sinus are candidates for this procedure. This procedure, performed with the patient under local anesthesia in the physician's office, involves small elliptical incisions (with a No. 11 blade or a 2-mm

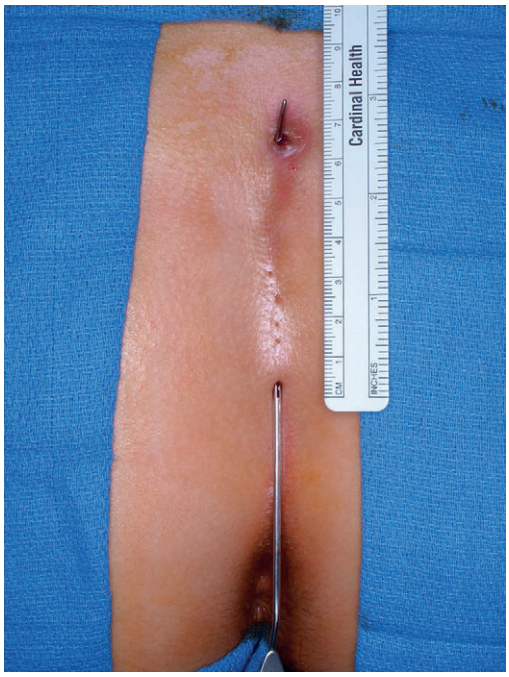

FIGURE 5 Probing the fistula tract: the first step before unroofing the pilonidal sinus.

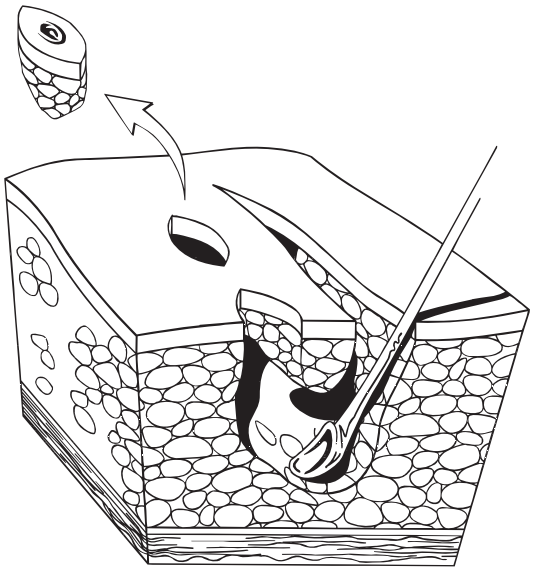

FIGURE 6 The incision is made lateral to the pilonidal sinus cavity, and the cavity is curetted. Pits are excised separately or en bloc. *(Adapted from Nivatvongs S: Pilonidal disease. In Gordon P, Nivatvongs S, editors:* Principles and practice of surgery for the colon, rectum, and anus, *St. Louis, 1992, Quality Medical.)*

punch biopsy blade) around the midline pits; these pits are closed with a fine monofilament suture. A lateral incision 1 to 2 cm off the midline enables access to the underlying abscess cavity. This abscess cavity is débrided with a curette and left open. Making the lateral wound elliptical enables adequate drainage and eliminates the need for packing. Patients return in 7 to 10 days for suture removal, and the wounds fully heal in approximately 2 weeks.

An alternative technique involves the use of trephines (small circular punch knives). In this technique, the midline pits are excised, as are their connections with the underlying abscess cavity, and the abscess cavity is débrided with the trephines. All wounds are left open.

The Goals of Surgery in Patients With Chronic Disease

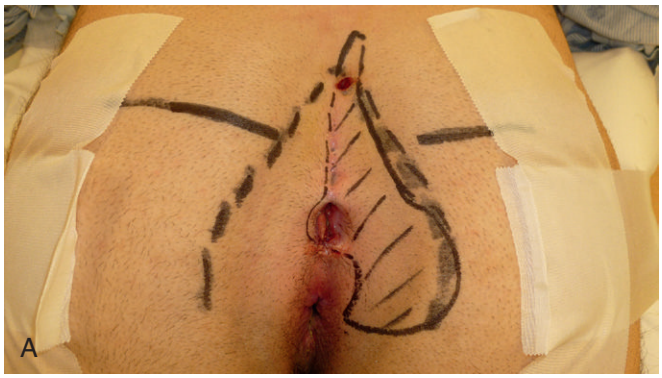
The management of chronic pilonidal disease remains controversial. The first aim of surgery, however, is indisputably to eliminate the chronic infection and relieve pain and discharge in the least disfiguring manner possible with the shortest recovery possible. The second aim should be to decrease the possibility of future hair insertion into the vulnerable midline skin of the natal cleft by making it less deep. Unfortunately, many traditional surgical techniques have failed to adhere to these goals. Two commonly performed procedures are midline operations that involve a wide excision of the affected area in the natal cleft, often down to the sacrococcygeal fascia, with either a midline closure or marsupialization of the large resulting defect. Both these procedures introduce wounds in a persistently deep natal cleft. When wounds are closed in such environment, there is a high chance that the wound will open. Although open wounds may heal, they often do so at a high cost. Many of these wounds linger for months, necessitating daily meticulous care and packing. Data concerning the true recurrence rates after such procedures are limited. Evidence is increasingly in favor of a flap-based procedure with an off midline closure.

Asymmetric Flap Techniques

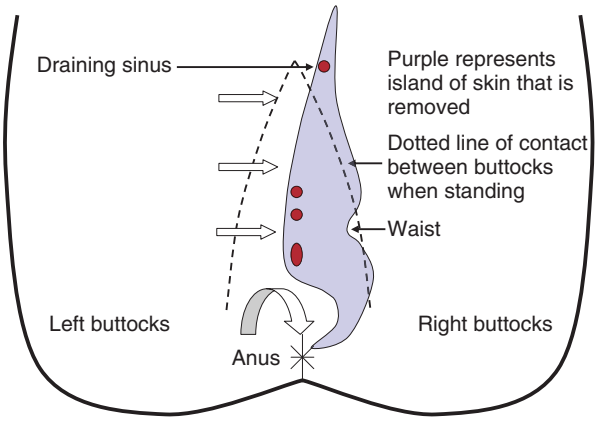
The Karydakis Flap

Dr. George Karydakis first developed the concept of eccentric excision for pilonidal disease and published his experience in 1973. In this technique, which is essentially an advancement flap procedure, an elliptical excision of skin encompasses the dilated midline pits and sinus tract and the underlying chronic subcutaneous abscess centered 2 cm off of the midline. After the excision, the skin and subcutaneous fat from the opposite side of the cleft is mobilized to produce a thick flap, which is advanced across the midline and sutured to the skin on the side of the excised tissue. The flap is further fixed to the underlying sacrococcygeal fascia. A Penrose or closed suction drain is placed at the upper end of the wound deep to the flap for several days to a week. This operation demonstrates some important concepts: wounds off the midline (where they are exposed to air) do heal, and shallower clefts help prevent recurrent disease because these clefts do not collect debris and do remain well aerated.

The results of a Karydakis flap operation are quite good, with a recurrence rate of only 1%, but complication rates are fairly high, at approximately 8% or 9%. Complications that occur include infections and fluid collections that necessitate drainage, but these rarely result in a failure of the operation. The operation, however, causes a significant degree of pain and can require a several-day hospitalization for pain control.



The Cleft Lift Procedure



The next evolution of the Karydakis operation, the cleft lift procedure, was originally developed by Dr. John Bascom. The goals of the cleft lift are to render the natal cleft shallow and to lateralize the incision. A cutaneous flap is both advanced and rotated across the midline of the natal cleft to make the cleft more shallow and therefore correct the anatomy that leads to recurrent pilonidal disease. In this procedure, the only tissue that is excised is an ellipse of skin rather than the skin, fat, and fascia of the Karydakis procedure. The abscess cavity wall is preserved and used in the closure to prevent dead space. Skin is necessarily removed so that the cleft has a smooth contour after the underlying tissue is brought together to eliminate the deep midline in the cleft. This operation is performed on an ambulatory basis and has become this author's preferred method of treating pilonidal disease that necessitates surgery.

The cleft lift operation requires meticulous planning and technique and is performed as follows. Preoperatively, the patient is asked to stand, and the line of skin contact of both buttocks is marked with an indelible marker. This defines the natal cleft lateral boundaries and serves as a guide for placing the wound so that it ends up in a well-aerated position. For orientation purposes, a second line perpendicular to the first is drawn where the patient's buttock cheek meets a chair in the seated position (see Figure 1, *A*).

General or regional anesthetic is used (a spinal anesthetic is preferred because patients can comfortably position themselves). Local anesthesia with sedation is not sufficient owing to the large size of the dissection. Patients are positioned prone (jackknifing is not necessary), and the buttocks are taped apart. The natal cleft, lower back, buttocks, and perianal tissues are shaven with clippers. The clinician must be careful not to injure fragile skin during this process because it can lead to wound complications. A field block with 0.5% bupivacaine with 1:200,000 epinephrine is administered.

An asymmetric ellipse of skin, which will eventually be excised, is marked on one side of the natal cleft, often the one that contains the sinus (Figure 7, *A* and *B*). The more scarred side is excised if the patient has undergone prior pilonidal surgery. The ellipse does not have to include the sinus, which will heal when the primary openings and underlying abscess have been removed. For a better cosmetic result, however, it is preferable to remove the sinus opening. The cephalad portion of the ellipse should be at least 2 cm above the top

B Open arrows indicate the advancement and rotation of the flap across the midline and around the anus.

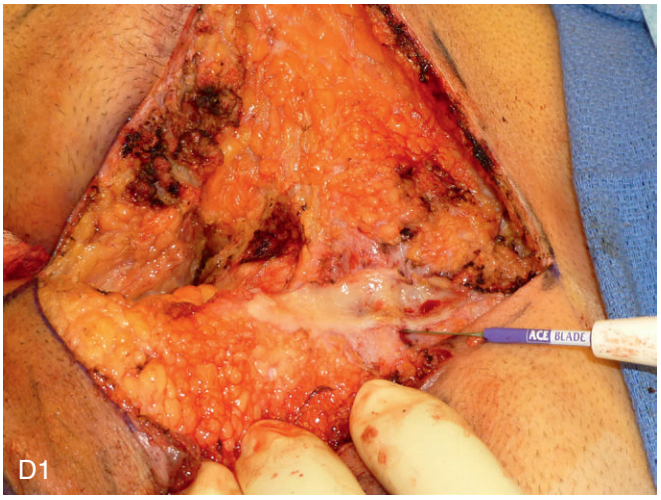


FIGURE 7 The cleft lift procedure. **A,** Operative planning photo showing markings of where buttocks meet (*dashed lines*), where the buttock meets the chair (*solid horizontal line*), and asymmetric ellipse of skin to be excised (*hatched area on right*). In this photograph, the right cephalad wound is the draining sinus, and the caudal wound is the large midline pilonidal opening. **B,** Operative planning diagram. **C,** Excised skin, including sinus opening at superior border and caudal wound in lower third (note that flap of skin shrinks in size after excision). **D,** Before and after cross-hatching: (1) intact fibrous abscess cavity wall, and (2) abscess wall after cross-hatching to disrupt fibrous fixation.

of the natal cleft to prevent the creation of a divot that can lead to recurrent disease. The anal aspect of the ellipse ends in a curve pointing toward the right or left posterolateral portion of the anus. It is important that the ellipse include all the primary midline openings. The lateral edge of the ellipse closely approximates the skin contact marking that was made preoperatively, but it comes in as a "waist" on a 45-degree angle to the lowest pit, inasmuch as this is the most challenging portion of the wound to close in a tension-free manner.

The medial line of the ellipse of skin to be removed is incised with electrocautery on the cutting mode or with a No. 15 blade. Cautery offers the advantage of being able to incise very precisely while remaining perpendicular to a contoured skin surface. It is very important that as much of the natal skin opposite from the excision is preserved for reconstructive purposes. The incision is made just to the opposite side of the dilated midline pits. The incision is carried around the lowest pit and ends in a comma-shaped or reverse

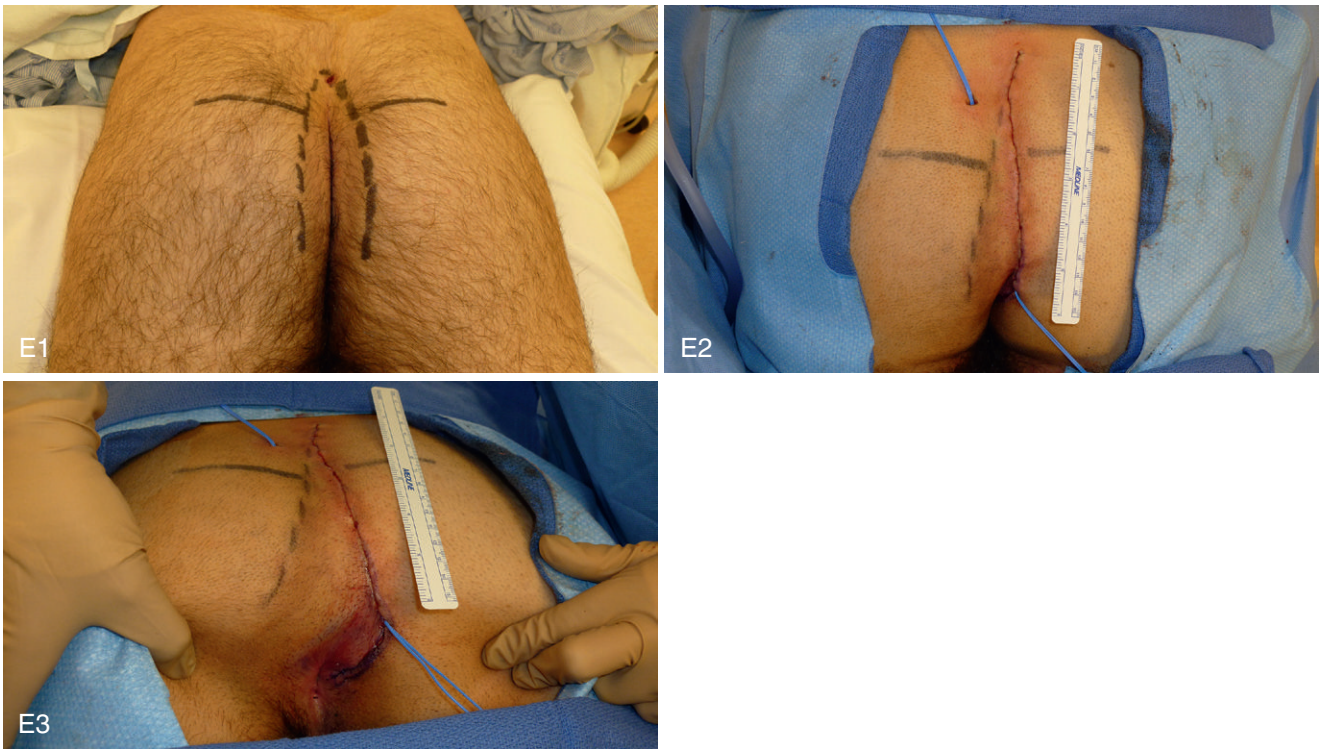

FIGURE 7, cont'd E, Comparison of the appearances of the natal cleft before and after surgery. (1) Preoperative deep and hirsute natal cleft; (2) immediate postoperative view of natal cleft that has been rendered significantly shallower with incision in open air, and (3) anus exposed to demonstrate lowest portion of incision.

comma-shaped curl pointing toward the corresponding posterolateral portion of the anus.

A skin flap is elevated off the opposite side of the natal cleft with electrocautery, extending out past the marked line of skin contact on that side. The flap is kept thin (3 to 5 mm in thickness, as in a mastectomy flap) at the cephalad aspect of the wound. The flap abruptly thickens toward the anal aspect. Dissection exposes the sacrococcygeal fascia overlying the coccyx. The anococcygeal ligament is exposed and divided to enable rotational mobility of the flap around the anus. This is the more challenging portion of the procedure (and an unfamiliar area for many surgeons), and care must be taken to avoid injuring the rectum, which lies immediately underneath the anococcygeal ligament. Once the flap is adequately mobilized, the ellipse of skin to be removed is elevated off that side of the natal cleft out to the lateral markings. This skin is dissected just beneath the dermis; all the underlying subcutaneous fat is preserved.

At this point, the tape is removed from the buttocks, and the coverage flap is draped across the midline while an assistant pushes the buttocks together and the lateral border of the ellipse of skin to be excised is marked again to ensure that the flap will adequately cover the resulting wound. The island of skin is then detached from its lateral attachment. The skin island typically measures 12 to 18 cm in length and 4 to 5 cm in width in the middle (depending on the body habitus of the patient and how close the lowest midline pit is to the anus; see Figure 7, *C*).

A large wound results from this excision. The abscess cavity and the long sinus tract can be seen (see Figure 7, *D1)*. The abscess cavity and sinus tract are now unroofed and curetted free of debris. The abscess cavity wall is not removed, but occasionally the inner portion is excised if it contains a large amount of inspissated hair. Removal of the abscess cavity wall in its entirety would create dead space, in which infected fluid could accumulate and lead to an early recurrence of the abscess. The abscess cavity wall instead is cut into cubes of tissue left attached to the underlying tissue (see Figure 7, *D2*). This is performed by making cross-hatch incisions to break up the scar to enable its rotational mobility during the next stage of the procedure. The wound is irrigated with antibiotic solution, and hemostasis is once again achieved with electrocautery.

The fibroadipose tissue of the buttock cheeks are next serially sewn together with numerous sutures of 2.0 absorbable monofilament suture as the assistant forcibly pushes the buttocks together. Numerous layers are required to take all tension off the flap. A passive drain (e.g., two Silastic vessel loops) is placed through a cruciate incision to the right upper aspect of the flap and is brought out through the wound itself at the inflection point where the wound dives down toward the anus (3 cm from the end of the anus). The superficial layers of the flap closure are created with 3.0 absorbable monofilament sutures, and the skin is closed with either interrupted or running 3.0 rapidly absorbing monofilament suture material (see Figure 7, *A* to *C*). Steri-Strips are applied to the wound, and the passive drain is tied to itself outside the patient to form a continuous loop. The incision often extends close to the anus to avoid a "dog ear" during the wound closure.

Patients are discharged the day of the procedure. They are instructed to have a caregiver roll gauze over the flap from the anal end to the upper margin to expel fluid from the upper drain hole three times a day. The drain is removed 9 days after the procedure, and patients are allowed to return to full activity at that time. The procedure does not cause significant pain because the flap is denervated during the procedure. Sensation is regained after a period of 6 to 9 weeks (see Figure 7, *E*).

Differences Between the Cleft Lift Procedure and Other Flap Procedures

The only tissue removed during the cleft lift procedure is skin. Hence, no dead space is created, and infected fluid does not have any place in which to accumulate. The procedure also seems to cause less pain

than other procedures in which thick tissue flaps are moved. Patients are administered broad-spectrum antibiotics for 2 weeks after the procedure because these wounds are all chronically infected, many grossly so at the time of surgery.

Complications include stitch abscesses and, very rarely, wound breakdown. Even in the rare event that a wound fully opens, complete healing usually occurs within a month with dressing changes because these wounds are lateralized and now well aerated. The result of the cleft lift procedure appears to be durable. Recurrence rates are similar to those of the Karydakis flap procedure, but there seems to be fewer major complications that necessitate intervention. Healing of the closed wound is usually rapid, and patients recover quickly, often participating in sports within 2 weeks of surgery (Figure 8, *A* to *C*).

The Limberg Flap

Another flap procedure that is more invasive but successfully employed for treating pilonidal disease is the rhomboid, or Limberg, flap. The asymmetric variation of this flap is preferred because it keeps the incision away from the midline. In this procedure, the abscessed area is excised down to the presacral fascia by means of a diamond-shaped incision. Next, a rhomboid flap is mobilized full thickness down to the gluteal fascia and rotated to cover the defect. This flap procedure is complex, somewhat morbid, and leaves a disfiguring scar. It is rarely needed.

SURGICAL PITFALLS

The surgeon must keep the following pitfalls in mind:

1. Be sure the diagnosis is pilonidal disease. Pilonidal disease is common and can coexist with other infections of the natal cleft. Make certain that the pilonidal disease is active when a treatment is undertaken, to ensure that the episodes of abscess are indeed caused by the pilonidal pits rather than a concurrent perianal abscess. Be certain that the draining sinus tract does not represent hydradenitis suppurativa. In pilonidal disease, there are often multiple primary pit openings in the natal cleft midline, but if a draining sinus exists, it is usually singular. In hydradenitis suppurativa affecting the natal cleft area, there are often multiple draining sinuses or abscesses that can occur on both sides of the cleft. Also, ensure that openings draining close to the anus do not represent secondary openings of an anal fistula. Often, these openings can be gently probed in the physician's office with a lacrimal probe to determine whether they track toward the anus or upward to the midline pits, which would confirm their cause. Imaging studies, such as MRI, are almost never required unless underlying osteomyelitis is suspected.
2. Do not miss the lowest pit. Patients must be examined carefully in the physician's office to determine where the lowest midline pit is so that surgery can be well planned. This exercise can be difficult, particularly in very hirsute patients or those suffering pain from a chronic infection. The surgeon must spread the patient's buttocks widely (usually with the aide of an assistant), have good lighting, and be prepared to clean the area of debris in order to have an adequate view. The same holds true in the operating room. Failure to incorporate the lowest pit in the skin excision specimen will surely lead to a recurrence.
3. Surgical procedures (including flaps or soft tissue rearrangements) aimed at excising or flattening the cephalad aspect of the cleft but fail to address the causative primary pits will lead to treatment failure. In circumstances in which a pit lies within 1 to 2 cm of the anal verge and a cleft lift procedure is being performed, the pit can be excised and closed with fine absorbable sutures. These closed excisions will heal when the wound

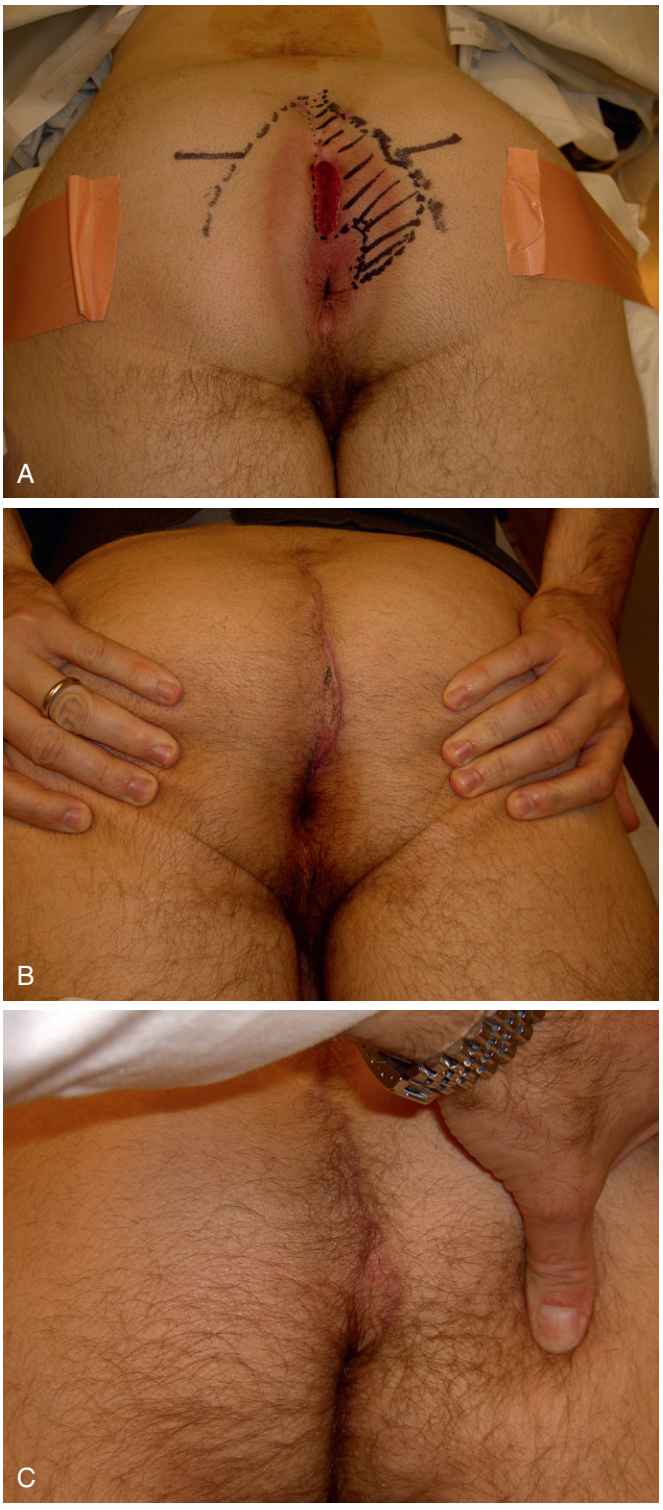

FIGURE 8 Before and after surgery. **A,** Before surgery: large pilonidal wound arising from confluent pits with preoperative planning markings. **B,** Seven weeks after surgery: postoperative shallowness of the natal cleft and near complete healing of wound. **C,** Four months after surgery: regrowth of hair, well-healed shallow natal cleft, and no recurrence of pilonidal disease.

has been rotated off the midline (around the anus) and detached from the sinus tract.
4. Failure to adequately rotate skin around the anus (often as a result of incomplete division of the anococcygeal ligament) during a flap procedure can result in a midline wound and lead to disease recurrence.
5. Avoid repeated wide excisions in the midline without rendering the cleft shallow.
6. Failure to excise an adequate length of skin during a flap procedure can lead to the creation of a midline divot in the residual cleft. Divots trap debris, and pits often develop in divots over time, leading to a recurrent pilonidal abscess. To avoid creating divots, the excision must start above the cephalad aspect of the natal cleft (generally 2 cm).

WHO SHOULD PERFORM SURGICAL PROCEDURES ON PILONIDAL DISEASE

Most general and colorectal surgeons have had little to no formal training in reconstructive flap procedures. Consequently, most are still performing outmoded procedures for pilonidal disease, including wide excisions with either midline closures or wide excisions with marsupialization. Earlier simple disease can be treated by any surgeon by unroofing of the sinus or by pit excision and lateral drainage.

If the disease recurs or if a patient has a complex primary pilonidal sinus, a flap procedure should be performed by an experienced surgeon. Unfortunately, few asymmetric flap procedures are currently being performed for more significant pilonidal disease. To offer patients optimal care for pilonidal disease, surgeons should feel comfortable in performing an asymmetric flap procedure. If a treating surgeon is not comfortable with one of these techniques, then the patient should be referred to a surgeon who is adept in performing flap procedures for complex pilonidal disease. Surgeons who do not perform surgery for pilonidal disease occasionally, have patient populations with high recurrence rates. Patients with advanced disease or recurrent disease from a failed procedure should be referred to a surgeon well versed in reconstructive flap procedures for this disease. There are many intricacies and tricks that can be learned only with experience. Furthermore, a surgeon performing a flap procedure should be very familiar with the cause and pathogenesis of pilonidal disease. Poorly performed flap procedures that leave a residual deep cleft or leave a low-lying pit are just as prone to failure as are misguided excisional procedures.

CANCER AND PILONIDAL DISEASE

Squamous cell carcinoma very rarely occurs in the setting of pilonidal disease. Those that arise are probably similar to scar carcinomas that result from chronic inflammation. The observation of a quickly expanding ulcer with heaped up edges or a fungating mass should prompt a biopsy of the edge of the lesion. If a cancer diagnosis is confirmed, treatment typically involves a wide local excision down to and including the sacrococcygeal fascia. A large flap is usually required to close the defect. Adjuvant chemotherapy or radiation therapy should be guided by the pathologic features and the general recommendations for squamous cell carcinoma.

SUMMARY

Pilonidal disease is a conceptually simple and common disease that affects young adults. It is thought to be an acquired disease, and the theory of congenital origin has fallen out of favor. The causes of pilonidal disease are a deep natal cleft and repetitive mechanical motion that lead to the trapping of hair or debris under the skin surface to form an abscess. Afflicted individuals may present with an acute abscess necessitating drainage or with the more chronic phase of the disease, a pilonidal sinus. Simple surgical procedures such as pit excision with lateral drainage or unroofing are reasonable first procedures to be performed. Major excisions in the midline should be avoided because they often do not heal, which makes the condition worse and more difficult to treat. More contemporary flap procedures that render the natal cleft shallow with off-midline closure are best used to treat advanced disease and have low recurrence rates. The cleft lift procedure is very effective, can be performed in an outpatient setting, has low morbidity and low recurrence rates, and may be considered the preferred flap procedure in treating pilonidal disease.

Lower Gastrointestinal Bleeding

Skandan Shanmugan, MD, and Sharon L. Stein, MD

DEFINITION

Lower gastrointestinal bleeding (LGIB) is bleeding that arises distal to the ligament of Treitz. LGIB accounts for approximately 20% of all major gastrointestinal bleeds. It is predominantly a disease of the elderly, with a mean age at presentation of 63 to 77 years. The incidence of hospital admission from LGIB is approximately 21 to 40 cases per 100,000 adults. Most patients have a self-limited course; in 80% to 90% of cases, bleeding stops spontaneously. However, as many as 25% of patients have rebleeding during or after hospital admission. The mortality rate from LGIB ranges from 2% to 4%. The successful management of LGIB depends on the accurate identification of the source of bleeding and definitive management, which may be medical, endoscopic, angiographic, or surgical.

The approach to LGIB can be challenging and requires a systematic algorithm for evaluation with concurrent stabilization of the patient and planning for definitive therapy (Figure 1). The management of LGIB necessitates a multidisciplinary approach with experienced endoscopists, radiologists, and surgeons. Although portions of the algorithm may be performed by nonsurgeons, the surgeon should follow the patient with significant LGIB and guide the diagnostic and therapeutic process. LGIB can range in severity from trivial to massive and from acute to chronic. Significant LGIB can be a serious and potentially life-threatening situation.

ETIOLOGY

The sources of LGIB are varied. Among the more common causes for bright blood per rectum or hematochezia (bloody stools) is upper gastrointestinal bleeding (UGIB), which occurs in approximately 10% to 15% of patients with LGIB. An additional 5% to 10% of bleeding may arise from small bowel sources such as Meckel's diverticulum, small bowel tumors, or angiodysplasia. Colonic sources of bleeding include diverticular bleeds, bleeding from neoplasia or polyps, and various types of colitis (Table 1). Approximately 10% to 20% of LGIB do not have a clear etiology and remain obscure despite thorough evaluation.

Diverticulosis

The prevalence of diverticulosis, or colonic outpouching, increases with age; in Western society, approximately two thirds of the population have diverticulosis by age 85 years. Twenty percent of patients with diverticulosis present with abrupt, painless bleeding or hematochezia during their lifetime, and 5% have severe hemorrhage. Although most diverticula are located in the sigmoid and descending colon, diverticular bleeding is fairly equally distributed between the right and left sides of the colon. Risk factors for bleeding diverticulosis include advanced age, the use of nonsteroidal antiinflammatory drugs (NSAIDs) or anticoagulation therapy, diabetes mellitus, and ischemic heart disease. The pathogenesis is believed to be the rupture to the submucosal branch of the penetrating arteries or vasa recta into the colonic lumen as a result of stretching of the weakened diverticular wall. Observation alone is generally recommended after the first episode of diverticular hemorrhage. However, after a second episode, the risk of subsequent episodes is approximately 50%; thus, elective resection has been recommended after a second episode of diverticular bleeding. Surgical intervention consists of resection of the affected segment of colon.

Neoplasia

Occult bleeding, bright red blood per rectum, and hematochezia are all potential signs of benign adenomatous polyps and adenocarcinoma of the colon and rectum. Polyps account for 7% to 33% of cases of massive LGIB. Initial therapy is limited to biopsy of suspicious masses, local abatement of bleeding if possible, and the evaluation for a synchronous lesion via endoscopy before surgical resection. In cases of malignant disease, appropriate oncologic resection is warranted. If the patient's condition is hemodynamically stable, an appropriate staging workup should be done prior to resection.

Colitis

Colitis includes inflammatory bowel disease (IBD), ischemic colitis, and infectious colitis. Ulcerative colitis (UC) and occasionally Crohn's disease (CD) may manifest as bloody diarrhea, but less than 6% of patients have progression to massive LGIB that mandates an emergent operation. The recommended procedure is a total abdominal colectomy, with or without an end ileostomy; the rectum is generally not resected at this time because of the increased operative time and morbidity associated with the proctectomy. In addition, bleeding from the affected rectum dissipates greatly after diversion of fecal stream. Rectal preservation also allows for a formal proctectomy and ileal pouch–anal anastomosis (IPAA) for patients with UC or an ileoproctostomy for patients with rectal-sparing CD.

Ischemic colitis accounts for 3% to 12% of patients with LGIB, and these patients often present with an acute onset of cramping abdominal pain out of proportion to the physical examination results. Often ischemia follows surgical interventions such as abdominal aneurysm repair or cardiac procedures. Diagnosis can be confirmed via colonoscopy with visualization of edema, erythema, submucosal hemorrhage, necrosis, or ulceration at the watershed areas of the splenic flexure and sigmoid colon. Patients with signs of advanced ischemia should immediately proceed to surgical resection. In questionable cases, a gentle biopsy of the mucosa can be performed; if bleeding occurs, ischemia is generally still reversible. If no bleeding occurs, mucosa is nonviable and surgical resection is recommended. Nonoperative treatment is supportive with fluid resuscitation, antibiotics for bacterial translocation, and close observation. Surgical intervention is also warranted if the patient has signs of peritonitis or perforation develops or becomes hemodynamically unstable.

Infectious colitis may rarely cause hematochezia from pathogens such as *Escherichia coli, Salmonella, Shigella, Campylobacter jejuni, Entamoeba histolytica, Histoplasma,* and *Cytomegalovirus.* In infectious colitis, LGIB may be preceded by nonbloody diarrhea. Treatment is generally supportive with appropriate antimicrobial agents, bowel rest, and serial examinations.

Arteriovenous Malformation

Colonic arteriovenous malformation (AVM) includes vascular ectasia, angioma, and angiodysplasia and results from obstruction of

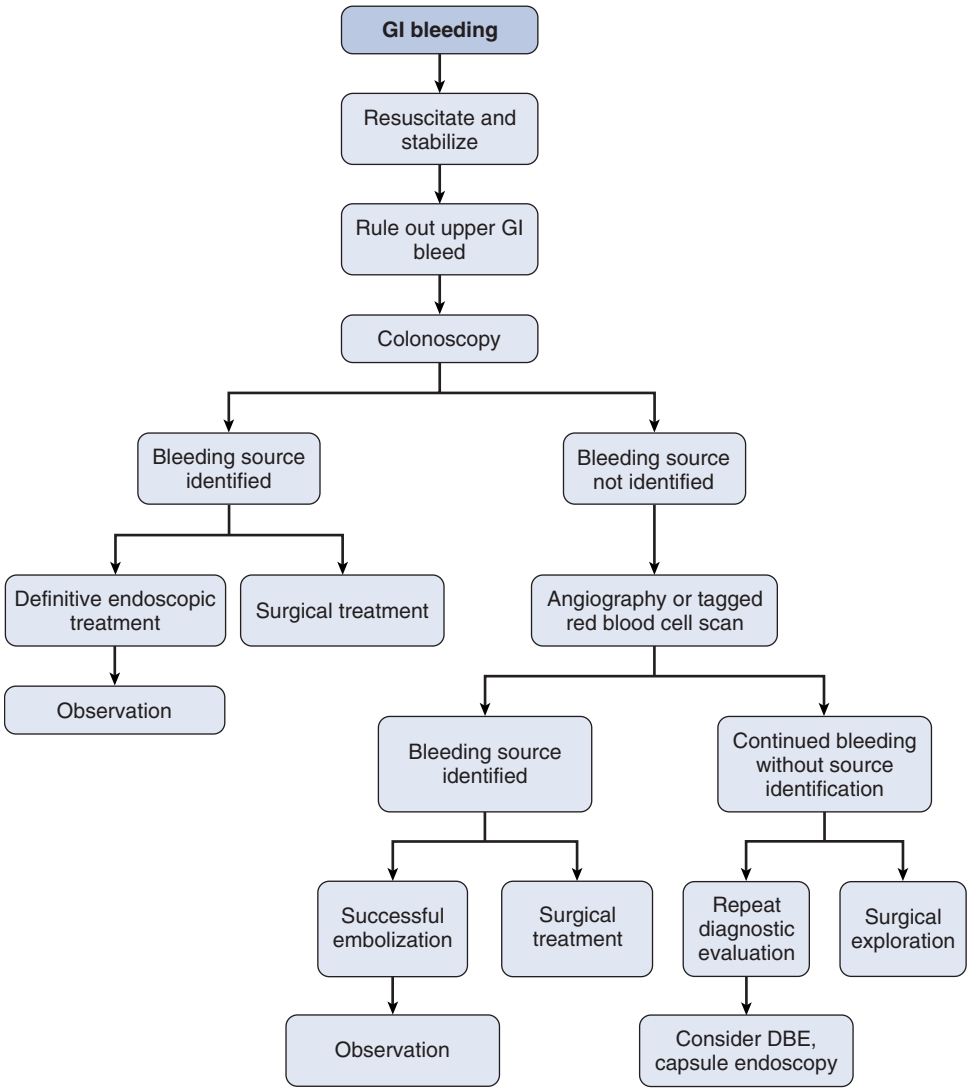

FIGURE 1 Approach to acute lower gastrointestinal *(GI)* bleeding. *DBE,* Double-balloon enteroscopy.

TABLE 1: Bleeding diagnoses in patients discharged with acute lower gastrointestinal bleeding in the National Inpatient Sample, 2002

Sources of acute lower gastrointestinal bleeding	
Diverticular	33.1%
Cancer/polyp	21.3%
Anorectal	21.0%
Colitis/ulcer	10.9%
Intestinal ischemia	6.6%
Angiodysplasia	6.0%

Adapted from Strate LL, Ayanian JZ, Kotler G, et al: Risk factors for mortality in lower intestinal bleeding, Clin Gastronenterol Hepatol *6(9):1004–1955, 2008.*

the submucosal veins commonly found at the cecum. LGIB caused by AVMs can be slow, chronic, and intermittent. Bleeding from AVMs resolves spontaneously in 90% of the cases, although recurrence occurs in up to 70% of patients. Definitive surgical or colonoscopic treatment is required for identified sources.

Anorectal Disease

Hemorrhoids, fissures, anorectal fistula, and solitary rectal ulcers must not be overlooked as causes of a minor or major LGIB. A thorough anoscopy with good lighting can quickly eliminate anal sources of bleeding. Often treatment is supportive with appropriate bowel regimen, but occasionally surgical interventions are necessary, especially in patients with comorbidities and coagulopathies. Elimination of the possibility of a more proximal cause of hemorrhage is also important with a colonoscopic evaluation in patients who present with significant LGIB.

Small Bowel Bleeding

Small intestinal hemorrhage accounts for 5% to 10% of LGIB and should be considered as a potential source when the upper

gastrointestinal tract, colon, and anorectum have been completely evaluated and excluded as a source for LGIB. The most common causes of small intestinal hemorrhage include angiodysplasia, jejunoileal diverticula, Meckel's diverticulum, neoplasia, enteritis, and aortoenteric fistulas.

Iatrogenic Cause of Bleeding

Other rare but sometimes life-threatening causes of LGIB include aortoenteric fistulas, postoperative hemorrhage, and post polypectomy bleeding. Aortoenteric fistula formation with severe hemorrhage has been reported from several weeks to years after aortic graft surgery. Fistulization to small bowel or duodenum at the junction of the aorta is the most frequent anatomic location and usually presents with a "herald bleed." These patients need immediate resuscitation and emergent operative management with resection and extraanatomic bypass.

Staple-line hemorrhage after colonic anastomoses is rare and usually self limited but occasionally may be severe enough to require endoscopic evaluation. Although endoscopy often reveals a spontaneously resolved bleeding site, treatment with epinephrine injection, coagulation, or clipping may obviate the need for operative revision in cases with ongoing bleeding. LGIB is a more common complication after colonoscopic polypectomy, with a reported incidence rate of 0.2% to 6%. Postpolypectomy hemorrhage is usually immediate but can occur up to 1 month after colonoscopy, especially in patients on anticoagulation therapy or antiplatelet agents. Postpolypectomy hemorrhage is generally managed with a repeat colonoscopy and endoscopic therapies such as snaring, thermal coagulation, epinephrine injection, or the application of a hemoclip.

DIAGNOSTIC ASSESSMENT AND THERAPY

Initial Evaluation and Resuscitation

Lower gastrointestinal bleeding may be acute or chronic in nature and can vary from minor, major, or massive in quantity and acuity. Patients with chronic LGIB may present with anemia, fecal occult positive stools, or intermittent hematochezia. If LGIB is acute, these patients may have hemodynamic instability or altered mental status. Patients with minor LGIB have hemodynamically stable conditions and can be evaluated and treated as an outpatient. These patients often present with anorectal disorders such as hemorrhoid disease and anal fissures, but more serious etiologies such as IBD, AVMs, and colon cancer should be considered as potential sources. Patients with major LGIB present with significant bleeding. By definition, a patient who needs 2 or more units of blood has a major LGIB. Patients with massive LGIB have an ongoing transfusion requirement, continued hemodynamic instability that necessitates intensive care monitoring, and possibly need vasoactive support.

Initial evaluation of the patient with an unstable condition must be accompanied by simultaneous resuscitation. The basics of cardiopulmonary resuscitation must be followed, including placement of two large-bore intravenous catheters and resuscitation to correct volume deficits. An immediate type and crossmatch should be sent to the blood bank along with pertinent laboratory tests, such as complete blood count, serum electrolyte values, creatinine values, CO_2 levels, prothrombin time, partial thromboplastin time, platelet count, and bleeding time. A thorough patient history and physical examination should include identification of any medications including typical anticoagulants (warfarin, antiplatelet agents, NSAIDs) and dietary supplements such as fish oil, ginseng, and gingko, which also affect the clotting cascade.

Description of the quality and color of blood may help identify upper or lower sources. Bright red blood per rectum is most typically from a lower gastrointestinal (GI) source; however, blood changes color as it is oxidized during its passage through the GI tract, and a brisk upper GI bleed may present as bright red blood per rectum. As many as 10% to 20% of patients initially believed to have a LGIB turn out to have an upper gastrointestinal source for the bleeding. For the patient with a hemodynamically unstable condition, a nasogastric tube and lavage should be included in the initial diagnostic evaluation. If clear bile is returned, indicating evaluation of the stomach and proximal duodenum, an upper GI source is significantly less likely. In addition, sources of anal bleeding should be promptly identified. A thorough anoscopy with adequate lighting can help identify bleeding hemorrhoids, fissures, and proctitis as part of the initial evaluation of LGIB.

The primary diagnostic tool for the evaluation of LGIB is colonoscopy. When colonoscopy fails to find the source of bleeding, mesenteric angiography can be used in a patient with significant bleeding, and radionuclide scanning if the patient's condition is stable. In cases where the bleeding source cannot be identified with these modalities, capsule endoscopy, small bowel enteroscopy, and computed tomographic (CT) angiography scans may have a role in establishing the etiology of the bleeding (see Figure 1). The specific diagnostic method selected depends on the presence of active bleeding, the severity of the bleed, the stability of the patient's condition, and the availability of these diagnostic modalities. Approximately 85% of all lower gastrointestinal bleeds resolve spontaneously.

Colonoscopy

Colonoscopy is an extremely valuable tool in the evaluation and management of LGIB and should be the first choice for most patients with LGIB. Colonoscopy has the advantage of being both diagnostic and therapeutic. Although patients typically undergo a bowel preparation before colonoscopy, blood acts as a strong cathartic. In the presence of major or massive LGIB, bowel preparation is often unnecessary and colonoscopy can be performed on an urgent basis. With a simple rectal washout, the source of left-sided bleed may be visualized. In addition, if the endoscopist is able to visualize the unprepped right colon with no signs of old or new blood, the left side of the bowel is strongly indicated to be the source of bleeding. If the endoscopist can pass into the terminal ileum and no blood is found, the discovery helps to eliminate the small bowel as the source of bleeding. For the patient with a hemodynamically stable condition, a bowel prep provides improved visualization of mucosal abnormalities such as vascular ectasia.

Definitive identification of the bleeding site requires visualization of active bleeding or fixed clot and is identified in 55% to 97% of cases. Visualization of blood or loose clot in the luminal surface without active bleeding can help localize the bleeding to one segment of the colon, but remember that blood may pass antegrade or retrograde in the intestines.

The endoscopist should be well prepared for the bleeding colonoscopy. Multiple flushes or power washer, endoclips, and various methods of cauterization should be available before the endoscopist starts the procedure. Treatment then depends on the etiology of bleeding. Benign etiology, such as diverticular bleeding or vascular ectasia, is treated locally when the bleeding source is identified. In these cases, injection of epinephrine, placement of a hemoclip, or thermal coagulation may be appropriate. Diseases such as ischemic colitis or UC may be amenable to medical therapy after identification. Bleeding polyps may be removed if they fail to show malignant characteristics; a malignancy can be treated with cauterization or endoclips to stop the bleeding but should be referred for more definitive surgical intervention. Internal hemorrhoids and rectal varices may also be treated with band ligation, and radiation proctitis can be treated with formalin fixation. Even if the endoscopist fails to treat

the bleeding, a colonoscopy often provides information about the location of bleeding, which allows the surgeon to perform a limited resection if other treatment modalities are unsuccessful or inappropriate.

Disadvantages to colonoscopy include its relative contraindication in an unstable condition, the risk of perforation (especially in the setting of colonic inflammation, colitis, or therapeutic maneuvers), and the risks of sedation or anesthesia. In the case of massive LGIB, it may be impossible to identify or treat the source of bleeding endoscopically. In these cases, the next step is typically mesenteric angiography.

Selective Mesenteric Angiography

Selective or superselective mesenteric angiography has become widely used in the evaluation of LGIB because of its diagnostic and therapeutic benefits. The technique is performed via transfemoral placement of an arterial catheter. The superior mesenteric artery (SMA) is generally visualized first, followed by the inferior mesenteric artery (IMA) and the celiac axis. Radiologists often request a CT angiogram before angiography to limit the scope of invasive angiography and isolate the bleeding source.

Bleeding can be detected at rates as low as 0.5 to 1.0 mL per minute with angiography, with a sensitivity ranging from 40% to 95%. Although extravasation is unequivocal evidence of a bleeding source, angiography can also show more subtle findings such as tumor blush or angiodysplasia. When bleeding is identified, transcatheter therapy can be instituted to stop the bleeding, by means of either intraarterial vasopressin or transcatheter arterial embolization (TAE). Because vasopressin has a rebleeding rate that approaches 5%, most centers have adopted superselective TAE using microcoils or other agents. With superselective techniques, the rate of bowel ischemia and rebleeding after embolization is significantly low. Remember that even patients who have had bleeding controlled angiographically should have a colonoscopy because 5% to 30% have neoplastic lesions found.

At times, the angiographer may identify the source of bleeding but be unable to perform definitive therapy. Reasons include risk of ischemia to the bowel, inability to cannulate the vessel, and failure of embolic techniques. In these cases, the patient may require surgical intervention for treatment. The surgeon may request that the angiography catheter be left in place to allow the surgeon to identify the exact segment of bowel during surgery, which is particularly useful when a small bowel source may otherwise be difficult to identify.

Some investigators have used "provocative" measures such as the infusion of vasodilators, heparin, or thrombolytic agents to increase the accuracy and sensitivity of selective angiography, with acceptance of the risk of potential bleeding complications. This method is primarily used in patients with intermittent recurrent bleeding, for which other modalities have failed to show the source of bleeding. It has a sensitivity range of 29% to 40%, and typically, cases with positive test results go on to have embolization or surgery.

Technetium-Labelled Red Blood Scanning

Technetium-labelled red blood cell scanning (TcRBC) is a minimally invasive, high-sensitivity method to identify sources of bleeding. Blood is taken from the patient and labelled with technetium 99 m. The blood is then reinfused, and images are taken to evaluate the source of bleeding. Bleeding rates as low as 0.1 mL per minute can be detected. Images taken within the first 2 hours are most accurate for surgical intervention, but images can be taken over a 48-hour period and may be useful in intermittent or recurrent bleeding. Morbidity with TcRBC is minimal because this is a noninvasive study.

TcRBC has several significant disadvantages. TcRBC should not be used in a patient with a hemodynamically unstable condition because the process takes several hours to complete. In addition, TcRBC is unable to identify the source of bleeding in 25% to 60% of scans. Sources are identified by geographic location in the abdomen. Bleeding in the upper abdomen may be obscured by the uptake from the spleen and liver; identification of site in the small bowel is difficult as proximity to the ligament of Treitz or ileocecal valve is not provided. Surgical intervention based solely on TcRBC is frustrating; a false localization rate of approximately 25% has been reported. TcRBC has been suggested as a screening test to establish bleeding before angiography for confirmation. However, in practice, this is difficult to endorse; the time to obtain the TcRBC may significantly delay treatment, and a CT angiogram is now used preferentially to localize the site of bleeding. In the critically ill patient, radionuclide scanning should be bypassed in favor of selective mesenteric angiography.

Other Options

Newer modalities, including CT angiography and magnetic resonance imaging (MRI) angiography, have been studied more recently. They are promising, seem to provide good sensitivity and specificity, and may add additional anatomic information but are diagnostic and not therapeutic. Information gleaned from these examinations may help narrow the focus of angiography and speed treatment when used before superselective mesenteric angiography.

When no source of colonic bleeding has been identified, and blood is found proximal to the ileal cecal valve on endoscopy, the small bowel must be evaluated. Double-balloon enteroscopy (DBE) or "push-pull endoscopy" can be used to elucidate small bowel sources. With an over tube used to stabilize placement in the small bowel, the entire small bowel from ligament to Treitz to ileocecal valve can be visualized. DBE has a diagnostic yield of approximately 80%. DBE is not widely available, requires an experienced endoscopist with special equipment, and may take several hours to complete, but it allows for real-time analysis of the small bowel and therapeutic endoscopic treatment of sources. When DBE is not available, capsule endoscopy (CE) offers evaluation of the small bowel. Contraindications to a capsule study include small bowel obstruction, and a small bowel follow through is generally performed before ingestion to rule out an obstructing lesion. CE has a diagnostic yield of approximately 70% without any therapeutic benefits.

Surgery

Most patients with LGIB never need surgery; only approximately 10% to 25% of patients need operative intervention, either emergent or nonemergent. The surgical strategy depends on the intensity, cause, and localization of the bleeding. The indications for surgery include continued or recurrent hemorrhage despite nonoperative attempts at localization, ongoing hemodynamic instability, transfusion requirement of greater than 6 to 10 units, or pathologic finding requiring surgical intervention. There are no absolute predictors of who will need an operation, but 50% of patients who need 4 or more units of blood in the first 24 hours eventually need surgery. Morbidity and mortality increase significantly in patients who have received 10 or more units of blood.

Every effort should be made to localize the bleeding source before surgery. If the patient's condition remains stable, diagnostic tests should continue until the source of bleeding is identified. When the bleeding site has been localized to the colon, segmental resections may be performed based on appropriate treatment for the underlying pathology. In the case of diverticular disease, the affected segment should be removed; in the case of cancer, an appropriate oncologic resection should be performed. Smaller wedge resections may be performed for a single bleeding AVM or ectasia. In the case of segmental resection for preoperatively identified source of bleeding, the

mortality rate is less than 10% in reported series. The rate of recurrent bleeding ranges from 0 to 15% after segmental colectomy for localized bleeding.

In cases where the bleeding cannot be localized before surgery, a thorough abdominal exploration may identify the source of bleeding. Running the small bowel during surgery may identify a small bowel lipoma or Meckel's diverticula. On-table colonoscopy and enteroscopy occasionally identify an intraluminal source of bleeding. To facilitate this, patients should be placed in the lithotomy position in the operating room. With the surgeon's assistance, an upper or lower endoscope may be advanced through the small bowel to evaluate for sources of bleeding. The surgeon gently manipulates the small bowel over the scope to advance the scope. If necessary, an enterotomy may be created for "on-field" insertion of the endoscope to complete evaluation of the small bowel. When found, the affected segment of small bowel can be resected, such as in the case of a Meckel's diverticula or small bowel AVM.

If localization techniques are not successful, but the bleeding appears to be originating from the colon, an emergency total abdominal colectomy (TAC) may be performed. TAC in this situation has a mortality rate of 10% to 30% but a rebleeding rate of less than 1%. If a more limited resection, such as segmental colectomy, is performed in this setting, the risk of rebleeding is approximately 35% to 75%, with a mortality rate of 20% to 50%.

Some surgeons advocate subtotal colectomy even if the bleeding source is identified because of the morbidity and mortality associated with reexploration from a repeat LGIB. Studies have shown comparable mortality rates for subtotal colectomy and segmental resection, and a frank discussion is warranted with the patient and family in regards to the risk and benefits of each approach and the postoperative effects on the quality of life. One of the often reported drawbacks to the TAC includes postoperative diarrhea and fluid losses. Preserving the distal terminal ileum may minimize this complication if a subtotal colectomy is necessary.

The choice of whether to perform a primary anastomosis should be based on three criteria: (1) definitive diagnosis of source of bleeding; (2) patient stability; and (3) patient comorbidities. In a patient with an unstable condition with a localized bleeding colonic segment, some have suggested a damage control approach; a temporizing surgical resection of the affected area is undertaken without an initial anastomosis or fecal diversion, accepting the necessity of a second-look operation. If the surgeon is not confident in the identification of the source of bleeding, an end ileostomy or colostomy is also suggested. Use of the end stoma helps elucidate the location of bleeding in the case of recurrence. In addition, use of temporary or permanent stoma should be based on the surgeon's clinical judgement of patient stability and ability to heal the anastomosis.

SUMMARY

The approach to massive LGIB involves a thorough history and physical examination with concomitant resuscitation. A multidisciplinary effort including endoscopists, radiologists, and surgeons working together can most effectively diagnose and treat sources of LGIB. Although most bleeding resolves spontaneously or with nonoperative techniques, localization of bleeding helps limit morbidity and mortality for those who need surgery. Appropriate surgical intervention depends on underlying pathology and the overall clinical picture.

Cystic Disease of the Liver

Cristina R. Ferrone, MD

OVERVIEW AND CLINICAL PRESENTATION

As a result of increased imaging, up to 5% of the population is diagnosed with one or more hepatic cysts. These cysts can be classified as benign or malignant, genetic or acquired, and infectious or parasitic. Most cysts are seen in women and are asymptomatic. When the cysts are symptomatic, patients often present with vague abdominal pain, fullness, or abnormalities in liver function tests. Depending on the location, large cysts may present with symptoms of early satiety, gastric outlet obstruction, intestinal obstruction, or liver function test abnormalities with or without jaundice from extrinsic compression of the bile ducts. If a patient has sudden intracystic hemorrhage develop, the patient may present with acute onset abdominal pain from sudden cyst enlargement and stretch of the Glisson's capsule. Rarely do cysts rupture or become torsive or infected. Luckily, most hepatic cysts are benign and asymptomatic and therefore do not require any intervention.

DIAGNOSTIC EVALUATION

The main reason to workup and treat hepatic cysts is to rule out malignancy or to treat symptoms. Routine laboratory tests are normal unless a very large cyst compresses the biliary system or synthetic compromise occurs from polycystic disease. If a parasitic etiology is suspected, *Echinococcus* serology should be performed. Patients with pyogenic abscesses often present with fevers, elevated white blood cell counts, and potentially positive blood cultures as a result of bacteremia.

Aspiration of cyst fluid is rarely helpful. Simple cysts contain a cellular thin straw-colored fluid, whereas the fluid is dark with intracystic hemorrhage. Bile-tinged fluid indicates a communication with the biliary tree, which needs to be addressed if an intervention is planned. Unfortunately, no markers have been identified to reliably diagnose a cyst with malignant potential or malignant disease.

Modern imaging modalities allow for assessment of the size, the location within the liver, and the relationship of the cyst to biliary and vascular pedicles. Imaging features that raise the suspicion of neoplasia include thickening or nodules of the cyst wall, multilocular lesions, septa, and papillary projections. Parasitic or hydatid cysts include "daughter" cysts or mural calcifications, and pyogenic cysts often present with edema and mural enhancement. Debris within the cyst requires a more extensive evaluation. Most frequently, it represents hemorrhage into the cyst, but it could be indicative of malignant disease or a parasitic infection.

IMAGING MODALITIES

The most inexpensive modality for evaluation of hepatic cysts is ultrasound scan (US). In the hands of an experienced operator, the sensitivity and specificity of US is greater than 90%. Simple cysts appear as homogeneous anechoic lesions with smooth borders. Nodules, septations, and echogenic areas should not be visualized. If a patient experiences hemorrhage into a simple cyst, blood can appear as echogenic material within a cyst, but unlike a neoplastic lesion, it should move with the patient.

Both computed tomographic (CT) scan and magnetic resonance imaging (MRI) are extremely useful in delineating the size and location of hepatic cysts. These modalities are not as operator dependent and can be compared with imaging done at different institutions and at different time points. CT scans should be performed with intravenous contrast so that the arterial/portal vein and delayed venous phase images can be used to fully assess the relationship of the cyst to the vasculature. Low-density fluid (<10 Hounsfield units) is seen in simple cysts (Figure 1). High-density fluid, nodules, septations, and an irregular thickened wall should raise the suspicion for malignancy. If cysts are very small, a CT scan may not be able to differentiate between a cyst and a mass.

Simple cysts may appear as hypointense lesions (T1-weighted image) or hyperintense lesions (T2-weighted image) on MRI (Figure 2). Hemorrhage into a cyst or the mucinous contents of a cyst adenoma increase the signal on T1-weighted images. If communication with the bile duct is suspected, a magnetic resonance cholangiopancreatography (MRCP) should be performed.

SIMPLE CYSTS

The most common type of hepatic cyst is a simple cyst. These congenital cysts are identified in up to 5% of the population. Most patients have a single cyst, but patients may also have multiple cysts (Figure 3). These cysts are lined with simple epithelium (single layer of cuboidal or columnar) that secretes fluid similar in composition and color to serum. They are thought to arise from aberrant intrahepatic bile ducts.

Simple cysts have no malignant potential; therefore, resection should only be considered for cysts in which there is diagnostic uncertainty or that are symptomatic. They usually do not communicate with the bile duct. Symptoms usually arise when the cyst is large (>5 to 8 cm) or pedunculated or when intracystic hemorrhage

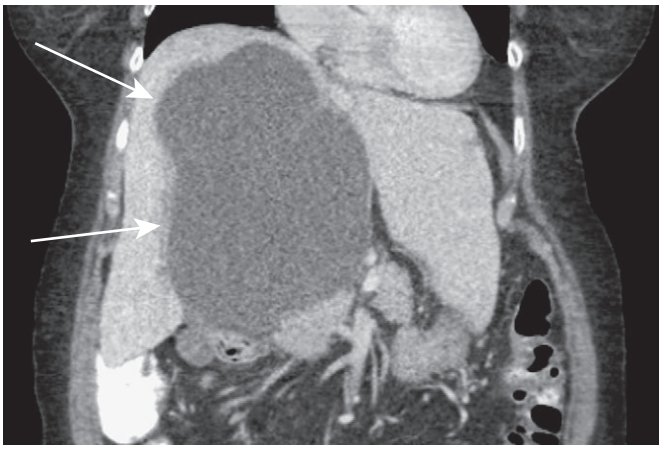

FIGURE 1 A single 16-cm simple hepatic cyst in a 73-year-old woman is shown on computed tomographic scan, with *arrows* indicating cyst.

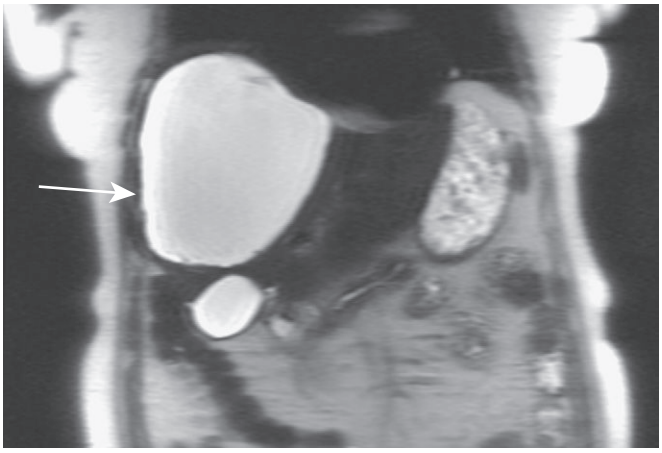

FIGURE 2 A 16-cm simple hepatic cyst is seen in a 63-year-old woman. The cyst is hyperintense on T2-weighted magnetic resonance images, with the *arrow* indicating the cyst.

has occurred. Patients can present with abdominal fullness, pain, early satiety, or laboratory abnormalities. Percutaneous aspiration can be helpful in deciphering whether the abdominal pain is the result of the cyst. It is not a method for treatment of the cyst because recurrence occurs in 100% of patients and because there is a risk of infecting the cyst. Aspiration also allows for biochemical and cytologic analysis of the fluid. If mucin is seen in the fluid or cytology identifies atypical cells, a cystadenoma or cystadenocarcinoma is more likely. If bile is identified in the cyst fluid, the cystobiliary communication should be worked up with an MRCP or endoscopic retrograde cholangiopancreatography (ERCP).

Treatment of the hepatic cyst is warranted in patients with symptomatic cysts or with diagnostic uncertainty. Surgical deroofing (marsupialization, fenestration) is a very effective treatment and should be considered first-line treatment for medically fit patients in whom the cyst is not deep in the parenchyma. Either via laparoscopy or open technique, a large portion of the cyst wall is removed. Ideally as much cyst wall as possible should be removed without a liver resection. This allows for the fluid secreted by the epithelium to be reabsorbed by the peritoneum and for the cyst cavity to collapse over time. Surgical deroofing allows for pathologic evaluation of the cyst wall but also allows for visual inspection of the intrahepatic cyst wall, which is left in place. If any nodules are identified in the intrahepatic portion, they should be biopsied. If a bile leak is identified, it should

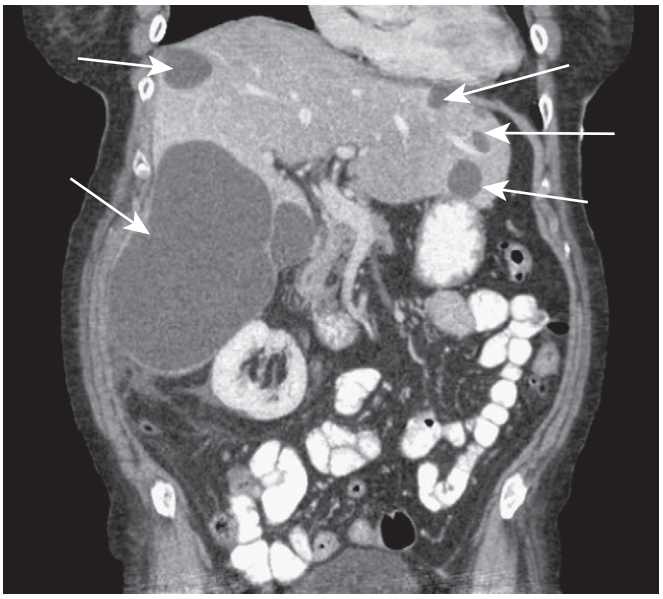

FIGURE 3 Multiple simple hepatic cysts in a 71-year-old woman are shown on computed tomographic scan, with *arrows* indicating cysts.

be oversewn. With a laparoscopic approach, the morbidity of the procedure is minimal. Usually 2 5-mm ports and a single 12-mm port are placed. A 5-mm laparoscope is used for visualization, and the other two ports are used as working ports to first aspirate the cyst contents (which are sent to cytology) and then resect the cyst wall. The cyst wall is then placed in a laparoscopic bag and taken out through the 12-mm port. Omentum can be sewn to the cyst cavity to prevent it from closing over and recurring. In very large cysts in which the amount of fluid secreted by the cyst wall is of concern, an electrocautery or argon beam can be used to fulgurate the cyst wall epithelium. A formal hepatic resection or enucleation can also be performed, but this increases the operative time, complexity, and morbidity of the procedure with an unclear benefit.

A potentially effective nonsurgical technique is aspiration and injection of a sclerosing agent. This can be performed percutaneously with radiologic guidance or laparoscopically with direct vision. The entire cyst contents need to be aspirated and sent for cytology to rule out malignancy and test for bile. If malignancy is not suspected and there is no communication with the biliary tree, a sclerosing agent, such as hypertonic saline, tetracycline, 95% ethanol, or other, can be injected into the cyst. The volume of sclerosing agent depends on the size of the cyst. Approximately 25% of the total cyst volume, but not more than 100 mL, is injected into the cyst. The sclerosing agent is left in the cyst for 10 minutes, with the patient changing position every few minutes to allow for contact of the agent with the entire cyst wall. After 10 minutes, the agent is aspirated. The sclerosing agent damages the epithelial lining, affecting its ability to secrete fluid and electrolytes into the cyst cavity. Symptomatic recurrence of the cysts occurs in approximately 5% to 10% of patients after sclerosis. However, in the patients with recurrence after sclerosis, a surgical intervention is more difficult and is associated with an increased morbidity.

POLYCYSTIC LIVER DISEASE

Differentiation of multiple simple cysts from polycystic liver disease (PCLD) can be difficult. Currently, no widely accepted definition of this rare condition exists; however, a familial pattern or involvement of other organs, such as the kidneys or the brain, is often found.

Isolated autosomal dominant polycystic liver disease (ADPCLD) is very rare, with a prevalence rate of 0.01%. It is associated with a mutation on chromosome 19 that affects hepatocystin. In patients who also have autosomal-dominant polycystic kidney disease (ADPKD), the mutation is in either chromosome 4 or 16 and results in alterations of the genes encoding the polycystin-1 and polycystin-2 proteins. These mutations result in bile duct overgrowth and failure of intralobular ducts to involute or connect with extralobular bile ducts. Cysts form from cell proliferation and fluid secretion into the biliary microhamartomas, which develop as a result of failure of duct development.

Most patients with PCLD are asymptomatic. Because of the great reserve of the liver, the remaining hepatic parenchyma is often sufficient. However, patients can rarely have liver failure develop. Often patients report abdominal fullness and distention, which can be associated with early satiety and shortness of breath. Rarely patients have development of obstruction of the portal vein, which results in portal hypertension and ascites, or obstruction of the inferior vena cava (IVC), resulting in lower extremity (LE) edema or Budd-Chiari syndrome. Cyst infection with gram-negative bacteria is very uncommon but potentially fatal. Patients should be treated with intravenous (IV) antibiotics and drainage of the infected cyst.

Cysts are staged via the Gigot classification, which is based on number, size, location, and remaining hepatic parenchyma via CT imaging (Table 1). Because most patients are asymptomatic, no treatment is recommended. For patients with symptoms, multiple options can be considered. If patients have large cysts, aspiration and sclerosis can be considered, but the recurrence rate is much higher (25% to 50%) than that for simple cysts. Laparoscopic or open fenestration can also be considered for large cysts, but because of the rigidity of the liver, they often do not collapse. In addition, the secretion of fluid and electrolytes can result in ascites. A more aggressive approach includes fenestration and resection. This is associated with higher morbidity but also a better chance at durable symptom relief. The most aggressive approach is liver transplantation. If transplantation is considered, it should occur before severe debilitation from pain, cachexia, and abdominal distention to limit the morbidity and mortality of the operation.

NEOPLASTIC CYSTS

Cystadenomas and Cystadenocarcinomas

Cystadenomas account for less than 5% of all hepatic cysts and are identified more frequently in women in their fourth or fifth decade. Originally, cystadenomas were described by Edmonson in 1958 as: (1) multilocular, (2) lined by columnar epithelium, and (3) accompanied by densely cellular ovarian-like stroma. Devaney and colleagues broadened the definition by including unilocular cysts, a cuboidal epithelial lining, and those without an ovarian stroma.

Lesions with ovarian stroma, or true cystadenomas, occur frequently in segment IV of the liver and can become as large as 40 cm. The ovarian stroma contains estrogen and progesterone receptors. One hypothesis is that during embryonic development, ectopic ovarian cells shed into the liver as the gonads descend from the diaphragm into the pelvis. These cells then release hormones and growth factors, which promote epithelial proliferation and development of the cystadenoma. This is a theory similar to that of mucinous cystic neoplasms of the pancreas, which almost exclusively occur in the distal body and tail of the pancreas.

Cystadenomas without an ovarian stroma can occur in both genders. They tend to more commonly communicate with the biliary tree. In most patients, carbohydrate antigen (CA) 19-9 and carcinoembryonic antigen (CEA) levels in the cyst fluid are increased. The cysts have three distinct layers: epithelial layer, mesenchymal stroma, and an outer layer of collagen connective tissue. These cysts are surrounded by a dense pseudocapsule that allows them to be enucleated. Pathologically, cystadenomas are lined by mucin-secreting columnar or cuboidal epithelium. They have a dense layer of mesenchymal stroma composed of well-vascularized atypical spindle cells lying below the cuboidal cell layer. Early changes of malignant progression include intestinal metaplasia.

Most patients are asymptomatic, but patients are seen with abdominal distention, early satiety, and liver function test abnormalities. Radiologically, the findings are more likely to be complex cysts with mural nodularity, internal septation, or papillary projections. US and MRI are the best imaging modalities for these lesions because CT scan often does not show the septations (Figure 4). Aspiration of the cyst may aid in cyst characterization if mucin or elevated CEA/CA 19-9 is identified. However, CA 19-9 is also expressed by normal biliary epithelium and the epithelium of simple cysts, making it an unreliable marker. Cystadenomas are premalignant lesions; however, differentiation of cystadenoma from cystadenocarcinoma is difficult unless invasion of adjacent structures is identified.

In patients with benign cystadenomas, enucleation or resection should be considered. Fenestration and sclerosis are not good options because of the malignant potential of these lesions and the high recurrence rates. If malignancy is identified, a formal resection should be considered.

Cystadenocarcinomas are primary cystic cancers that do not communicate with the biliary tree and account for 0.4% of all hepatic malignancies. Cystadenocarcinomas with ovarian stroma occur exclusively in women, and those without ovarian stroma occur twice

TABLE 1: Gigot classification of polycystic liver disease

Category	Description
Type 1	Limited number (<10) of large cysts (>10 cm) with large areas of normal
Type 2	Diffuse involvement of the parenchyma by medium-sized cysts with large areas of uninvolved liver tissue
Type 3	Massive and diffuse involvement of the liver by small and medium-sized cysts with very little spared parenchyma

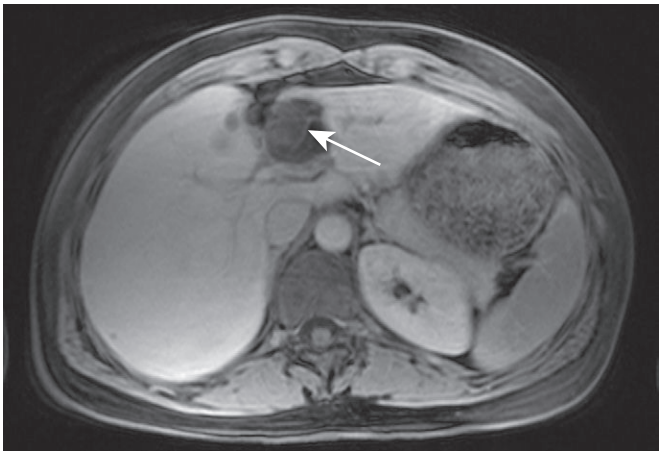

FIGURE 4 Hepatic cystadenoma lined by ovarian stroma in segment IV of the liver is seen in a 38-year-old woman. The *arrow* marks septation on the T1-weighted magnetic resonance image.

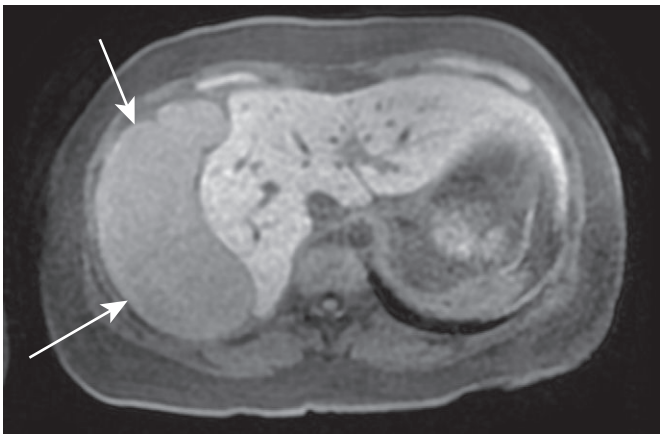

FIGURE 5 A 13-cm posttraumatic subcapsular hepatic cyst is seen in a 45-year-old man. The cyst is hyperintense on T1-weighted magnetic resonance images as a result of hemorrhage within the cyst (*arrows* indicating the cyst).

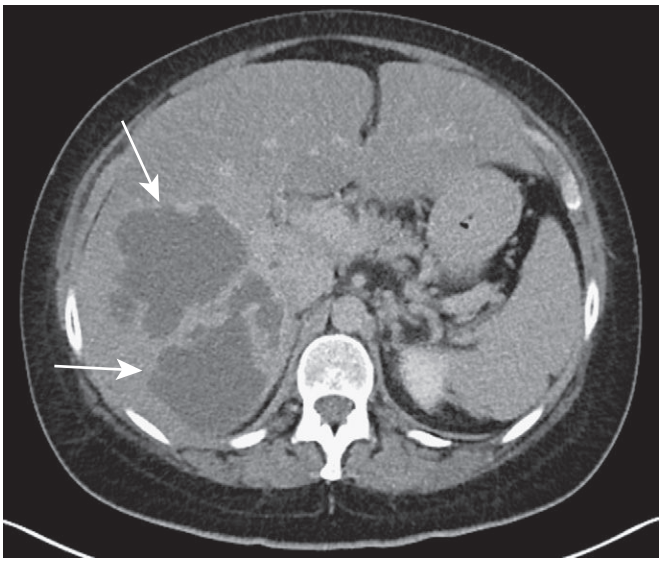

FIGURE 6 A large pyogenic abscess from *Escherichia coli* in a 57-year-old woman with diabetes is seen in delayed images on computed tomographic scan, with *arrows* indicating abscesses.

as often in men than in women. Most cases occur in patients in their 50s and 60s. Most patients present with nonspecific symptoms, such as abdominal pain or distention, and 20% present with biliary obstruction. On imaging, cystadenocarcinomas are more often large and have thicker septa, cystic debris, and bile duct dilation. Early changes of malignant progression include intestinal metaplasia in the epithelium that progresses to malignant tubopapillary epithelium. Patients should undergo a formal surgical resection because the tumor extension cannot reliably be assessed. Rupture of the cyst should be avoided as it may lead to carcinomatosis. Cystadenocarcinomas with ovarian stroma have a more favorable prognosis than those without ovarian stroma, as a result of less frequent parenchymal, vascular, and lymphatic invasion.

Intraductal Papillary Mucinous Neoplasm of the Bile Duct

Intraductal papillary mucinous neoplasm of the bile duct (IPMN-B) is a new pathologic classification for bile duct lesions with innumerable frond-like intraluminal papillary infoldings that produce mucin. Previously, these lesions were classified as biliary papilloma, mucin-producing peripheral cholangiocarcinoma, or intraductal variant of peripheral cholangiocarcinoma. These tumors are clinically, histologically, and phenotypically similar to intraductal papillary mucinous neoplasms (IPMNs) of the pancreas. Macroscopically, communication with the biliary system exists, and the tumors are divided into two types: the duct ectatic type with diffusely dilated bile ducts and the cystic type that presents as a large cystic mass. Invasive carcinoma is identified in 60% or more of the patients. An equal distribution is seen amongst gender, and the incidence peaks in patients in their sixth decade. Most patients present with nonspecific symptoms; however, mucobilia may result in obstruction of the biliary tree. Patients should undergo a formal hepatic resection and intraoperative cholangiogram to rule out biliary obstruction from mucus or tumor. In patients with a malignant component, the 5-year survival rate is between 60% and 80%.

TRAUMATIC CYSTS

Blunt trauma can result in intrahepatic hematomas or bilomas, which can develop into traumatic hepatic cysts (Figure 5). These are not true cysts because they lack an epithelial lining. They are usually managed conservatively. If patients have development of a persistent bile leak or symptoms of pain or compression from progressive cyst enlargement, an intervention may be warranted. If biliary decompression via ERCP and sphincterotomy fails, surgical ligation of the leaking bile duct should be considered. Patients with compressive symptoms can be managed in a manner similar to that of simple cysts with unroofing or excision.

PYOGENIC LIVER ABSCESS

Pyogenic liver abscess is defined as a bacterial infection that results in single or multiple collections of pus within the liver (Figure 6). Hepatic infection can occur via five routes: (1) portal vein, (2) hepatic artery, (3) biliary tree, (4) adjacent organ infection, or (5) direct trauma to the liver. The most common causes of liver abscesses used to be appendicitis and diverticulitis. Currently, biliary malignancies and associated biliary interventions are the most common cause of liver abscesses. Patients usually present with fever, leukocytosis, and general malaise. Diabetes mellitus is associated with a tenfold risk for a liver abscess compared with the general population. CT scan is the most useful imaging modality because of its high sensitivity for detection of a liver abscess and for its ability with detection of other potentially contributing intraabdominal pathology. In Western series, *Escherichia coli* and *Streptococcus milleri* are the most common pathogen; in the East, the most common is *Klebsiella pneumoniae*. Treatment is centered on appropriate antibiotics and adequate drainage of pus. Percutaneous drainage is often sufficient for drainage. Surgical intervention should be considered if percutaneous drainage fails, if there is intraperitoneal rupture of the abscess, if the underlying cause needs to be addressed surgically, or if the abscess is large, multiloculated, and filled with debris.

The Management of Echinococcal Cyst Disease of the Liver

Susan C. Pitt, MD, and Henry A. Pitt, MD

Echinococcal cyst disease of the liver, also termed hepatic cystic echinococcosis or hydatid cyst disease, is a zoonosis caused by the canine tapeworm of the genus *Echinococcus*. The disease is endemic in the Mediterranean, Africa, the Middle East, South America, Asia, and parts of Europe in areas where sheep farming is predominant. Dogs (including wolves, foxes, and coyotes) are the primary host for this intestinal tapeworm, and sheep are the major intermediate host, although deer, elk, caribou, yaks, goats, camels, and other livestock also can carry the larval form. Infection in humans is generally incidental and is encountered most often in the United States either in immigrants or in Americans who have traveled to endemic areas. The combination of immigration and tourism has made hepatic echinococcosis a worldwide disease that may present many years after exposure. Antiparasitic chemotherapy with mebendazole or albendazole alone is not as effective as treatment combined with surgery. Percutaneous aspiration is another treatment option. This chapter reviews the available approaches to management of echinococcal cyst disease of the liver.

PATHOLOGY AND CLASSIFICATION

Hepatic hydatid disease results from fecal-oral transmission of the larval form of the dog tapeworm *Echinococcus granulosus*. Ova are shed in the feces of intermediate hosts (sheep, goats, or other herbivores) and inadvertently ingested in contaminated food and then penetrate the intestinal wall entering into the portal circulation. Once in the circulation, embryos can infect any tissue, such as the liver, where 55% to 80% of cases are reported, or the lungs (10% to 40% of human cases), the brain, or the bones. Another species found more commonly in elk or caribou, *Echinococcus multilocularis,* causes a hepatic infiltrative, potentially lethal form of the disease that is even less common in North America than *E. granulosus.* In the liver, *E. granulosus* has a two-layer cyst wall, an inner active cyst wall that consists of a single cell germinal layer where the echinococcal scolices and daughter cysts develop and an outer thicker acellular layer. This outer, reactive fibrous layer is called the pericyst and is calcified in approximately 50% of patients. Budding of the inner germinal layer within the cyst is termed daughter cysts or hydatid sand. The daughter cysts may float in the cystic fluid; and in approximately one third of patients, cyst expansion may result in rupture into the biliary tree, erosion through the diaphragm into the pleural cavity, or rarely, rupture into the peritoneum. On the other hand, mature cysts may become inactive, asymptomatic, and further calcified and have negative serology results.

Classification of echinococcal cyst disease of the liver has changed over the last 20 years. In the early 1980s, Gharbi published an ultrasound classification of hepatic echinococcal cysts that divides the cysts into five types (I to V) based on morphologic imaging appearance. However, in 2003, the World Health Organization Informal Working Groups on Echinococcosis (WHO-IWGE) put forth a standardized system to characterize the cysts that incorporates both the functional status of the parasite (active, transitional, or inactive) and the ultrasonographic (US) appearance of the cysts. Table 1 summarizes the WHO-IWGE classification system, which has aided the selection of optimal therapy and been applied to other imaging modalities, such as computed tomographic (CT) and magnetic resonance imaging (MRI) scans.

PRESENTATION AND DIAGNOSIS

Patients with echinococcal cyst disease of the liver can have a widely varied presentation that ranges from an extended asymptomatic period to rupture of the cyst into the peritoneal cavity with an acute abdomen and anaphylactic shock. Most patients, however, have uncomplicated disease that may be asymptomatic or present with right upper quadrant pain or fullness from cyst expansion, hepatomegaly, or fever. Obstructive jaundice, cholangitis, and productive cough from rupture into the pleural cavity and the lung are less common presenting symptoms. With the increase in abdominal imaging studies, incidental discovery of a cyst before symptom development is another common presentation. The diagnosis of this disease is centered on clinical findings, imaging, and serology and is confirmed with either demonstration of protoscoleces on direct microscopy or changes in US appearance that are pathognomonic for cystic echinococcosis.

Laboratory Tests

Evaluation may include various laboratory tests to help establish the diagnosis. A routine complete blood count (CBC) with differential may show eosinophilia in approximately 40% of patients, and assessment of liver function tests (LFTs) may reveal normal or mildly elevated transaminases. In addition, mild increases in the alkaline phosphatase or γ-glutamyltransferase (GGT) are seen in up to a third of patients. Classically, the Casoni's skin and Weinberg's complement fixation tests were used for diagnosis, but they have been replaced by a specific enzyme-linked immunosorbent assay (ELISA) that has sensitivity of 64% to100% depending on the antigen preparation. In patients with active cysts, complement fixation and indirect hemagglutination test results are positive 85% to 90% of the time. Immunoelectrophoresis also is diagnostic in approximately 90% of hepatic and 70% of pulmonary cysts, and hydatid antigen blotting can be used with 95% sensitivity and 100% specificity. Direct microscopic examination of protoscoleces from cyst fluid aspiration can help confirm the diagnosis and assess the viability of the cyst.

Imaging

US and CT scans are the most widely used imaging modalities for diagnosis of liver cysts, including echinococcal disease of the liver (Figure 1). These studies show position, size, number of cysts, proximity to vascular structures, and evidence of extrahepatic cysts. The WHO-IWGE's classification system which characterizes the cysts based on US appearance has standardized cyst description and attempted to facilitate the use of US as the primary diagnostic tool (see Table 1). Because of its low cost and its specificity of 90%, US is the preferred first-line imaging study worldwide. The classic findings for hydatid cysts are thick walls, unilocular or multilocular, often with calcifications, and daughter cysts.

When compared with US, CT scan may offer more detailed information about the location and depth of the cyst, which is useful for operative planning. MRI scans also can be used to demonstrate cyst characteristics and their relation to vascular and biliary structures. Magnetic resonance cholangiopancreatography (MRCP) offers further detail of the biliary tree and can delineate cystobiliary fistulae

or associated abscesses in complicated cysts. MRI also can provide additional information about the liquid areas within the cyst matrix with T2-weighted imaging sequences when compared with CT scan. Hydatid cysts also need to be differentiated from simple congenital cysts, amebic abscesses, and cystadenomas (Table 2).

Endoscopic retrograde cholangiopancreatography (ERCP) also may be useful in the workup of hydatid cysts, especially in patients with cholangitis or jaundice, because communication with the biliary tract occurs in up to 25% of cases. ERCP delineates biliary anatomy, shows communication between the cysts and bile ducts, and can be used to drain the biliary tree before surgery (Figure 2). Routine use of ERCP is controversial but is advocated by the authors' group to completely define the bile duct anatomy and visualize any clinically silent connections between the bile ducts and the cysts. When operative treatment for hydatid disease is undertaken, intraoperative US (IOUS) also should be considered to confirm the relationship of bile ducts and vessels to the cyst with greater resolution than with a transabdominal probe.

TABLE 1: World Health Organization Informal Working Groups on Echinococcosis classification of hepatic echinococcal cysts

Cyst type (gharbi)	Status	Ultrasound features	Remarks	Treatment approach
CL (none)	Active	Unilocular, anechoic Usually round Cyst wall *not* visible	Early, not fertile Needs additional diagnostic tests	Needs diagnosis
CE 1 (type I)	Active	Unilocular, anechoic Round or oval Cyst wall *visible* Hydatid sand *(snowflake)*	Usually fertile *Pathognomonic*	<5 cm—ABZ >5 cm—PAIR + ABZ
CE 2 (type III)	Active	Multivesicular, septated Round or oval Cyst wall *visible* *Rosette, honeycomb-like*	Usually fertile *Pathognomonic*	PT or surgery + ABZ
CE 3 (type II)	Transitional	Detached floating membrane Less round, complex mass *Water lily sign*	Starting to degenerate *Pathognomonic*	PT, PAIR, or surgery + ABZ
CE 4 (type IV)	Inactive	Heterogenous, hypoechoic degenerating membrane No daughter cyst *Ball of wool*	Most not fertile Needs additional diagnostic tests	Surgery + ABZ, or watch and wait
CE 5 (type V)	Inactive	Thick, calcified wall Arch-shaped *Cone-shaped shadow*	Most not fertile *Highly suggestive* Needs diagnostic confirmation	Surgery + ABZ, or watch and wait

ABZ, Albendazole; *CE,* cystic echinococcosis; *CL,* cystic lesion; *PAIR,* puncture, aspiration, injection, and reaspiration; *PT,* percutaneous therapy.

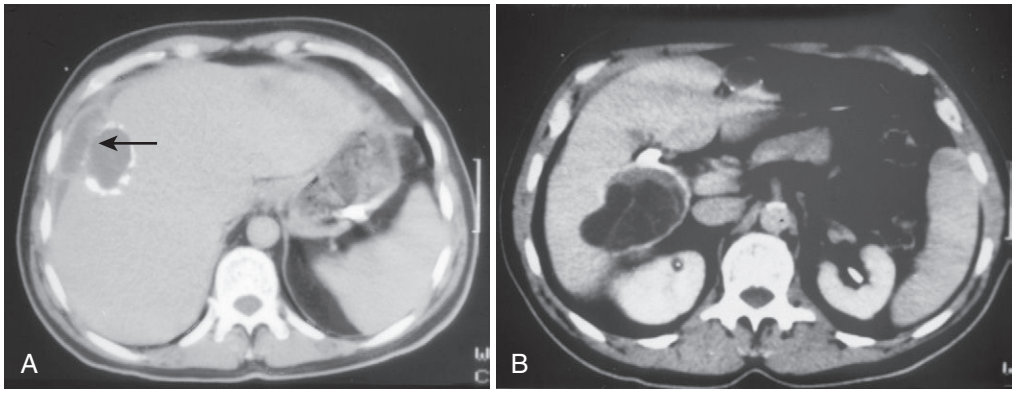

FIGURE 1 **A,** Computed tomographic (CT) scan shows rupture of hepatic cyst through the diaphragm *(arrow)* into the pleural space. **B,** CT scan in the same patient shows a calcified cyst near the gallbladder fossa and a small superficial cyst on the left.

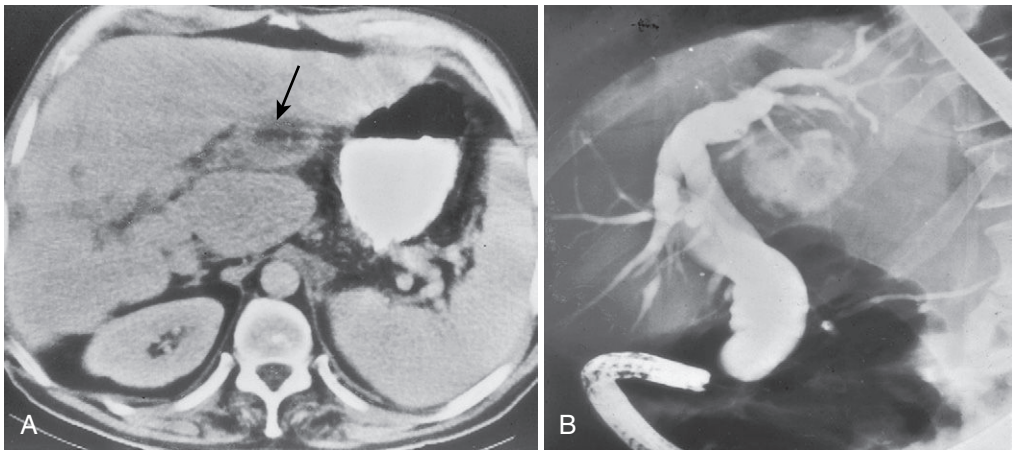

FIGURE 2 **A,** Computed tomographic scan shows a cyst in segment III of the liver. **B,** Endoscopic retrograde cholangiopancreaticography in the same patient shows biliary communication and an abnormally dilated biliary tree.

TABLE 2: Hepatic cyst differential diagnosis and imaging features

	Hydatid	Amebic	Congenital	Cystadenoma
Number	Single with daughter cysts	Single (or few)	Any	Single with loculations
Wall character	Thick, uniform, ± calcification	Thick, uniform	Thin, uniform	Variable, mural nodules, possible septations
Cyst contents	Clear or bilious, gelatinous; hydatid sand	Red-brown, "anchovy paste"	Clear, low-density	Green-brown, mucinous, low-density

TREATMENT

The principles of treatment of echinococcal cyst disease of the liver include early intervention to prevent secondary complications, eradication of the parasite, and prevention of disease recurrence with minimization of morbidity and mortality. Although most cysts are asymptomatic, complications such as cholangitis, anaphylaxis from cyst rupture, and pulmonary infection do occur and necessitate complete and thorough therapy. Protection of the patient against spillage of scolices and management of any complications that develop are imperative. Surgery remains the predominant therapeutic modality, but systemic chemotherapy; puncture, aspiration, injection, and reaspiration (PAIR); other percutaneous interventions; and watchful waiting also play a role in hydatid cyst management. Factors such as patient health, cyst characteristics, and the presence of complications all contribute to the decision over which treatment is most appropriate for each individual patient. The optimal or "best" treatment option for this disease has yet to be identified, and clinical trials comparing all of the available modalities do not exist. Therefore, available medical and surgical expertise and equipment, patient compliance, and the presence of recognized or national treatment centers should be weighed in the decision-making process.

Nonoperative Therapy

Benzimidazoles

Systemic chemotherapy with antihelminthic drugs, benzimidazoles, is the mainstay of medical treatment for echinococcal disease of the liver. Albendazole (10 to 15 mg/kg/d oral divided twice daily) is the drug of choice because it is readily absorbed from the gut, metabolized in the liver to its active form, and concentrated better in cystic fluid when compared with mebendazole. Formal assessment of the optimal treatment dose and regimen has not been performed, and recommendations vary from continuous treatment for 3 to 6 months with monotherapy to immediate discontinuation after surgery. These agents are not indicated for the treatment of inactive or calcified cysts except in complicated lesions. Monitoring of leukocyte counts and LFTs are essential because side effects include neutropenia, hepatotoxicity, nausea, and alopecia. More recent data suggest that albendazole combined with the antiparasitic drug praziquantel (a synthetic isoquinoline-pyrazine derivative, 40 mg/kg once a week) is more effective than albendazole alone. When used without other therapeutic modalities, the success rate of monotherapy with these drugs is approximately 30% and, thus, is only recommended in specific smaller (<5 cm) liver cysts (WHO cystic echinococcosis type 1 [CE1] and CE3). Therefore, additional percutaneous or surgical therapy should be used in conjunction with medical treatment (see Table 1). When combined with surgery, albendazole has been shown to both reduce the number of viable cysts at the time of surgery and decrease disease recurrence.

Percutaneous Therapy

Percutaneous treatment of hepatic cystic echinococcosis has become increasingly acceptable in recent years for carefully selected patients. Therapy can consist of either PAIR aimed at destroying the germinal cyst layer or needle decompression and catheter drainage with the goal of evacuating the entire endocyst. Catheter drainage is generally reserved for giant (>10 cm) unilocular cysts where the catheter is left in place until the daily output is less than 10 mL per day. Current consensus guidelines recommend PAIR for high risk patients, those who refuse surgery, those with failure of medical management alone, patients with infected cysts, and cyst recurrence after surgery. Cysts that are greater than 5 cm and classified as CE1 or CE3 are most

amenable to primary treatment with PAIR plus a benzimidazole. PAIR is contraindicated in patients with biliary fistulae, complicated cysts, and inaccessible or high-risk locations (superficial), and those with CE2, CE4, CE5, inactive, or calcified cysts. Symptomatic pregnant women and children over 3 years of age should be evaluated with care and individual treatment decisions made with regard to the use of PAIR.

The PAIR procedure consists of percutaneous puncture and aspiration of the cyst with US guidance followed by injection or instillation of an indwelling scolicidal solution for 10 to 30 minutes, then reaspiration of the agent, and final irrigation with 0.9% saline solution. Protoscolicides typically used include either hypertonic 20% sodium chloride or 95% ethanol. The goal is to reduce the size and volume of the cyst, detach the inner germinal layer from the pericyst with the scolicidal agent, thicken the cyst wall, and eventually solidify the cyst. To prevent spillage of protoscoleces and improve efficacy of the therapy, albendazole should be administered at least 4 hours before PAIR (or up to 1 week before) and for 1 month after the procedure. Data have shown that combined treatment of PAIR plus albendazole is superior to either alone.

More than 4000 PAIR interventions have been performed over the last 20 years, proving the safety of the procedure. A 2003 meta-analysis compared PAIR plus albendazole or mebendazole with surgical therapy and found that PAIR and chemotherapy had a higher cure rate, less recurrence, fewer complications, and decreased length of stay. However, the surgical group was a historic control of mixed cases performed before 2001, and more than half of the patients did not receive any antihelminthic drug therapy, the standard of care, which makes interpretation of the results difficult. Thus, better data are needed comparing the various therapies before the optimal treatment of hepatic hydatid cysts can be fully determined.

Operative Therapy

Surgical management of echinococcal cyst disease of the liver was the only treatment option before the 1980s and has long been the primary therapeutic modality. The indications for surgery include large CE2 to CE3 cysts with multiple daughter cysts; superficial singular cysts at risk for spontaneous or traumatic rupture; infected cysts or those with biliary communication, particularly when percutaneous therapy is not available or possible; and cysts with a mass effect on adjacent vital organs. Evaluation of cyst type, size, location, presence or absence of complications, and patient factors (comorbidities, compliance) should be considered when choosing surgical intervention versus other therapies. Operative management is generally contraindicated in patients unfit for surgery and for inactive asymptomatic cysts, poorly located cysts, and very small cysts. The tenants of treatment with surgery remain to completely inactivate the scolices, eliminate the parasite and viable cyst contents, prevent recurrence or spillage of cyst contents, manage the cyst cavity, and prevent untoward morbidity and mortality.

A variety of surgical techniques exists, including open and laparoscopic cyst evacuation, pericystectomy, liver resection, and transplantation. Proper preoperative evaluation of the location of bile ducts and vascular structures with US, CT, or MRI should be obtained. If a bile duct connection is suspected, preprocedure ERCP should be performed. The use of IOUS also is helpful in identifying and avoiding key structures. These operative therapies should all be used in conjunction with a benzimidazole (administered for at least 1 day before surgery and for up to 1 month after surgery, if viable scolices are present) to decrease the risks of residual or recurrent disease.

Scolecoidal Agents

Inactivation of protoscolices and prevention of their spillage during surgery with scolecoidal agents is strongly recommended. In the past, considerable controversy existed over the use and type of scolecoidal agents. Formalin, cetrimide, and chlorhexidine all have been used, but the safety and efficacy of these agents has not been established. The WHO recommends 20% hypertonic saline solution that should be in contact with the germinal layer of the cyst for at least 15 minutes before intervention. Hypertonic saline solution and other agents should be avoided in patients with cystobiliary fistulas because of the risk of chemically induced sclerosing cholangitis if it enters the biliary tract. Care should be taken to prevent the development of hypernatremia, another potential side effect of hypertonic saline solution that is seen with overuse. Peritoneal contents can be protected with protoscolicide-soaked surgical sponges. In addition, preevacuation injection of hypertonic saline solution into the cyst should be avoided because intracyst pressure is already high and may increase the likelihood of protoscolex spillage. A meticulous surgical technique is warranted rather than overreliance on scolecoidal agents.

Open Cyst Evacuation

As one of the safest surgical approaches, open evacuation of hydatid cysts is considered a conservative surgical therapy and is most suitable for peripherally located cysts on or near the surface of the liver. When anterior, an abdominal approach is best, whereas cysts in segments VI and VII are more amenable to a lateral flank approach. Figure 3, *A,* depicts evacuation of the cyst contents via aspiration; subsequent injection of a scolecoidal agent is optional at this time. Note, the field is lined with hypertonic saline solution–soaked gauze in the event of spillage. The cyst cavity is then opened, and the contents are aspirated with a large suction device with high negative pressure (Figure 3, *B*). Removal of daughter cysts, resection of the active cyst lining, and meticulous clearance of any remaining debris can be performed once the cyst is opened completely. The cyst may then be irrigated with a scolecoidal agent, as described previously. However, if the cyst fluid is bile stained or communication with the bile ducts was shown on preoperative ERCP, intracavity scolecoidal agents should be avoided. Simple closure of any biliary connection should be performed with absorbable sutures, and the cyst cavity filled with omentum. If the cystobiliary fistula cannot be easily closed, external drainage with a closed suction drain may be warranted.

Laparoscopic Cyst Evacuation

A laparoscopic approach to echinococcal liver disease uses the same principles as open surgery. Several reports have shown that carefully selected patients with peripherally located hepatic hydatid cysts may be safely managed with laparoscopic cyst evacuation. Anterior cysts without thick calcified walls and those in segments VI and VII (with a right lateral approach) are particularly amenable to this approach. One technique uses an 11-mm trocar placed just above the cyst, through which 10% povidone-iodine–soaked sponges are placed to act as a scolecoidal agent. The cyst is then punctured with a 14-gauge needle and aspirated, causing the endocyst to shrink away from the wall and rest at the bottom of the cyst. The 11-mm trocar is then upsized to 18-mm so that the germinal membrane can be aspirated. The laparoscope is then inserted directly into the cyst to identify any remaining daughter cysts or biliary fistulae, and the cyst cavity is irrigated with 20% hypertonic saline solution. Excision of the cyst wall followed by omentoplasty or closed suction drainage is then performed to complete the procedure.

Advantages to the laparoscopic approach include a reduced hospital stay, decreased hospital cost, and earlier return to productive activity. With laparoscopy, short operative times (less than 90 minutes) and low complication rates also have been reported. In properly selected patients with uncomplicated cysts, conversion to an open procedure should occur in less than 5% of cases. However, despite improved visualization, this approach has not gained widespread acceptance because of the relative inability to avoid or control

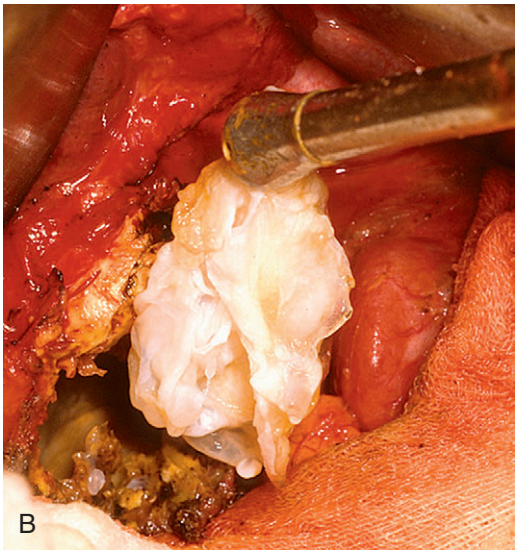

FIGURE 3 **A**, Open cyst evacuation shows cyst aspiration *(upper left),* suction removal of daughter cysts *(upper right),* resection of the active cyst lining *(lower left),* and omental packing with suture tacking *(lower right).* **B,** Operative picture shows the daughter cysts. *(From Cameron JL, Sandone C:* Atlas of surgery: gallbladder and biliary tract, the liver portosystemic shunts, the pancreas, Philadelphia, *1990, BC Decker.)*

peritoneal spillage in the setting of high intra-abdominal pressures from the pneumoperitoneum, a limited area for manipulation, and difficulty aspirating thick cyst contents. Techniques to minimize spillage of cyst contents include insertion of iodine-soaked sponges as described, fixing the cyst to the abdominal wall, lavage with scolicidal agents, and creation of a scolicidal pool around the liver by operating in the reverse Trendelenburg's position. Whatever approach is used, oral albendazole both before and after surgery is still indicated. In addition to simple drainage, laparoscopic partial cystectomy and even total pericystectomy also have been described.

Pericystectomy

The surgical literature divides the approaches to echinococcal cyst disease of the liver into conservative approaches, such as cyst evacuation, and more radical approaches, which include pericystectomy, liver resection, and transplantation. Pericystectomy involves complete resection of the cyst wall either closed, without entering the cyst cavity itself, or open, by sterilizing the contents with protoscolicidal agents, evacuating the cyst tissue, and then removing the pericyst tissue (see Figure 3, *A*). This procedure can be performed with electrocautery or a dissector either along a plane outside the pericyst or along the cyst wall itself. When dissecting around the cyst, some authors advocate use of a cleavage plane between the inner layer of the host's reaction towards the parasite and the outer layer, or adventitia, which limits damage to the liver parenchyma and allows safer removal (see Figure 3, *B*). Similar to cyst evacuation, pericystectomy is best performed on cysts along the periphery of the liver.

The advantage of this procedure over simple cyst drainage is a decreased risk of cyst content spillage into the peritoneal cavity when performed as a closed pericystectomy, which avoids potential anaphylaxis and decreases the risk of recurrence. Complete removal of the adventitia and elimination of the need for scolecoidal agents can be achieved with a closed procedure. The disadvantages of pericystectomy are an increased risk of bleeding or damage to bile ducts in proximity to the cyst wall because of the need for hepatic parenchymal transection. When encountered, vascular and biliary structures can be controlled with clips or sutures as illustrated in Figure 4, and the cavity may be closed over a drain. Pericystectomy is preferred to cyst evacuation because of a lower risk of secondary echinococcosis from protoscolex dissemination. However, the conservative approach of cyst evacuation is well suited for endemic areas where operations are performed by nonspecialty trained general surgeons and resources are limited.

Liver Resection/Transplantation

Another "radical" surgical approach to the management of hepatic echinococcal cyst disease is liver resection, which can range from nonanatomic wedge resection to formal hemihepatectomy. Although formal liver resection for benign disease may seem excessive, hepatic resection is now very safe, especially when performed by surgeons and centers with expertise in liver surgery. Multiple indications for liver resection exist, including complicated cysts with large biliary fistulae and small peripheral cysts where the cut surface of the liver is less with resection than with pericystectomy. Liver resection also should be considered for multiple cysts within proximity to one another or major structures, such as portal or hepatic veins or bile ducts, or when the resection would be relatively safe as seen with cysts confined to the left lateral segments II or III. Patients with recurrent disease who have failed more conservative management also are candidates for liver resection. Formal resection of the liver should be initiated only if complete excision of all cysts is possible. In one study, operative time, length of stay, postoperative morbidity, and cyst recurrence were shown to be increased in patients treated with liver resection compared with pericystectomy. However, resection avoids pedunculated ischemic hepatic tissue, which can be seen with pericystectomy.

FIGURE 4 **A,** Pericystectomy is shown depicting removal of the calcified pericyst *(top right),* suture closure of a communicating bile duct *(middle left),* and (optional) closure of the cavity over a drain *(lower right).* **B,** Operative picture shows cyst removal. *(From Cameron JL, Sandone C:* Atlas of surgery: gallbladder and biliary tract, the liver portasystemic shunts, the pancreas, *Philadelphia, 1990, BC Decker.)*

Perhaps the most radical of surgical management options, liver transplantation, is rarely indicated in the treatment of hepatic hydatid disease not amenable to alternative therapies. As opposed to *E. granulosus,* which tends to form solitary cysts, *E. multilocularis* can produce a more complicated form of the disease with multiple cysts known as alveolar echinococcosis. These cysts can result in fulminant liver failure from sclerosing cholangitis, Budd-Chiari syndrome, or biliary sclerosis. In such unusual cases, orthotropic liver transplantation may be indicated.

Summary

Uncomplicated Disease

Patients with uncomplicated echinococcal cyst disease of the liver typically are asymptomatic with incidental cyst discovery on imaging or at abdominal surgery for other reasons. However, they may present with right upper quadrant pain without fever, chills, jaundice, or a cough. A complete history and physical examination should be performed, laboratory tests including LFTs and serology should be sent, and the WHO-IWGE type should be determined with US imaging or other available studies. For patients with CE1 or CE3 (Gharbi types I or II) cysts, particularly if they are anterior, peripheral, unilocular, less than 5 cm, and not heavily calcified, PAIR or laparoscopic cyst evacuation should be considered depending on local expertise (Table 3). Alternatively, uncomplicated cases with CE4 or CE5 (Gharbi types IV or V) cysts that are posterior, central, greater than three in number, large (>5 cm), or calcified should undergo open evacuation or resection when surgery is indicated. The WHO guidelines further suggest that in uncomplicated CE4 or CE5 cysts proven to be inactive, a watch and wait approach may be undertaken with long-term US imaging follow-up, especially if local surgical expertise is not available. WHO cystic lesions are frequently early hydatid or possibly other hepatic cysts and should not be treated until their parasitic origin has been confirmed. The decision to perform cyst evacuation, pericystectomy, or liver resection should be individualized on the basis of patient and cyst characteristics and surgeon experience.

TABLE 3: Treatment options summary

PAIR or laparoscopic evacuation	Open evacuation or liver resection
Uncomplicated Cases	
CE1 or CE3 cysts (Gharbi I or II)	CE 4 or CE 5 cysts (Gharbi IV or V)
Anterior location	Posterior or central location
Small size (<5 cm)	Large size (>5 cm)
Few number (1-3 cysts)	Multiple (>3 cysts)
Minimal or no calcification	Heavy calcification
Complicated Cases	
Infected cysts meeting previous criteria	Infected cysts meeting previous criteria
	Biliary or pulmonary communication
	Peritoneal rupture

Albendazole or mebendazole should be used in conjunction with all treatments.
CE, Cystic echinococcosis; *PAIR,* puncture, aspiration, injection, and reaspiration.

Complicated Disease

Patients with complicated hepatic hydatid cysts can be secondarily infected or have biliary obstruction, cystobiliary fistulae, or rupture into the biliary tree, peritoneal, or pleural cavities. Secondary bacterial infection usually occurs as a result of biliary communication and should be treated with appropriate systemic antibiotics and adequate cyst drainage. In carefully selected patients, percutaneous drainage may be needed before definitive surgical treatment. In the 5% to 15% of patients with hydatid cysts on imaging who present with jaundice or cholangitis, ERCP is indicated to both evaluate potential fistulae between the cyst and biliary tree and drain the biliary system with a stent. A sphincterotomy alone may not be adequate treatment. Once drainage is sufficient and cholangitis has resolved, open cyst evacuation should be performed and biliary fistulae closed as described previously. Cyst diameter greater than 7.5 cm is a risk factor for a biliary-cyst communication even in asymptomatic patients with an 80% likelihood of a fistula being present at surgery. Therefore, one should be prepared to deal with a biliary fistula in the operating room in patients with large cysts. A concomitant cholecystectomy and intraoperative cholangiogram to ensure complete cyst debris clearance from the bile ducts also may be required. In rare instances, a biliary-intestinal anastomosis or liver resection may be needed to fully treat cystobiliary fistulas.

Complicated disease also occurs occasionally when hydatid hepatic cysts rupture into the peritoneum or through the diaphragm into the pleura and lung (see Figure 1), which can result in widespread disseminated disease. Free rupture of a cyst into the peritoneal cavity presents with peritonitis, shock, and/or anaphylaxis. Treatment of the allergic reaction and surgical evacuation are necessary. In these situations, an open surgical approach is recommended to thoroughly control the spread of disease throughout the abdomen. Supportive and intensive therapy also is usually required for the care of these patients. On the other side of the diaphragm, the workup for patients with pulmonary complications includes imaging, serology, and bronchoscopy when bronchocystic fistulae are suspected. Benzimidazoles alone can be used for small, uncomplicated lung cysts. However, surgical management for these patients often includes evacuation of cysts from both the liver and the pleural spaces. Open cyst evacuation with closure of the diaphragm and drainage are indicated but should be as conservative as possible. For extended pulmonary involvement, severe suppuration, or other complications, pulmonary resection also may be required. In the chest, as in the abdomen, care must be taken to prevent spillage of cyst contents to avoid recurrent infection or anaphylaxis.

RESULTS

Morbidity and Mortality

Advances in the management of patients with echinococcal cyst disease of the liver have decreased the morbidity and mortality of the disease in recent years. In a 2003 meta-analysis of patients with all types of disease (uncomplicated and complicated) that compared 769 patients who underwent PAIR with 952 who had surgical intervention, minor and major morbidity rates for each modality were 8% and 13%, respectively, for PAIR as opposed to 25% and 33%, respectively, for surgery. The overall mortality rate reported in the same study was 0.1% for PAIR and 0.7% for surgery, demonstrating the relative safety of both approaches. Thus, in patients with uncomplicated hydatid cysts who undergo elective percutaneous or laparoscopic drainage procedures, open evacuation, pericystectomy, wedge resection, or left lateral sectionectomy, mortality should be very low, with morbidity rates ranging from 15% to 20%. A recent retrospective analysis of patients undergoing surgical treatment of hepatic echinococcal infection reported 0 mortality and 47% morbidity for resection procedures, but only a 17% morbidity rate for cyst evacuation. Not surprisingly, less invasive techniques were associated with reduced hospital stay and cost. In patients with complicated disease who undergo open evacuation, pericystectomy, or resection, morbidity is in the range of 40% to 50%, and mortality should be less than 5% (reports range from 0.5% to 4%). The presence of sepsis, peritoneal rupture, underlying comorbid disease, and malnutrition all are factors that increase mortality.

Long Term

Overall, the long-term cure rate for appropriately and adequately treated patients with echinococcal hepatic cysts is excellent and ranges from 90% to 95%. Medical treatment with benzimidazoles alone should only be used in patients who are otherwise not candidates for percutaneous or surgical therapy because recurrence rates are approximately 70% to 80%; therefore, when possible, medical therapy should be used in combination with a drainage or resection procedure. In uncomplicated cases, open surgical, laparoscopic, and percutaneous drainage techniques all have low recurrence rates around 10%. Because of the endemic nature of this disease and potential for reinfestation, long-term follow-up is necessary with serologic tests and imaging studies. WHO guidelines recommend follow-up visits including US imaging and laboratory tests (CBC and LFTs) every 3 to 6 months initially, then yearly once the situation is stable. Serologic tests also can be followed; but although a persistence of raised or a further increase in antibody levels may indicate residual or recurrent disease, these finding may occur even with full, adequate treatment. Currently, new antigens show promise in reliability for posttreatment monitoring. Patients with echinococcal cysts complicated by infection, cholangitis, pleura extension, or peritoneal rupture have unique problems. If the complication such as cholangitis can be treated before definitive cyst treatment, the long-term outcomes are similar to those of uncomplicated echinococcosis. However, patients with rupture into the pleural cavity or the peritoneum may have a recurrence rate as high as 25%.

Cavernous Hepatic Hemangioma

Teviah E. Sachs, MD, MPH, and
Michael A. Choti, MD, MBA, FACS

Cavernous hemangiomas are the most common benign tumor of the liver. They are typically found incidentally during an evaluation for other reasons. With increasing use of cross-sectional imaging, surgeons are being asked to evaluate and manage these patients with increasing frequency. The reported incidence of hepatic hemangioma ranges from 0.4% to 20%, depending on autopsy studies, and they are more common in women with an approximate 3:1 ratio. Developing as congenital, non-neoplastic proliferation of vascular endothelial cells, the precise etiology of these tumors is unknown. Evidence to date shows that they have no malignant potential.

Hepatic hemangiomas can range from sub-centimeter in size to very large, sometimes encompassing the majority of the liver. Tumors of 5 cm or greater in diameter are typically referred to as giant hemangiomas (Figure 1). The term *cavernous* hemangioma is not related to size but rather is based on the histologic appearance, where a capacious vascular space is seen microscopically (Figure 2). Fibrous septa are seen between the vascular channels, as well as occasional calcifications and fibrosis in larger lesions. Hemangiomas can also display evidence of intraluminal microthrombus. On gross inspection, hemangiomas are well circumscribed, dark in color (often having a purplish hue), and soft and pliable, as one would expect from their vascular character (Figure 3). When found on the periphery of the liver, they often have a bulging appearance beneath the liver capsule.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

Whereas there are no known specific causes of hepatic hemangiomas, their predisposition for females makes some suspect a hormonal association. Specifically, some evidence suggests that *growth* of hemangiomas can be related to steroid administration, pregnancy, or oral contraceptive use. In addition, exacerbation of symptoms can sometimes be seen with changes in estrogen milieu, such as pregnancy or hormone use.

The majority of hepatic hemangiomas are found incidentally during evaluation for other disease processes. They are asymptomatic in more than half of cases referred for surgical evaluation. Historically, the incidence of these tumors was based on autopsy series. However, the rise in number of imaging studies performed has made incidental identification the most common method of diagnosis. Whereas the age of onset is unknown, the majority of these tumors are diagnosed between the fourth and sixth decades of life. Hemangiomas are more commonly found in the right hemiliver and can be multiple in 10% to 40% of cases.

The natural history of cavernous hemangiomas within the liver is uneventful in most cases, and most remain asymptomatic. Although cavernous hemangiomas can grow and symptoms may develop (sometimes years or decades later), the majority remain stable. Regression can be seen in 10% to 15% of cases. For those patients who present symptomatically, symptoms are often variable. Any nonspecific symptoms attributed to these lesions should be made with care, as other sources may be the cause. Right upper quadrant fullness and mild discomfort are the most common complaints. Patients will often describe symptoms that can be mistaken for symptoms of chronic cholecystitis or symptomatic cholelithiasis. The pathogenesis of this pain is unknown and likely multifactorial. Localized right upper quadrant pain can be due to infarction or thrombosis of the tumor itself. More commonly, patients may have more chronic or intermittent dull pain due to tumor engorgement and resultant stretching of Glisson's capsule. This stretching is transmitted via the autonomic C fibers and mediated by the celiac ganglion, resulting in nonspecific visceral pain that is difficult to differentiate from other intra-abdominal processes. In addition, diaphragmatic peritoneal irritation can cause referred pain to the right subscapular or shoulder region.

Less common presentations for symptomatic hepatic hemangiomas may include fever, nausea and vomiting, cardiac manifestations, jaundice, and, in rare cases, rupture. A patient with fever may undergo an intensive evaluation before a large hepatic hemangioma, often with thrombosis, is identified. Giant hemangiomas that cause compression of the duodenum or stomach may cause nausea, vomiting, early satiety, dyspepsia, or, in rare cases, gastric outlet obstruction. Pedunculated hemangiomas on the undersurface of the liver may be mistaken for tumors of the duodenum or kidney or as enlarged lymph nodes, compressing surrounding structures (see Figure 3). If large enough, giant hemangiomas can lead to development of arteriovenous shunting, which, in severe cases, can lead to cardiac hypertrophy and congestive heart failure. When these tumors compress the common bile duct extrinsically, the affected individual may have jaundice due to biliary obstruction.

Rupture is an exceedingly uncommon event, presenting variably with tachycardia, hypotension, anemia, and diffuse or focal abdominal pain. Such patients require immediate attention and, often, urgent intervention. Early reports estimated the mortality rate with rupture to be approximately 75%. However, with the advent of technology leading to earlier identification and therapy, more recent estimates of the mortality rate are as low as 30%. Often, giant asymptomatic hemangiomas are referred to a surgeon for resection because of a perceived risk of rupture by the physician or patient. Despite the large size and vascularity of these hemangiomas, the rate of spontaneous rupture is exceedingly rare with estimates of less than 1%. A recent review of the literature showed that only 46 cases of true spontaneous rupture have been reported. Similarly, even nonspontaneous rupture, such as that from trauma, anticoagulation, or comorbid disease, is rare, with only 38 cases reported in the literature during the same time period. Rupture has been associated with pregnancy and hormonal therapy, although this is not well described. Therefore, the risk of rupture should almost never be a reason for recommending surgical resection, regardless of size or risk factors.

There are no specific laboratory tests that are useful in diagnosing hepatic hemangiomas. However, abnormalities in liver function tests can be found, particularly when associated with proximity and compression of the biliary tree. In such cases, test findings may show bilirubin or alkaline phosphatase elevation. Thrombocytopenia can occur in rare cases due to platelet sequestration, as well as low fibrinogen levels due to fibrinolysis within the tumor itself (Kasabach-Merritt syndrome). Although this syndrome can occur at any age, it is more common in children. In addition, hepatic hemangiomas can be found in association with other vascular syndromes and disease states. Klippel-Trenaunay-Weber syndrome, in which patients display hepatic hemangiomas in conjunction with diffuse varicosities, most often affects the extremities. Although not a hallmark of diagnosis, hepatic hemangiomas are associated with von Hippel-Lindau disease, Osler-Rendu-Weber disease, Maffucci syndrome, and systemic lupus erythematosus.

The presence of hepatic hemangiomas can complicate the evaluation of patients with malignancy. Elevation in tumor markers alpha fetoprotein (AFP), CA-19-9, or carcinoembryonic antigen (CEA) in

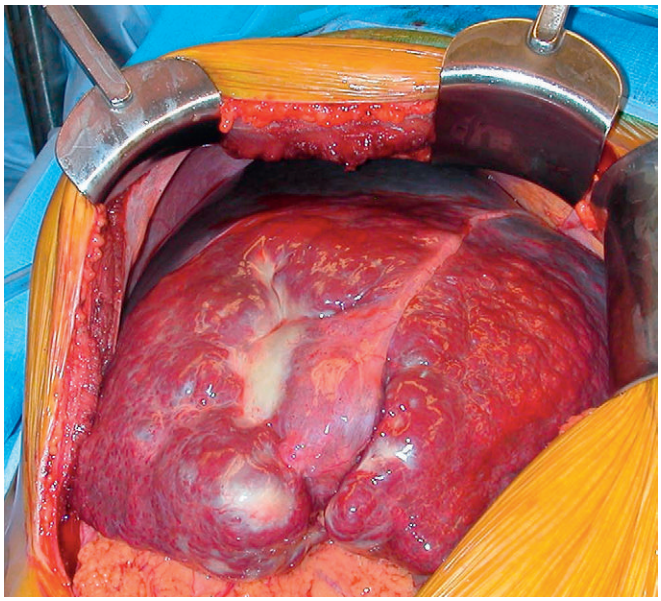

FIGURE 1 Giant hepatic hemangioma of the left hemiliver associated with abdominal pain.

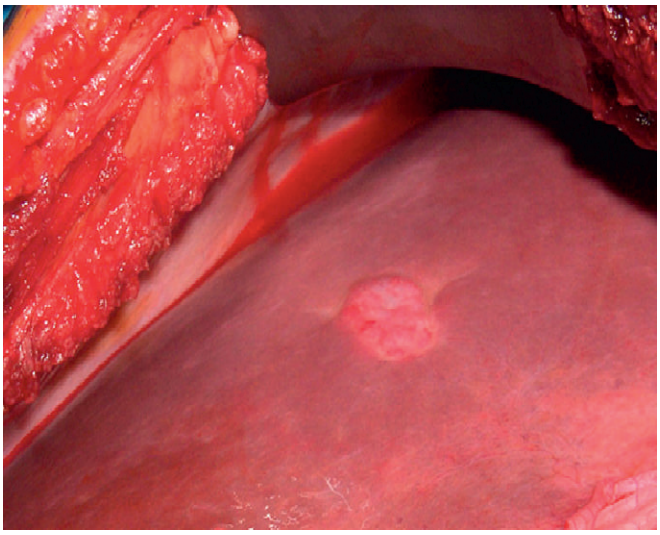

FIGURE 3 A small incidental hemangioma identified intraoperatively.

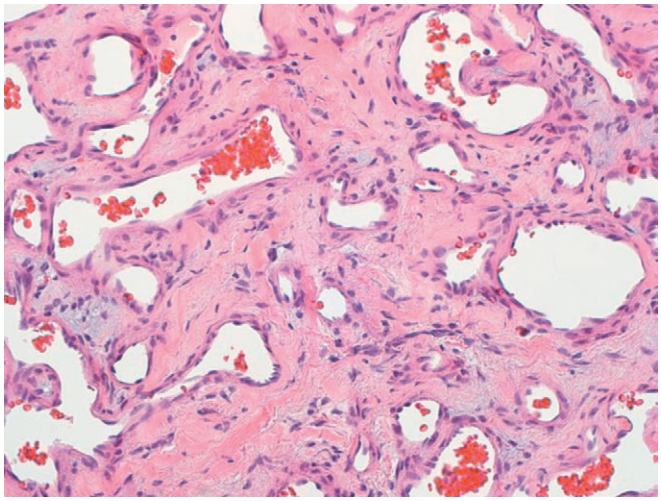

FIGURE 2 Photomicrograph of a section of a cavernous hepatic hemangioma, demonstrating the extensive vascularity and ill-defined network of capillaries and larger vessels.

a patient with suspected hepatic hemangioma should question this diagnosis and raise the suspicion of a malignancy. In addition, in a patient being staged for extent of primary or metastatic disease within the liver, the presence of small hemangiomas can result in a false assumption of added malignancy, leading to overestimation of the extent of disease. These patients may be incorrectly excluded from resection of their malignancy.

DIAGNOSIS

Unlike some other benign tumors of the liver, hepatic hemangiomas are typically easy to diagnose on imaging evaluation. Contrast-enhanced computed tomographic (CT) scan is the most common way these lesions are identified and diagnosed. When getting a CT scan for evaluating for hemangioma, it is important to try to obtain a *delayed phase* as well as arterial and venous phases (Figure 4). This

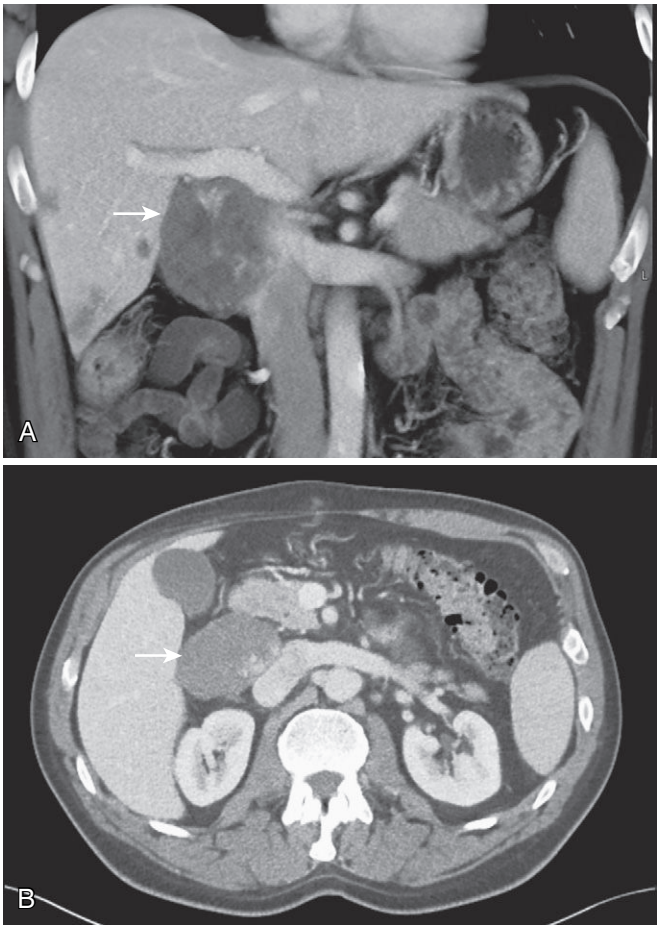

FIGURE 4 Contrast-enhanced, coronal (**A**) and axial (**B**) computed tomographic (CT) images showing an asymptomatic hemangioma (*arrow*) of the caudate lobe. Despite imaging, this mass was initially thought to be arising from the duodenum.

accentuates the late contrast puddling that is pathognomonic of these low-flow vascular tumors. The sensitivity of standard arterial and portal phase contrast CT scans is approximately 70%, while the addition of the delayed phase increases the sensitivity to over 90%. The classic CT findings are peripheral enhancement on arterial phase, with centripetal filling on portal venous phase and retention of contrast on washout or delayed phase.

Magnetic resonance imaging (MRI) is also a highly accurate method of diagnosing hepatic hemangiomas. These lesions display low signal intensity on T1 images and, importantly, a classic bright signal on T2-weighted noncontrast images due to their high water content. With use of contrast, much like CT scanning, hemangiomas display early peripheral enhancement and delayed centripetal filling (Figure 5). Studies report that MRI is superior to CT scan in sensitivity and specificity—both over 90%—for diagnosing hepatic hemangiomas. Availability, cost, and patient concerns may lessen the need for MRI as an additional required test, particularly if a multiple-phase CT scan confirmed the diagnosis. However, MRI should be considered in unclear cases. In addition, long-term surveillance with MRI may limit unnecessary radiation exposure.

Other imaging modalities have been described for diagnosing hepatic hemangioma, including planar scintigraphy (tagged red blood cell scans) and angiography. Although potentially helpful in selected cases, these studies are rarely necessary and currently uncommonly used. Ultrasound (US) imaging can also diagnose these tumors. The classic US appearance is that of a well-circumscribed, homogeneous, hyperechoic lesion (Figure 6). However, less than half of these lesions meet these criteria. Larger tumors often display fibrosis, thrombosis, and central necrosis, leading to heterogeneity on US. Larger lesions may have a hypoechoic center, and tumors can appear isoechoic on compression. Contrast-enhanced US can be useful in selected cases, increasing its sensitivity to 70% to 90%.

With use of quality contrast-enhanced cross-sectional imaging, the diagnosis of hemangioma is rarely in question, allowing for confidence in management strategy in most cases. However, in some situations, other tumors can be confused with this lesion. In particular, other vascular tumors such as angiosarcoma, epithelioid hemangioendothelioma, and hemangiopericytoma can mimic cavernous hemangioma. Unlike other solid lesions of the liver, biopsy of hemangiomas should be avoided because of risk of bleeding. In addition,

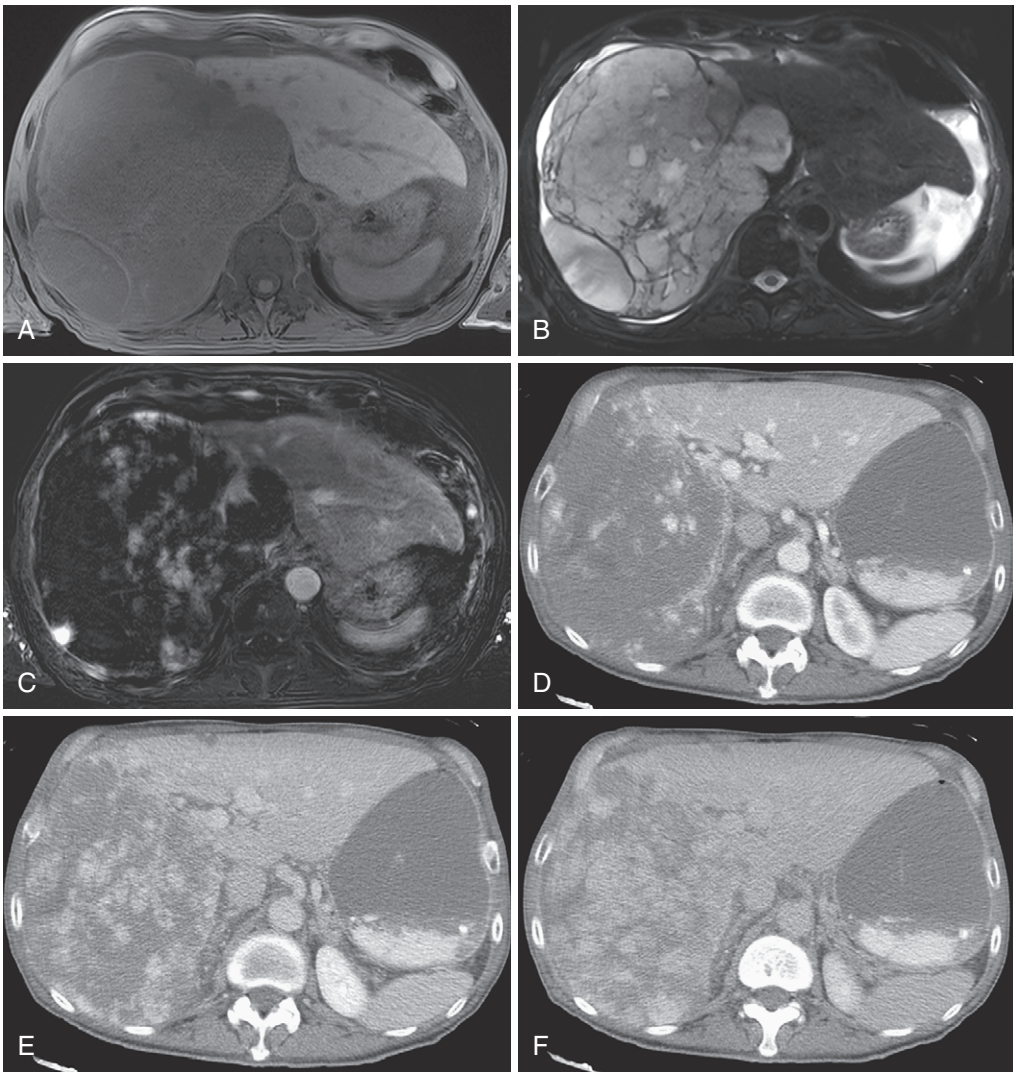

FIGURE 5 Giant cavernous hepatic hemangioma as seen on magnetic resonance imaging (MRI) (**A–C**) and CT scan (**D–F**). **A,** T1-weighted MRI without contrast. **B,** T2-weighted MRI without contrast. **C,** MRI with contrast, showing peripheral enhancement. **D,** Arterial phase computed tomographic (CT) scan showing classic peripheral enhancement. **E,** Portal venous phase CT scan showing centripetal enhancement. **F,** Delayed phase CT scan showing washout and equilibration.

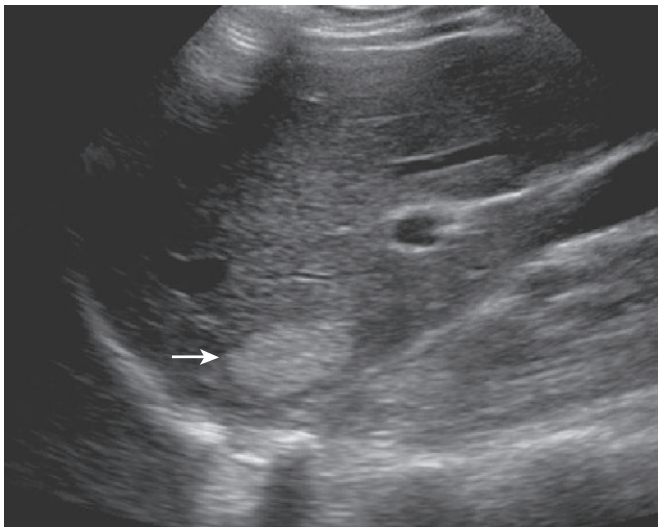

FIGURE 6 Ultrasound image demonstrating a small hepatic hemangioma *(arrow)* with classic findings of a well-circumscribed, homogeneous, and hyperechoic lesion.

percutaneous biopsy, either fine-needle or core, often will fail to provide evidence to support the diagnosis of hemangioma.

MANAGEMENT

As the preponderance of evidence suggests that cavernous hemangiomas rarely symptomatically progress or rupture, asymptomatic hepatic hemangiomas rarely require resection. Even large lesions can be reliably followed with serial imaging and patient follow-up, and rarely do they require subsequent intervention. Although CT scans can also be used for surveillance, the accumulated lifetime radiation risk makes this less appealing than US or MRI for monitoring. Importantly, image monitoring is less useful than symptom assessment in patient follow-up. Tumors that increase in size do not necessarily produce symptoms, and, in some cases, pain can develop even without a measurable growth in the lesion.

Intervention can be divided into acute and elective. Hemangiomas that are life threatening (e.g., in individuals with Kasabach-Merritt syndrome) or result in traumatic or spontaneous rupture or hemorrhage require acute intervention. In the case of acute hemorrhage, arterial embolization can be considered, but only as a temporizing measure, and should be followed by definitive resection when the patient is appropriately stable. If arterial embolization fails to control the hemorrhage, emergent operation is indicated. Surgical intervention, when performed, is done electively in most cases. It should be reserved for those who are clearly symptomatic or in rare cases where diagnosis is uncertain. When offering therapy to the symptomatic patient, the severity of the symptoms must be weighed against the morbidity of the procedure. Location, size, and approach are important factors when assessing surgical risk.

Surgical Resection

Various surgical techniques are available for use in the surgical resection of a hepatic hemangioma. In most cases, *enucleation* is the preferred approach to these tumors. Formal liver resection, whether anatomic or nonanatomic, is rarely necessary. Studies have demonstrated a decrease in blood loss, operative time, and complications with enucleation over standard resection. The operation is carried out along the plane of the pseudocapsule, carefully and deliberately. Initially, it may be necessary to divide a centimeter or two of parenchyma before the pseudocapsule is defined. Staying near the tumor but avoiding entering the lesion will limit potential complications. Once the pseudocapsule has been identified, the surgeon can often use a gentle dissecting technique to separate the tumor from the parenchyma enough to identify vessels, which are then controlled using surgical clips, ties, or energy devices. As with standard liver resection, dissection can be achieved using blunt techniques, ultrasonic dissection devices, or an energy-based dissector. Staplers are useful for larger pedicles. Strict adherence to the plane of the pseudocapsule will minimize the risk of parenchymal injury and bile leak. In addition, care must be taken to avoid injury to pedicles within the liver that can often be splayed and immediately adjacent to the tumor. The use of a temporary inflow occlusion (Pringle maneuver) can be particularly helpful during enucleation of large hemangiomas to minimize blood loss and decompress the tumor engorgement, facilitating the dissection.

For lesions that are amenable to a laparoscopic approach, this technique may provide advantages over an open operation. Hemangiomas that are peripherally located are best suited to a laparoscopic resection. Lesions that are centrally located, are high on the dome, or are abutting major vascular and biliary pedicles may be more challenging when attempted by laparoscopy.

Intraarterial and Ablative Therapies

For patients who are unstable because of rupture, or for whom comorbid disease is prohibitive, bland transarterial embolization (TAE) is a therapeutic option. In more elective cases, some studies have reported transient pain relief with embolization of hemangiomas. However, TAE is rarely of durable benefit, in part likely due to the lack of dominant arterial pedicle. In selected cases, embolization can be used as a bridge to surgery in the unstable patient or in rare instances where a markedly symptomatic patient is not a candidate for surgery.

Percutaneous or intraoperative radiofrequency ablation and microwave ablation have also been reported as alternatives to surgery and have shown symptom improvement in some cases. Complete ablation is usually not possible in symptomatic patients because of the size and proximity to major vascular and biliary pedicles. Partial ablation might improve symptoms in some cases but should be reserved for highly selected situations.

INFANTILE HEPATIC HEMANGIOMA

Infantile hepatic hemangiomas are rare and the majority are detected incidentally. Although similar on imaging to adult hepatic hemangiomas, these tumors are pathologically distinct. They are composed primarily of endothelial cells, which has given rise to another name: hemangioendotheliomas. These are not to be confused with epithelioid hemangioendotheliomas, which are malignant; nor are they the same as adult hepatic hemangiomas, which are primarily vascular tumors. These hemangioendotherlial tumors are known to undergo interval periods of both rapid growth and involution. MRI is the most conclusive imaging modality for diagnosis of these lesions. Treatment has centered on steroids, immunomodulating agents, radiation therapy, and embolic therapy. When large enough, these tumors can cause significant symptoms in infants, including congestive heart failure, respiratory distress, gastric outlet obstruction, and coagulopathy. When coagulopathy and thrombocytopenia are encountered with these large hepatic lesions, known as the Kasabach-Merritt syndrome, treatment must be prompt.

SUMMARY

With the increased use of abdominal imaging, cavernous hepatic hemangiomas are being identified with increasing frequency. Fortunately, a definitive diagnosis can be made noninvasively in most cases, and asymptomatic patients can be managed conservatively with confidence. Biopsy is not necessary and should not be used for diagnosis. In cases where patients' symptoms affect their quality of life, or in the rare cases where malignancy cannot definitively be excluded, resection should be offered. When possible, enucleation is preferred to standard hepatic resection and can be done with minimal morbidity or mortality, even in large and centrally located tumors. Minimally invasive approaches can be considered in some cases.

The Management of Benign Liver Lesions

Kenzo Hirose, MD

Incidentally identified liver lesions are an increasingly prevalent issue in view of the growing frequency with which patients undergo imaging studies. Patients undergo computed tomographic (CT) scan of the abdomen and pelvis for a variety of indications, which leads to the identification of many liver lesions that otherwise would be clinically silent. The majority of these lesions are benign and require no further treatment or monitoring, but many will require specialized expertise for their diagnosis and management. A working knowledge of the diagnosis, natural history, and treatment of these lesions is important for any surgeon treating affected patients. A close working relationship with a radiologist, especially one with expertise in magnetic resonance imaging (MRI) of the liver, is particularly important because many of these lesions are diagnosed primarily on the basis of cross-sectional imaging.

DIAGNOSIS AND IMAGING OF BENIGN LIVER LESIONS

Although many benign liver lesions are identified incidentally, a full history and physical examination is mandatory in the initial evaluation of a patient with a liver lesion. Important points to document include symptoms of pain, weight loss, early satiety, anemia, a known history of liver disease or cirrhosis, use of oral contraceptive pills or anabolic steroid use, a history of malignancy, and prior attempts at biopsy or instrumentation. On physical examination, the physician should assess for signs of chronic liver disease, tenderness, palpable masses, and signs of other concomitant malignancy. Laboratory evaluation, including observation for tumor markers (alpha-fetoprotein, cancer antigen 19-9 [CA19-9], carcinoembryonic antigen, chromogranin) can be helpful if there is a suspicion of malignancy.

Ultimately, however, the mainstay of diagnosis of benign liver lesions is cross-sectional imaging, and a good working knowledge of imaging modalities and findings is important for assessing these patients. With contemporary imaging modalities, the need for biopsy of benign liver lesions has become relatively uncommon. The radiographic armamentarium that is available for characterization of liver lesions includes ultrasonography, multiphasic CT, MRI, sulfur colloid scintigraphy, fluorodeoxyglucose-labeled positron emission tomography (PET), and tagged red blood cell scanning. The major contemporary methods for evaluation of liver lesions are contrast–enhanced CT and MRI. Proper intravenous contrast phases must be used to characterize liver lesions. Rather than use of standard single-phase CT of the abdomen and pelvis, patients should undergo dynamic postcontrast imaging with precontrast, early arterial phase (30-second), portal venous phase (60-second), and equilibrium (90-second) phases. It is not uncommon for even a large liver lesion to be missed on single-phase CT but appear clearly on a dedicated liver protocol imaging study. Benign lesions of the liver are listed in Box 1; this chapter focuses on the most common diagnoses.

Characterization of the lesion as cystic or solid is the first step in radiographic assessment. Simple liver cysts have a very characteristic appearance on various imaging modalities, including anechogenicity and increased acoustic through-transmission on ultrasonography, water density on CT (–10 to 10 Hounsfield units), and homogeneous bright signal intensity on T2-weighted MRI. Cysts should be further assessed for signs of complexity, including internal septa, wall enhancement, and mural nodularity. Such findings should raise the suspicion of a biliary cystic neoplasm such as biliary cystadenoma or cystadenocarcinoma. Other findings, such as thickening of the wall, proteinaceous debris within the lesion, and loculation, in the correct clinical context, may be suggestive of liver abscess. Findings of a hydatid cyst would include the identification of endocyst/pericyst interface, calcification, and daughter cysts in the periphery of the main cyst.

Solid lesions can be further characterized by their enhancement pattern on postcontrast imaging. The most common benign neoplasm of the liver is hepatic hemangioma, characterized by high T2 signal intensity ("light bulb sign") on MRI and low attenuation on precontrast CT. On both MRI and CT, hepatic hemangiomas demonstrate peripheral nodular enhancement or "puddling" in early arterial phase contrast imaging with centripetal enhancement or filling in during portal venous and equilibrium phases. Figure 1 illustrates typical MRI findings of a hepatic hemangioma. Contrast agent–enhanced MRI has excellent diagnostic accuracy for hemangiomas larger than 2 cm, and, in general, no further diagnostic testing is necessary.

The two next most common benign lesions include focal nodular hyperplasia (FNH) and hepatic adenoma (HA). Differentiating these two entities is often a radiographic and diagnostic dilemma because they share many similar imaging characteristics. Furthermore, the natural history and management of these two lesions differ

significantly, as discussed later in this chapter. FNH is a benign polyclonal proliferation of all cellular elements of the liver, thought to be induced by an arterial malformation or a focal area of arterial hyperperfusion. HA on the other hand, is a monoclonal proliferation of hepatocytes that have the potential for spontaneous bleeding and malignant transformation. Figures 2 and 3 demonstrate the most typical findings seen in FNH and HA on contrast agent–enhanced MRI. FNH demonstrates hyperenhancement with arterial phase contrast agent and isointensity on venous phase imaging. These lesions can be relatively "stealthy" as they are composed largely of normal hepatocytes; they can be missed on standard, single-phase contrast CT because their attenuation is similar to that of background liver tissue during the venous phase. The classic finding is of a central scar, which is more often seen in larger lesions and may exhibit postcontrast enhancement as well.

The radiographic findings in HA can be varied, depending on whether they are the steatotic or inflammatory subtype. Adenomas tend to be hypointense on T1-weighted imaging, are also enhanced in the early arterial phase, and also tend to be isointense or hypointense on portal venous phases. Persistent enhancement through the portal venous and equilibrium phases is characteristic of an inflammatory adenoma. The presence of intralesional fat is characteristic of a steatotic HA and is useful for distinguishing adenoma from FNH. Fat-suppressed in-phase and out-of-phase imaging sequences can be helpful in assessing lipid content within the lesion. The presence of hemorrhage within the lesion also indicates HA rather than FNH.

Use of liver-specific contrast agents during MRI can also be especially useful in differentiating FNH from HA. Gadoxetic acid (Eovist) is an intravenous MRI contrast agent that is 50% cleared through hepatobiliary excretion. Hepatobiliary phase imaging with Eovist is typically performed 20 to 40 minutes after administration and

BOX 1: Benign lesions of the liver

Most Common
Hepatic cyst
Hepatic hemangioma
Hepatic adenoma
Focal nodular hyperplasia

Less Common
Biliary cystadenoma
Nodular regenerative hyperplasia
Angiomyolipoma
Endothelioid hemangioendothelioma
Bile duct hamartoma
Peliosis

Note delayed enhancement of central scar.

demonstrates uptake by normal hepatocytes and excretion into the biliary tree. Uptake of the contrast agent on hepatobiliary phase imaging with Eovist is a finding highly specific for FNH. HA, on the other hand, consists of neoplastic hepatocytes whose function is abnormal and, consequently, do not take up Eovist in hepatobiliary phase imaging. These radiographic findings, coupled with the appropriate clinical context, can help reliably distinguish HA from FNH. Radiographic findings on cross-sectional imaging for the most common benign lesions of the liver are listed in Table 1.

The role of nuclear medicine in the diagnosis of benign liver lesions has gradually decreased as the specificity of cross-sectional imaging has increased. Technetium 99m–tagged red blood cell scans have traditionally been used to identify hepatic hemangiomas, but they are no longer commonly used, in view of the high specificity of dynamic postcontrast cross-sectional imaging. Radiolabeled sulfur colloid scintigraphy has also been used to distinguish FNH from HA because of specific uptake by Kupffer cells, which are present in the FNH but not in HA. In most patients, assessment with contrast agent–enhanced MRI is adequate, but when the findings are equivocal or when the patient has a contraindication to intravenous contrast agents, there may be a role for sulfur colloid scintigraphy.

When findings of imaging studies are equivocal, percutaneous biopsy may be warranted. However, the decision to perform biopsy should be made carefully: the risks and benefits of biopsy should be weighed, and how the results will affect therapy should be considered. An absolute contraindication to biopsy is hepatic hemangioma because of the risk of massive hemorrhage. In most cases, high-quality, liver-specific cross-sectional imaging should enable the clinician to make this diagnosis. If the lesion is highly suspicious for malignancy on imaging and is amenable to surgical resection, then a percutaneous biopsy may not necessarily change management and, moreover, may lead to spreading of the tumor via the needle tract. In this case, the patient should undergo a diligent evaluation for a primary tumor, and if none is found, then the patient should undergo laparotomy and resection.

In the case of distinguishing FNH from HA, percutaneous biopsy may be helpful, but a few factors should be considered: these lesions may be difficult to identify on ultrasonography or noncontrast CT, which makes image-guided biopsy difficult; the histologic appearance of FNH can be difficult to distinguish from that of normal liver, which causes uncertainty about whether the actual lesion was sampled; HA are generally well vascularized, and biopsy significantly increases risk of bleeding; and both FNH and HA may have the appearance of a well-differentiated hepatocellular neoplasm and can be difficult to distinguish. In practice, percutaneous biopsy in the case of suspected FNH or HA often does not add information that aids

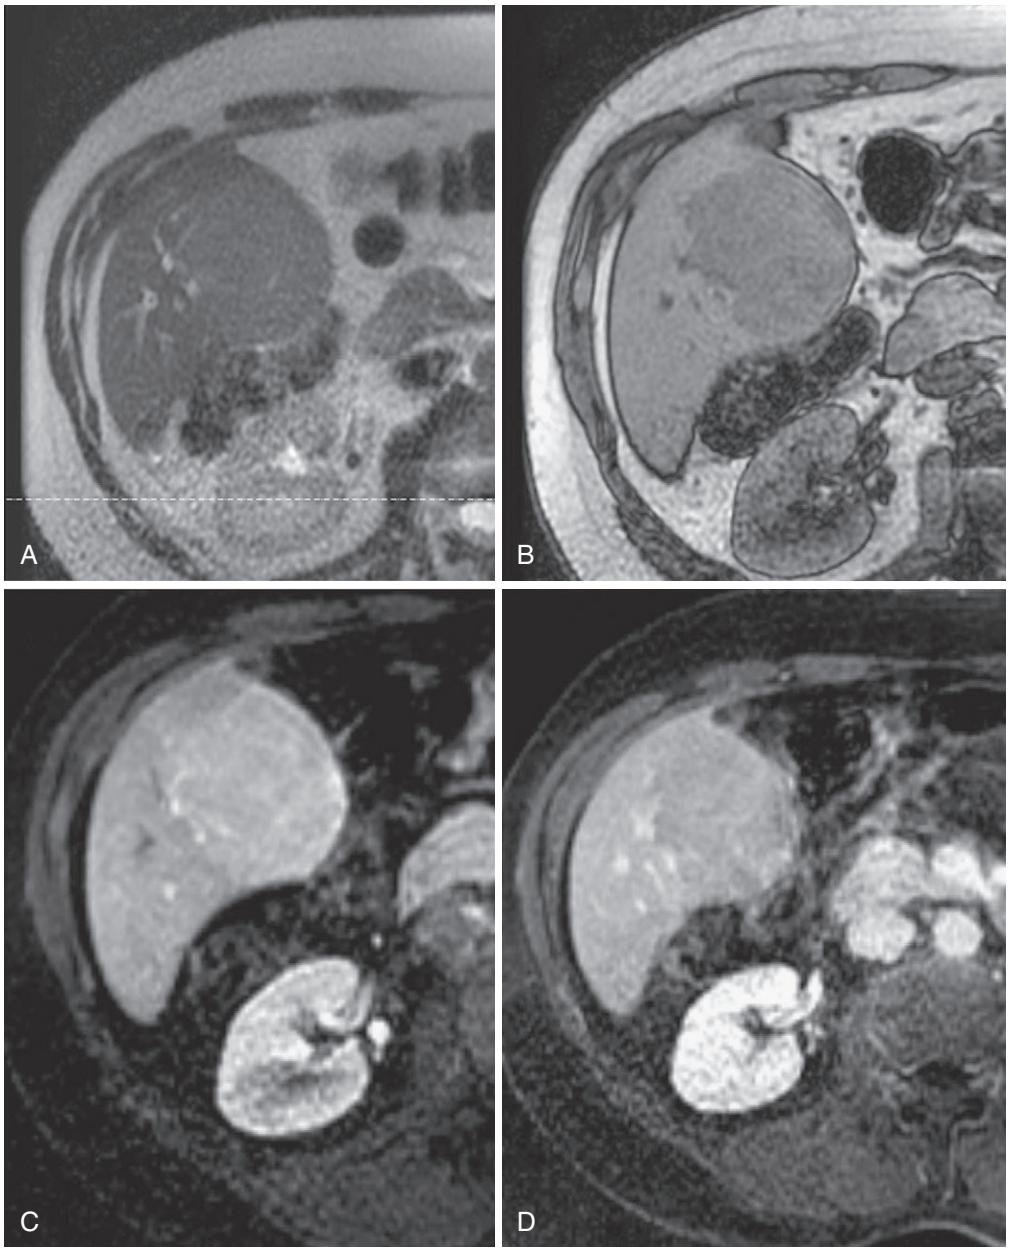

FIGURE 3 Typical magnetic resonance imaging (MRI) findings in hepatic adenoma. **A,** T2 weighted imaging with slight hypointensity. **B,** T1 weighted, out of phase, fat suppressed imaging sequence showing signal loss in lesion, suggestive of intralesional lipid content. **C** and **D,** Early arterial and portal venous phase post contrast sequences.

in clinical decision making. The field is in evolution, however, and more sophisticated molecular and genetic analysis of these biopsy specimens may lead to changes in clinical management, discussed in the following sections.

SURGERY FOR BENIGN LIVER LESIONS

In general, there are three indications for resection of benign liver lesions: (1) symptoms, (2) inability to rule out malignancy, and (3) prevention of malignancy or complications. Careful documentation of symptoms and review of imaging and or pathologic data are critical in deciding whether to proceed with resection.

Liver Cysts

Simple cysts of the liver are present in up to 5% of all adults, and most are benign. Asymptomatic cysts do not warrant intervention or serial examination. Potential symptoms may include pain, especially with cysts that are complicated by hemorrhage; shortness of breath, with lesions located in a subdiaphragmatic position; and early satiety or nausea, with lesions that cause mass effect on the stomach or duodenum. Symptoms are rare with cysts smaller than 5 cm. Liver cysts can manifest with acute symptoms when hemorrhage occurs within the cyst. These episodes of hemorrhage are rarely life-threatening and are generally self-limited. The cyst may take on a more complex appearance with an episode of bleeding, suggested by increased attenuation, heterogeneity, and layering of the fluid on cross-sectional imaging. It is important to distinguish these findings from those that may be suggestive of a biliary cystic neoplasm such as biliary cystadenoma or cystadenocarcinoma, as these lesions require a more formal resection.

When symptomatic, the ideal intervention for simple liver cysts is surgery. Needle aspiration of simple liver cysts should only be reserved to identify symptomatic response, as the cyst will inevitably recur and instrumentation of the cyst can lead to infection, bleeding, or inflammation that will make surgical intervention more difficult.

TABLE 1: Postcontrast cross-sectional imaging: typical findings of the most common liver lesions

Lesion	CT scan	MRI
Simple cyst	Density equivalent to water Does not communicate with biliary tree	Bright on T2-weighted imaging, water density May show proteinaceous density if prior hemorrhage has occurred
Hemangioma	Early peripheral nodular enhancement in arterial phase, centripetal filling in, follows blood pooling	Same contrast findings as for CT Bright on T2-weighted sequences ("light bulb" sign)
Hepatic adenoma	Hypervascular on early arterial imaging Isointense or hypointense on venous phase	Distinguished from FNH by presence of fat; may be appreciated on in-phase and out-of-phase imaging; lack of central scar
FNH	Hypervascular on early arterial phase imaging and isodense in comparison with surrounding liver on portal venous phase	Similar postcontrast findings as on CT; central scar may be enhanced on equilibrium phase images Will take up liver-specific contrast agents (e.g., gadoxetic acid [Eovist]) on hepatobiliary phase (20-30 min)

CT, Computed tomographic scan; *FNH,* focal nodular hyperplasia; *MRI,* magnetic resonance imaging.

Placement of a percutaneous drain into a simple liver cyst is almost never indicated.

The goal of surgery for simple liver cysts is elimination of symptoms. This is generally achieved by fenestration of the cyst, which entails excising a portion of the cyst wall, close to its margin with normal liver. This may be followed by ablation of the interior cyst wall with argon beam or electrocautery, although care must be taken not to damage any vascular or biliary structures that may be present along the inner wall of the cyst. Placement of a pedicled omental flap into the cyst cavity is a technique favored by some surgeons to prevent recurrence of the cyst. Complete resection of the cyst is generally not necessary except in cases in which an underlying cystadenoma or cystadenocarcinoma is suspected or in the setting of polycystic liver disease for which anatomic resection may be more effective. Simple cyst fenestration is often amenable to a laparoscopic approach with either ultrasonic shears or a bipolar vessel sealing device to excise the cyst wall. For cysts located in the right posterior sector, positioning of the patient in either the semilateral or full left lateral decubitus position can help optimize exposure laparoscopically.

Care should be taken in carrying the line of excision through adjacent liver parenchyma because large biliary and vascular structures can be compressed by the cyst and may not be clearly visualized on preoperative imaging. This is especially true in the setting of giant liver cysts (>20 cm) and may result in bile leakage or significant bleeding. Use of an Endo GIA vascular load stapler can help prevent this occurrence. If bleeding or bile leakage occurs, use of the stapler or clips or placement of a laparoscopic stitch can often remedy the situation. Bleeding from a rent in a major hepatic vein branch can be minimal in the presence of pneumoperitoneum, as the pressure of carbon dioxide often exceeds central venous pressure. If the patient becomes hemodynamically unstable or if laparoscopic maneuvers fail, then conversion to an open operation is necessary. If there was a prior episode of bleeding in the cyst, as evidenced by expression of thick chocolate-colored fluid from the cyst, there may be significant inflammatory adhesions of the cyst to the peritoneum or diaphragm. After completion of the fenestration, routine drainage of the resection bed is generally not performed. Short-term and long-term relief of symptoms in well-selected patients is excellent after surgery.

Hepatic Hemangioma

Hepatic hemangiomas are the most common benign neoplasm of the liver and can be definitively diagnosed with multiphasic (liver protocol) CT or MRI. Typical characteristics include peripheral "puddling" of early phase contrast agent in the lesion, followed by centripetal enhancement on later portal venous phase images, mirroring the blood pool. Hemangiomas are universally benign, with no risk of malignant degeneration and an exceedingly small risk of rupture or bleeding. Asymptomatic hemangioma may be managed safely with observation, without the need for serial imaging. Large hemangiomas can potentially cause symptoms from mass effect, including pain, shortness of breath, and early satiety. Lesions smaller than 5 cm rarely cause symptoms. Giant cavernous hemangiomas (>10 cm) of the liver are relatively rare but can be complicated by specific physiologic problems. Kasabach-Merritt syndrome can be observed with giant cavernous hemangiomas and is characterized by a consumptive coagulopathy, which leads to an appearance of disseminated intravascular coagulation. Typical findings include thrombocytopenia, hypofibrinogenemia, coagulopathy, and evidence of fibrinolysis. High-output cardiac failure resulting from arteriovenous shunting is usually observed only in the pediatric population.

In patients with symptoms or complications of hemangioma, intervention is warranted. Resection is the treatment of choice for patients who are healthy enough to undergo surgery. In many cases, enucleation is technically possible, as large hemangiomas tend to compress the adjacent liver parenchyma, creating a plane of dissection that is favorable to enucleation. Often a major arterial feeding branch can be identified that, when ligated, makes the hemangioma less tense and easier to manipulate. Extrahepatic clamping or ligation of the left or right hepatic artery can also facilitate dissection by decompressing the hemangioma. Formal anatomic resection is also an option and may be an appropriate choice with regard to the location and size of the hemangioma. For patients who are not candidates for surgery, bland embolization of giant hemangiomas has been performed in the past with some success. Pharmacologic therapies, including antiangiogenic medications, have been reported on an anecdotal basis and may represent another therapeutic modality for patients who cannot undergo surgery.

Focal Nodular Hyperplasia

FNH represents a nodular, polyclonal proliferation within the liver that contains all cellular elements of liver parenchyma. These lesions have no potential for malignancy or for spontaneous rupture or hemorrhage. The only two indications for resection of FNH are symptoms (e.g. pain, early satiety, weight loss) and inability to rule out malignancy. In general, the issue with this condition is

establishing a definitive diagnosis, which can often be achieved with modern imaging technologies. Patients without symptoms who have typical imaging findings of FNH should not be offered resection and generally do not need long-term surveillance. Patients who do experience abdominal pain must have a careful evaluation to rule out other sources of pain, especially in patients with lesions smaller than 5 cm. A detailed history, physical examination, and correlation of the patient's complaints to the anatomic findings on imaging are necessary before surgical resection is offered for this condition. Resection must not be offered on the basis of anatomic or technical considerations alone.

Hepatic Adenoma

HAs are benign neoplastic growths of hepatocytes that typically occur in the setting of a normal background liver and tend to be hormonally sensitive. The classic clinical presentation is that of a young woman (aged 20s to 40s) with a history of oral contraceptive use. Anabolic steroid use in men can also lead to the development of HA. Other risk factors include glycogen storage disease and pregnancy. Patients may present with a hepatic mass incidentally identified on cross-sectional imaging, with abdominal pain, or more acutely with spontaneous rupture or hemorrhage. Contrast agent–enhanced MRI with in-phase and out-of-phase imaging is the optimum diagnostic imaging method for this entity. Typical findings include arterial hyperenhancement without washout and "dropout" in fat-suppressed imaging sequences, which suggest the presence of lipid within the mass. The radiographic diagnosis can be more difficult in the setting of a steatotic liver.

Patients with a diagnosis of HA who are taking oral contraceptives or anabolic steroids should discontinue those medications and undergo interval reassessment. The risk of malignancy in HA is correlated approximately with size; the risk of an occult hepatocellular carcinoma (HCC) within the lesion increases once the adenoma is larger than 5 cm. In most series of resected HA findings suggest that the risk of having a previously undiagnosed HCC is between 4% to 15% in affected patients. In men, the risk of HCC in HA can be as high as 47%, prompting some authorities to recommend that all HA in men who are not taking exogenous steroids should be considered for resection. Most of these series are retrospective case series of relatively small numbers of patients who have undergone resection, and thus they introduce an element of selection bias. Furthermore, very few studies, outside of anecdotal reports, have enabled the researchers to estimate the risk of malignant transformation of HA over time. Because of the relative rarity of this lesion, characterization of the long-term natural history is difficult. However, current indications for resection of HA include (1) size larger than 5 cm; (2) symptoms, including bleeding; (3) inability to rule out malignancy; and (4) male gender. Patients with HA who do not meet criteria for resection should be monitored with serial cross-sectional imaging and alpha-fetoprotein levels.

Data have helped categorize HA by molecular changes that are correlated with clinical behavior and may help stratify these lesions by risk. The most intriguing of these data involve the gene that encodes beta-catenin, *CTNNB1:* 15% to 19% of all HA harbor an activating mutation of *CTNNB1* and have a significantly higher incidence of HCC. In one series, 6 (46%) of 13 resected HA with activating mutations of *CTNNB1* were found on final pathologic study to have either HCC, HCC within a background of HA, or borderline HCC/HA. Of lesions that did not have a *CTNNB1* mutation, only 8% were thus characterized. Two other categories of HA have been proposed in addition to *CTNNB1* overexpression: (1) HA with *HNF1a* gene inactivation (30% to 50% of all HA), which show significant intralesional steatosis, and (2) those with *CRP/SAA* expression (30% to 35% of all HA) which demonstrate inflammatory HA histology, and are more common in the setting of obesity, hepatic steatosis, and alcohol use (previously categorized as telangiectatic FNH). Of patients with either of these types, neither show as high a risk of HCC as those with *CTNNB1* overexpression. How these genotype-phenotype correlations will guide treatment is still in evolution, but risk stratification of HA with preoperative biopsy and genetic analysis may become a useful diagnostic test in the future.

In general, a wide margin of resection is not necessary for HA, as 90% of such lesions are benign. However, malignancy can be difficult to identify preoperatively, and frozen-section analysis is not reliable to distinguish well-differentiated HCC from HA. If possible, a negative margin resection should be performed in the case that HCC is identified on final histopathologic analysis. Aggressive vascular resection and reconstruction is not indicated in affected patients. HA characterized by high lipid content may be more difficult to palpate at operation; thus intraoperative ultrasonography and high-quality preoperative cross-sectional imaging are essential in guiding the resection plane. HA that manifest with acute bleeding are optimally treated with bland embolization to control the acute hemorrhage, followed by elective resection.

Formal resection at the time of acute hemorrhage is generally not recommended, although if the patient has life-threatening hemorrhage or if the lesion is refractory to transarterial interventions, then laparotomy may be necessary to achieve hemostasis. In these instances, the operation is analogous to a trauma laparotomy in which use of inflow occlusion (Pringle's maneuver), packing and pressure, topical hemostatic agents, and selective hepatic arterial ligation are potentially useful maneuvers. If formal resection is possible in an expeditious way, then it is also an option in the acute setting, although in patients with massive blood loss and hemodynamic instability, resection should not be attempted. Ethanol injection into the lesion, as well as radiofrequency energy (delivered either via ablation probe or a saline-linked radiofrequency device), can also be helpful to achieve hemostasis in this situation.

SUMMARY

Treatment of benign liver lesions requires a thoughtful assessment of clinical, radiographic, and pathologic data. The majority of these lesions do not require surgical intervention and can be managed safely by observation or monitored with serial imaging. Many affected patients require surgery, but clinicians must resist the temptation to recommend surgery simply on the basis of anatomic or technical considerations. The improvement in techniques of liver surgery, including the development of laparoscopic techniques, has reduced the rates of morbidity and mortality associated with these operations and in some ways has changed the risk/benefit balance of surgery. Although benign liver lesions represent a potentially ideal indication for laparoscopic liver resection, clinicians must be careful not to change the indications for surgery solely on the basis of ability to perform the operation.

The Management of Malignant Liver Tumors

Laleh G. Melstrom, MD, MS, and Yuman Fong, MD

OVERVIEW

Hepatocellular carcinoma (HCC), fibrolamellar hepatocellular carcinoma, and intrahepatic cholangiocarcinoma (ICC) are the malignant tumors discussed in this chapter; the surgical management of metastatic liver tumors is discussed elsewhere in this book. Surgical therapy, in the form of resection or transplantation, results in the best outcomes and may result in cure. Many patients with HCC or ICC, however, have associated liver parenchymal disease such as cirrhosis from viral hepatitis. This and other comorbid conditions may increase the risk that surgical therapy.

Selection of patients with primary hepatic malignancies for resection is generally based on the localized nature of the tumor, whether it is technically resectable, and the adequacy of residual liver to support life. Patients with unresectable small tumors are offered liver transplantation or thermal ablation. Large or multiple unresectable disease and disseminated disease are treated with combinations of transcatheter embolization and systemic therapies.

HEPATOCELLULAR CARCINOMA

HCC represents the most common solid tumor worldwide, occurring in nearly 1 million patients yearly. In the United States, approximately 25,000 patients present with HCC annually. This cancer is associated with liver parenchymal injury, such as that from chronic hepatitis B or C viral infection. Overall, the long-term survival in HCC is poor, at less than 5%, because for most patients, the associated liver cirrhosis precludes resection.

Surgical Resection

Surgical resection is generally offered to patients with liver-localized disease and adequate hepatic reserve for recovery. In general, these patients have class Childs A cirrhosis. Outcome after resection for HCC depends on whether the resection margin is tumor-free, degree of cirrhosis, presence of vascular invasion, presence of satellite lesions, tumor size (>5 cm), bilobar involvement, and involvement of regional lymph nodes.

Among patients with resectable tumors, most Western (American and European) series have demonstrated 5-year survival rates ranging from 27% to 64%, and Eastern (Asian) series have documented 5-year survival rates ranging from 21% to 49%. The lower survival rates likely relate to the increased rate of cirrhosis and hepatitis B infection. In modern large series, morbidity rates range from 30% to 50% and mortality rates range from 1.6% to 5.3%.

Liver Transplantation

Liver transplantation is generally offered to patients with cirrhosis who do not have major cardiopulmonary comorbid conditions and whose local disease is limited. The Milan criteria (Lim et al., 2012) are the most commonly used tumor criteria for selection of patients for transplantation. The criteria include either one tumor less than 5 cm in size or three or fewer lesions, each less than 3 cm. Of patients with such limited disease, 60% to 80% are alive 5 years after transplantation.

Thermal Ablation

Small tumors can also be effectively killed by radiofrequency ablation or microwave ablation. Treatment effectiveness is directly related to the size of tumor and ease of access. Ablations can be performed during open surgery, through laparoscopy, or through percutaneous access. Proximity of the tumor to major blood vessels may attenuate effectiveness by a "heat sink" effect. There have been three randomized trials published to date demonstrating equal survival outcome among patients who underwent resection and those who underwent radiofrequency ablation for small HCC. The rate of morbidity from radiofrequency ablation is usually less than 10%, and the rate of mortality is less than 0.5%.

Embolization

If a lesion is found to be unresectable intraoperatively or preoperatively, other treatment options include transarterial chemoembolization (TACE), transarterial embolization (TAE), and radioembolization. Thrombosis of the portal vein is considered a contraindication to TACE or any transarterial modality because of the risk of severe hepatic insufficiency after the procedure. Risks associated with transarterial therapies include the postembolization syndrome, characterized by fevers and abdominal pain. Other serious complications can arise such as gallbladder infarction, pancreatitis, hepatic insufficiency, and sepsis. Response rates can be as high as 80%. In both TAE and TACE, patients require interval treatments approximately every 3 to 6 months.

FIBROLAMELLAR HEPATOCELLULAR CARCINOMA

Fibrolamellar HCC is very different from HCC. This cancer usually occurs in patient with no parenchymal liver injury or cirrhosis. It also occurs in young patients, with a median age of 27 years. These tumors secrete characteristic hormones and proteins, such as neurotensin and vitamin B_{12}–binding protein. Thus fibrolamellar tumors may be the primary neuroendocrine tumors of the liver.

These tumors also behave like neuroendocrine tumors in that they are well circumscribed and most often separate from adjacent blood vessels, even when they are large. Thus they are much more likely to be resectable than classic HCC. In addition, they are slow growing, and complete cytoreduction for multifocal disease can result in long-term survival. Surgical resection results in a 5-year survival rate of 30% to 50%.

Fibrolamellar HCC represents nodal metastases in 15% to 30% of cases. Thus the lymph nodes in the porta hepatis, celiac region, and peripancreatic areas should be examined and, if suspect, either sampled or dissected. In cases of nodal recurrence after previous liver resection, exploration and dissection of the recurrent lymph nodes represent rational therapy.

INTRAHEPATIC CHOLANGIOCARCINOMA

ICC is also known as *peripheral cholangiocarcinoma*. These tumors are also associated with viral hepatitis and cirrhosis and, consequently, are much more common in Southeast Asia. In the United States, the incidence of ICC is approximately 5000 cases yearly. The incidence is increasing, probably because, as a result of better pathologic diagnosis, many tumors that used to be called *metastases of unknown origin* have been determined to be ICC.

Surgical resection remains the best option and the only potentially curative option. Diagnostic laparoscopy should be considered for patients with ICC because of the high incidence of peritoneal metastases. Because up to one third of patients have nodal metastases, the regional nodes should be sampled and formally dissected if the samples are positive for cancer. Series published on outcomes after resection for ICC show that the 5-year survival rate for R0 resections ranges from 44% to 63%. The mortality rate has been documented at 2% to 7%.

Most patients at presentation are not candidates for resection because of peritoneal, lung, or bone metastases.

TABLE 1: Child-Turcotte-Pugh score*

Measure	1 Point	2 Points	3 Points
Total bilirubin (mg/dL)	<2	2-3	>3
Serum albumin (g/L)	>35	28-35	<28
PT/INR	<1.7	1.71-2.30	>2.30
Ascites	None	Mild	Moderate to severe
Hepatic encephalopathy	None	Grades I-II (suppressed with medication)	Grades III-IV (refractory)

*The score employs five clinical measures: class A, 5-6 points; class B, 7-9 points; class C, 10-15 points.
PT/INR, Prothrombin time/international normalized ratio.

PREOPERATIVE ASSESSMENT

General Preoperative Assessment

Once a diagnosis is made, the patient's comorbid conditions, baseline liver function, tumor staging, and size of the future liver remnant (FLR) are all taken into consideration in the development of a treatment plan.

Assessment of medical condition and liver function is initiated with baseline blood work, including complete blood cell count, coagulation studies (prothrombin time/international normalized ratio [PT/INR]), complete metabolic panel, and hepatitis panel. Tumor markers (alpha-fetoprotein, carcinoembryonic antigen, cancer antigen 19-9) are studied to assist in diagnosis, as well as for determination of the usefulness of such markers for follow-up.

Defining tumor anatomy in relation to the healthy part of the liver is a key step in determining resectability. Imaging should include a triple-phase contrast computed tomographic (CT) scan of the abdomen and pelvis and a CT scan of the chest with intravenous contrast medium. Tumors that are hypervascular, such as HCC and metastatic neuroendocrine tumors, demonstrate increased uptake in the arterial phase, whereas tumors such as ICC and metastatic colorectal cancer demonstrate increased enhancement in the portal venous phase. CT scanning can be performed with concurrent magnetic resonance imaging of the liver in equivocal circumstances without a tissue diagnosis. A diagnosis of HCC can be made for lesions greater than 2 cm that appear hypervascular on two separate imaging modalities or for a focal hypervascular lesion greater than 2 cm and serum alpha-fetoprotein levels greater than 400 ng/mL. For larger high-risk tumors, a bone scan should also be considered for patients with HCC.

Comorbid conditions such as chronic renal failure, congestive heart failure, or severe chronic obstructive pulmonary disease may often preclude offering surgical management. In addition, comorbid conditions such as renal insufficiency, heart disease, and diabetes add a level of risk for postoperative morbidity and mortality.

Assessing liver function is important in determining whether a resection is feasible with acceptable morbidity and mortality risk. The Child-Turcotte-Pugh (CTP) score (Table 1)—which includes total bilirubin, serum albumin, PT/INR, the presence of ascites, and the presence of hepatic encephalopathy—subdivides liver disease into categories (A, B, and C) that translate into perioperative mortality risk for liver resection. CTP B and C scores imply risks for operative mortality of 30% and 80%, respectively. Traditionally, only patients with CTP A scores were considered candidates for surgical resection.

Other factors that ought to be taken into consideration include a platelet count of less than 100,000/mm^3, radiologic indicators of cirrhosis or portal hypertension (such as the contour of the liver and splenomegaly), periportal and abdominal wall collateral vessels, and esophageal varices. The presence of these factors may make a large liver resection prohibitively risky.

The Future Liver Remnant

In order to minimize the risk of hepatic failure postoperatively, a minimum volume of liver is necessary for adequate hepatic function. In general, in a healthy, noncirrhotic liver, an FLR of 20% is adequate. In patients with chronic liver disease, a FLR of 40% is correlated with acceptable risk. This value is calculated most frequently on three-dimensional CT volumetry, whereby the FLR is the total liver volume (as calculated slice by slice) minus the planned resection volume. Another formula-based estimate is total liver volume (TLV) (cm^3), which is calculated as $-794.41 + 1267.28 \times$ body surface area (m^2). The ratio of the FLR volume measured on CT scan to calculated TLV is known as the "standardized FLR." Studies have demonstrated that a standardized FLR volume of less than 300 mL/m^2 is correlated with death and liver failure. Inadequate FLRs are correlated with increased hepatocellular injury and inadequate liver regeneration, which are correlated with subsequent morbidity and mortality secondary to hepatic failure.

In both healthy and diseased livers, a reasonable strategy to induce contralateral liver growth before resection has been to utilize portal vein embolization (PVE). PVE is performed through percutaneous access of the ipsilateral portal vein with particle embolization, with the use of microparticles and microcoils. By impeding portal venous blood flow to the side of the liver ipsilateral to the tumor, hypoxia-induced growth factors and shunted portal venous flow induce growth to the contralateral lobe and thus potentiate growth of the FLR before resection. In addition, PVE is used as an in vivo assessment of regenerative capacity. In patients with liver disease, PVE has been shown to decrease hepatic insufficiency, perioperative complications, and postoperative mortality. Furthermore, TACE for HCC followed by PVE several weeks later has been a useful strategy to optimize both perioperative and oncologic outcomes in these patients. Some centers are utilizing preoperative hepatic arterial

embolization in primary HCC to induce necrosis and possibly to decrease tumor spillage and vascular spread of tumor cells intraoperatively. This may make resection more technically challenging secondary to the induced fibrosis.

OPERATIVE APPROACH TO RESECTION OF PRIMARY LIVER MALIGNANCIES

In general, the principles of liver resection revolve around controlling inflow and outflow vessels, parenchymal transection, and tumor clearance. These factors are all taken into account in the context of presumed adequate residual liver volume. Maintenance of a low central venous pressure is a key anesthetic principle to minimize backward bleeding from the hepatic veins during parenchymal transection. This entails accepting a urine output of 25 mL/hr and prompt reexpansion of intravascular volume after the resection is complete. The patient is kept in 15 degrees of the Trendelenburg position to maintain adequate cardiac preload and to decrease the risk of air embolism via openings in the hepatic veins during transection.

Incision and Access

Exposure is a key component of any hepatectomy. A right subcostal, hockey stick–type incision is the most commonly used for liver resection and gives excellent access and exposure for most right-sided tumors. For left-sided tumors, a midline incision extending superiorly to the xyphoid process should provide adequate exposure. Access to the suprahepatic portion of the inferior vena cava should be ascertained for particularly high-positioned tumors along the dome of the liver. The abdomen and chest should be prepared in such a way that a thoracoabdominal incision or sternotomy can be made intraoperatively if necessary.

Right Hepatectomy

After inspection of the peritoneal cavity, the falciform ligament is ligated and divided. The falciform ligament is tied with a long suture so that it can serve as a retraction handle. The liver is then mobilized by further dividing the falciform ligament to the dome of the liver. Intraoperative liver ultrasonography is performed to ascertain that all disease is identified. The triangular ligament is then divided. The liver is retracted to the patient's left side as the retroperitoneal attachments and the smaller branches from the right lobe to the inferior vena cava are ligated and divided. The gallbladder is then removed with suture ligation of the cystic duct stump.

Traditionally for major liver resections, the inflow and outflow vessels for the liver are dissected free outside the liver, controlled, and divided before liver parenchymal transection. The perforating veins to the retrohepatic portion of the inferior vena cava are usually dissected first. The right hepatic vein is then dissected and controlled by encircling it with a vessel loop. It is important not to divide the hepatic veins before the portal vein/hepatic artery (inflow). The right portal vein and right hepatic artery are then dissected free outside the liver and ligated with sutures or staples. Attention is then brought to the porta hepatis, where the hepatoduodenal ligament is controlled in preparation for a Pringle maneuver (intermittent occlusion of the inflow to the liver). The right hepatic vein is then divided before liver parenchymal transection.

More recently, the intrahepatic approach to vascular inflow control has been popularized. This technique is useful when the tumor is more than 2 cm from the hilus of the liver. When cancer is too close to the junction of the left and right inflow vessels, however, the risk of causing a positive tumor margin is too great with the intrahepatic approach.

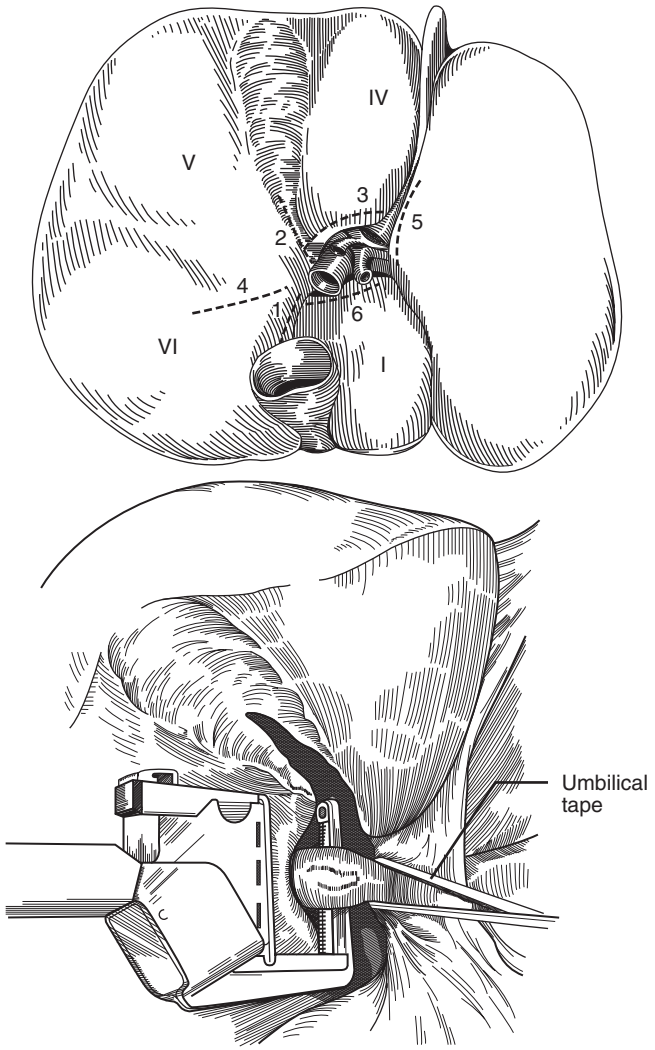

FIGURE 1 To access the right portal pedicle *(top)*, hepatotomies are made in the gallbladder fossa (2) and in the caudate process (1). The pedicle is encircled with a renal pedicle clamp, and a vessel loop is passed around it. The vessel loop is used to retract the main portal vein/left portal vein to the left as a TA stapler is passed and fired to divide the right portal pedicle *(bottom)*. *(From Fong Y, Blumgart LH: Useful stapling techniques in liver surgery,* J Am Coll Surg *185:93, 1997).*

In the intrahepatic vascular approach, two incisions are made: one in the gallbladder bed and one in the caudate process. These are utilized to isolate the anterior and posterior sectoral inflow pedicles with umbilical tapes. The pedicles are then divided with a TA stapler (Figure 1, bottom). The advantages of this approach are that it is fast and it minimizes injury to the contralateral pedicle. Once the inflow is divided, the right hepatic vein can be ligated and divided. This is most frequently done with an endovascular stapler or by suture ligation.

For parenchymal transection, the authors place a 0 chromic suture on a large blunt needle through the gallbladder fossa and another just to the left of the transection line as handles for ease in liver mobility. The transection line is identified by the demarcation seen after the inflow is divided. This line appears primarily to the right of the course of the middle hepatic vein. The parenchyma can be divided with various coagulation devices. The authors utilize the

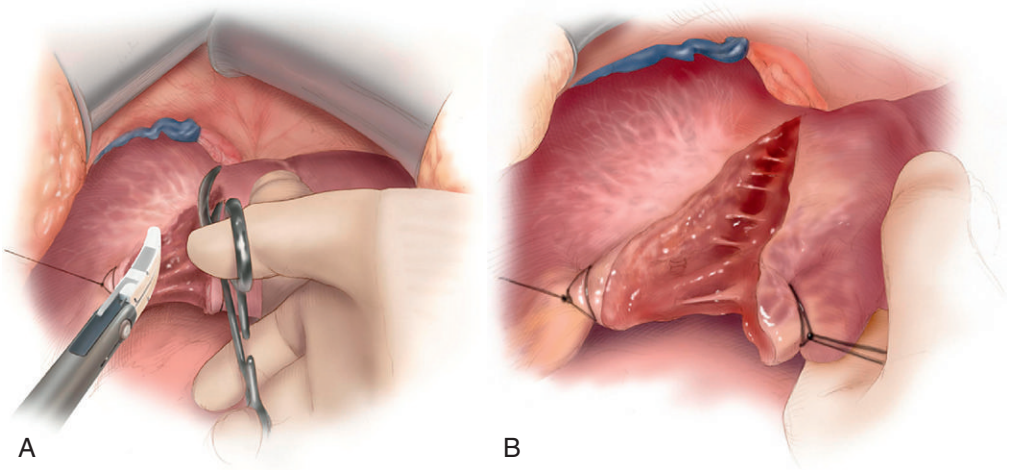

FIGURE 2 To divide the liver parenchyma, two stay sutures are placed for traction. The parenchyma is sequentially crush-clamped with a Kelly clamp; this demonstrates various size pedicles and veins. Those smaller than 5 mm are sealed and divided with the LigaSure device. If the structure is larger than 5 mm, the endovascular stapler, clips, and ties are used. *(From Patrlj L, Tuorto S, Fong Y: Combined blunt-clamp dissection and LigaSure ligation for hepatic parenchyma dissection: postcoagulation technique,* J Am Coll Surg *210:39, 2010.)*

traditional crush clamp technique with a Kelly clamp to sequentially crush liver parenchyma and reveal more prominent hepatic veins and pedicles (Figure 2). Vessels less than 5 mm in diameter can be divided with a LigaSure device (Covidien, Boulder, Colo) (see Figure 2). If they are larger, they should be tied or stapled. The parenchyma is methodically divided opening the line of transection like a book, layer by layer. As the authors approach the hepatic veins, the vein branches become more prominent, and the authors often utilize the vascular stapler.

After the specimen is delivered, the authors coagulate the surface with the argon beam, look for any profusely bleeding areas, and address those areas by coagulation or suture ligation. The authors then ask the anesthesiologist to initiate resuscitations to a central venous pressure of at least 8 cm H_2O in order to recognize any occult back bleeding from hepatic veins that are not adequately sealed.

Extended Right Hepatectomy

The principles of an extended right hepatectomy are the same as those for a right lobectomy except for the inclusion of segment IV of the left lobe and transecting the liver to the left of the middle hepatic vein. In this circumstance, the inflow is not completely controlled at the porta hepatis by dividing only the right portal vein and right hepatic artery. Recurrent inflow vessels arising in the umbilical fissure need to be ligated.

Left Lobectomy

The initial steps of a left lobectomy include mobilizing the falciform ligament and getting around the porta hepatis. The left triangular ligament is mobilized with care so as to not injure the left phrenic vein superiorly and the esophagus posteriorly. During mobilization of the left hepatic lobe, the ligamentum venosum is identified and divided after the liver is retracted to the patient's right. Branches from the left lobe and the caudate lobe to the inferior vena cava are identified and ligated to maximize mobility. The most challenging aspect of a left lobectomy is identifying and isolating the left and middle hepatic veins (particularly for large left-sided tumors).

The left lobe inflow has a much longer extrahepatic course than does the right. In extrahepatic control of inflow vessels, the left hepatic artery is identified, ligated, and divided first, followed by the left portal vein and then the bile duct. When intrahepatic pedicle ligation is used, hepatotomies are created in segments IV and II. The main left portal pedicle is then isolated and stapled.

Extended Left Hepatectomy

This will include a caudate resection and segments V and VIII. The challenging aspect of this procedure is defining the line of transection to the right of Cantlie's line that will remove segments V and VIII and not injure the right hepatic vein and the inflow to the posterior sector. In addition, often the segment VII inflow vessels arise from the anterior pedicle and not the posterior pedicle. Noting this anomaly and protecting the segment VII vessels are essential for saving enough functional liver.

Caudate Resection

The caudate can be approached from the right or left, depending on where the lesion is. The most tedious portion of resection of the caudate is meticulous isolation of perforating veins from the back of the caudate to the inferior vena cava. The most perilous aspect of this resection is losing control of the junction of the middle and left hepatic veins, where the highest caudate vein enters. In addition, the inflow from branches of the right and left portal vein need to be controlled.

Segmental and Wedge Resections

Lesions are often removed with wedge or segmental resections in order to preserve as much functional liver volume as possible. This is most relevant in the context of liver disease that precludes large anatomic resections. In segmental resections, vascular control is most often obtained in an intraparenchymal manner. (Figure 3 outlines the lines of segmental resection.)

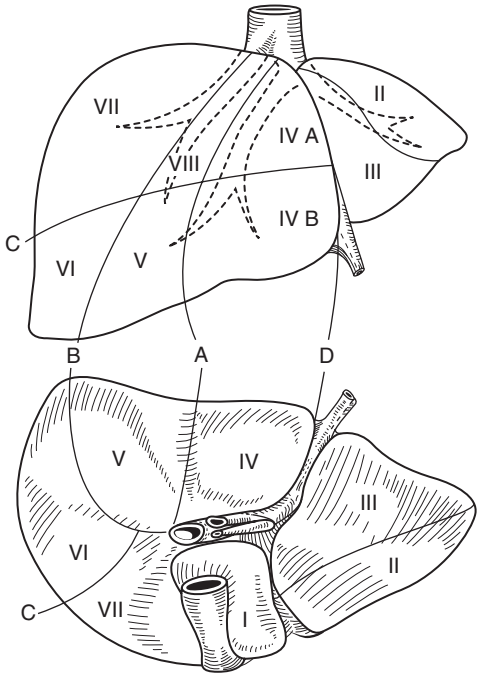

FIGURE 3 The lines of resection for the various segments. Segments VI and VII are resected in right posterior sectorectomy. Segments V and VIII are resected in right anterior sectorectomy. Segments IV, V, and VIII are resected in central hepatectomy. *(From Blumgart LH, editor:* Video atlas: liver, biliary & pancreatic surgery, *Philadelphia, 2011, Elsevier, p 73.)*

TREATMENT FOR HEPATOCELLULAR CARCINOMA: RESECTION VERSUS TRANSPLANTATION

Jayme E. Locke, MD, MPH, and Andrew M. Cameron, MD, PhD

INTRODUCTION

Hepatocellular carcinoma (HCC) is the most common primary hepatic malignancy worldwide. It is three times more common in men and is most prominent in Asia and Africa. More than 80% of HCCs arise in the setting of cirrhosis, and patients with cirrhosis have an annual HCC incidence of 3% to 10%. It is thought that HCC arises from adenomatous hyperplasia, which progresses to atypical hyperplasia and ultimately deteriorates to overt malignancy. In addition to a cirrhotic liver, risk factors for the development of HCC include viral hepatitis (especially hepatitis B), aflatoxins, azo dyes, aromatic amines, N-nitrose compounds, chlorinated hydrocarbons, hydrosol compounds, pesticides, radiation, Thorotrast, smoking, porphyria, Budd-Chiari syndrome, oral contraceptives, anabolic androgenic steroids, and alpha-1 antitrypsin.

Over the past decade, the management of patients with chronic liver disease has improved, and in parallel, the prevalence of viral hepatitis, including hepatitis B and hepatitis C, has increased. As a result, there has been a dramatic increase in the number of patients diagnosed with compensated HCC. HCC is now well recognized as an important complication of cirrhosis and is a leading indication for liver transplantation. Currently, one third of patients with end-stage liver disease who are awaiting liver transplant carry the diagnosis of HCC. If left untreated, the 5-year survival is less than 10% and median survival is less than 6 months. As with most malignancies, HCC is amenable to cure when identified at an early disease stage, highlighting the importance of routine surveillance in patients who are at risk. Combining serum alpha-fetoprotein (AFP) levels with ultrasonography has proven to be the most sensitive and specific modality for HCC screening. AFP levels greater than 400 ng/mL are highly suggestive of HCC, and ultrasonography can detect 60% to 80% of lesions that are 1 cm or smaller and 90% of lesions 3 cm or larger. Early identification of HCC increases potential therapeutic options, which include liver resection and transplantation. Patient selection for a given modality is dependent on tumor pathology, including stage, size, number, and location, and the patient's associated medical comorbidities and degree of underlying liver dysfunction. Treatment requires a multidisciplinary approach, and multiple modalities may be employed.

EVALUATION

HCC can present with a palpable liver mass, abdominal pain, and deterioration in functional status, or the tumor may be found incidentally during routine surveillance. Although relatively uncommon, paraneoplastic syndromes can occur, including polycythemia, polymyositis, hypoglycemia, and diarrhea. A history and physical exam directed at identification of underlying liver disease should be performed in order to assess disease severity and stigmata of portal hypertension. History of prior hospitalizations for gastrointestinal bleeding and the presence of caput medusa, ascites, gynecomastia, and muscle wasting are important physical findings. In addition, basic laboratory testing directed at identification of viral hepatitis, coagulopathy, and hepatorenal syndrome should be performed.

The leading cause of death after hepatic resection for HCC is liver failure, and as such, determining the hepatic reserve is of high importance. The severity of liver disease can be estimated using the Child-Pugh classification (Table 1) and the Model for End-Stage Liver Disease (MELD). Patients with Child-Pugh A cirrhosis are predicted to have a perioperative mortality rate of less than 5% and can typically tolerate having up to 50% of their liver parenchyma resected. Patients who have Child-Pugh B cirrhosis have a predicted perioperative mortality rate of 10% to 15% and should have no more than 25% of their liver parenchyma resected. Patients with Child-Pugh C cirrhosis have a perioperative mortality that is in excess of 25%, and therefore, liver resection is contraindicated. The MELD score, introduced in 2002, is used to prioritize patients on the liver transplant waiting list. The score predicts 3-month mortality and the rate ranges from 6% to 40%. Serum creatinine, total bilirubin, and international normalized ratio are used to calculate the score. Patients with scores of 15 or higher typically benefit from liver transplantation. To shorten waiting times and to increase access to liver transplantation for patients with HCC, 22 MELD exception points are routinely awarded to these patients.

In addition to various classification systems, evaluation of the functional hepatic capacity may aid in the determination of hepatic reserve. Specifically, the indocyanine green (ICG) clearance test is a useful tool in predicting liver failure following resection. ICG is injected into the patient's bloodstream, and levels are then measured 15 minutes after injection. In patients with a normal functioning liver, less than 10% of ICG dye should be detected. Patients with 15% to 20% of the dye remaining are predicted to tolerate a two-segment resection, a single segment or wedge is indicated when 21% to 30% of the dye remains, and patients with more than 40% of the dye remaining are predicted to have postoperative liver failure independent of resection size.

TABLE 1: Child-Pugh classification of cirrhosis

Parameter	1 Point	2 Points	3 Points
Albumin (g/dL)	>3.5	2.8-3.5	<2.8
Bilirubin (mg/dL)	<2	2-3	>3
INR	<1.7	1.7-2.3	>2.3
Ascites	None	Slight	Moderate
Encephalopathy	None	1-2	3-4

Child-Pugh classification is calculated by summing the points per parameter to arrive at a total between 5 and 15.
INR, international normalized ratio.
Grade A = 5-6, Grade B = 7-9, Grade C = 10-15.

IMAGING

HCC is diagnosed based on clinical and radiographic criteria, and a tissue diagnosis is not required. Percutaneous liver biopsy of the tumor is discouraged secondary to concern for seeding the biopsy track. Computed tomographic (CT) scan and magnetic resonance imaging (MRI) are the preferred imaging modalities for diagnosis of HCC. Triphasic hepatic CT imaging is ideal, as it allows for determination of tumor anatomy and proximity to major hepatic vasculature. Arterial enhancement followed by venous washout is the classic radiographic finding for HCC. In addition, CT imaging can be used to estimate the future liver remnant (FLR) and, as such, can help predict the likelihood of postoperative liver failure. FLR less than 40% is predictive of postoperative liver failure. MRI is equivalent to CT imaging in determining tumor anatomy and location, and it is an excellent alternative for patients with contrast allergies. In addition, both modalities have now replaced hepatic arteriography and can produce three-dimensional images that allow for estimation of liver volumes and perfusion territories and provide detailed intrahepatic anatomy. Ultrasonography is typically reserved for surveillance in patients at risk and, when needed, to assess intrahepatic and portal venous blood flow.

STAGING

The American Joint Committee on Cancer Tumor Node Metastasis (AJCC TNM) system uses tumor size, proximity to surrounding vasculature, local regional metastasis, and distant metastasis to determine prognosis for patients with HCC after liver resection (Table 2).

TABLE 2: AJCC/UICC TNM classification of hepatocellular carcinoma

T1	Single tumor without vascular invasion
T2	Single tumor with vascular invasion or multiple tumors, none >5 cm
T3	Multiple tumors, any >5 cm, or tumors involving major branch of portal or hepatic veins
T4	Tumors with direct invasion of adjacent organs other than the gallbladder, or perforation of visceral peritoneum
N1	Regional lymph node metastasis
M1	Distant metastasis

Stage	Tumor	Node	Metastasis
I	T1	N0	M0
II	T2	N0	M0
IIIa	T3	N0	M0
IIIb	T4	N0	M0
IIIc	Any T	N1	M0
IV	Any T	Any N	M1

The AJCC TNM classification is an oncologic standard that provides useful prognostic information about survival and disease recurrence. However, it fails to account for the severity of underlying liver disease and patients' functional status, which are major considerations in choice of treatment modality for HCC. Most recently, the Barcelona Clinic Liver Cancer (BCLC) staging system has emerged as the standard staging system for HCC. The BCLC is the only classification system that accounts for tumor-related variables (size, number, vascular invasion, local regional and distant spread), liver function (Child-Pugh), and health status of the patient (Eastern Cooperative Oncology Group Performance Status) (Figure 1).

TREATMENT

Liver Resection

Liver resection is the treatment of choice for HCC in patients without cirrhosis and can be performed in patients with cirrhosis if they have preserved liver function and portal venous pressures of 10 mm Hg or less. The ability to resect a given tumor is determined, in part, by the absence of distant metastases and tumor location in relation to major hepatic vasculature. Intraoperative ultrasound is a useful adjunct to ensure that resection can be performed safely and adequate tumor-free margins can be obtained (~1 cm). Anatomic resection is preferable, as it is thought to prevent intrahepatic metastases via the related portal vein tributary. Portal vein embolization can be used to increase the FLR and allow for resections that are more extensive. However, the effectiveness of portal vein embolization in patients with cirrhosis has not been established.

The main predictors of survival are tumor size, number, and presence of vascular invasion. In general, the survival rate is worse in patients with larger tumors, presence of micro- or macroscopic invasion, and in the setting of multiplicity, such that 5-year survival rates for patients with tumors up to 2 cm, 2 to 5 cm, and larger than 5 cm are 66%, 52%, and 37%, respectively (Table 3). Vascular invasion is the strongest predictor of tumor recurrence and correlates with tumor number and size. Approximately 70% of patients will experience disease recurrence within 5 years of resection. Neoadjuvant and adjuvant therapies have not been shown to afford any survival benefit in patients with HCC. Locoregional therapies, such as radiofrequency ablation (RFA), transarterial chemoembolization (TACE), and radiation, have been used to help downstage tumors initially regarded as unresectable.

Liver Transplantation

Over the past several decades, liver transplantation (LT) has evolved as the treatment of choice for patients with small HCC tumors, as it affords significant survival advantage over liver resection, particularly for patients with cirrhosis with limited hepatic reserve. LT simultaneously removes the tumor and corrects the underlying liver dysfunction.

NR, Not reported.

In addition, because HCC is often multifocal, total hepatectomy removes the source of potentially later-developing tumors.

During the late 1990s, the Milan criteria were introduced to help guide patient selection for LT. Adherence to the Milan criteria (solitary tumor up to 5 cm or three tumors up to 3 cm each) has improved the 5-year survival rate to over 70% and simultaneously decreased disease recurrence to less than 10% after LT (Table 4). The major limitation of LT as treatment for HCC is the scarcity of deceased donors, such that long waiting times increase the risk for disease progression. Currently, there is an approximate 20% dropout rate among patients waiting for LT that carry the diagnosis of HCC. As a result, bridging therapies, including RFA and TACE, have been introduced to maintain the tumor within listing criteria. Data from the International Liver Transplant Tumor Registry suggest that RFA combined with LT may improve overall survival. In addition, many have advocated for living donor LT to overcome the dropout rate experienced secondary to the shortage in donor organs. Although living donor LT reduces waiting time for the patient with HCC, reported outcomes have been inferior, with reduced survival and higher recurrence rates. Explanations for this phenomenon have included the loss of the observation period to assess tumor biology and less surgical oncologic clearance as the recipient inferior vena cava must be preserved.

The Milan criteria serve as a prognostic indicator of tumor biology. It has been suggested, however, that these criteria may exclude some patients with favorable biology. As a result, several efforts have been made to expand the Milan criteria. The University of California at San Francisco (UCSF) criteria include one tumor of 6.5 cm or less or multiple tumors of which the largest is 4.5 cm not to exceed 8 cm total. Alternatively, others have proposed downstaging tumors to within the Milan criteria using locoregional therapies such as RFA and TACE. Favorable results in terms of both survival and disease recurrence rates have been achieved using both the UCSF criteria and downstaging. However, these outcomes have been based on retrospective analysis of tumor burden at the time of explant, and no prospective validation has been performed.

LT has also been advocated as a salvage therapy for HCC recurrence after liver resection that is within the Milan criteria. Selected cases have shown similar 5-year survival rates among patients with salvage and primary LT. However, others have reported high operative mortality, higher recurrence rates, and a worse 5-year survival rate compared with primary LT. As a result, salvage LT remains controversial in the setting of a limited organ supply and unfavorable results.

Radiofrequency Ablation of Hepatic Metastases from Colorectal Cancer

Anna M. Leung, MD, and Anton J. Bilchik, MD, PhD

OVERVIEW

Colorectal cancer is the third most common malignancy in the United States. Worldwide every year, 1 million people are diagnosed with colorectal cancer. Fifty percent of these patients eventually have hepatic metastases develop; half do not have other metastatic sites. Surgical resection is the only treatment with proven potential for cure. However, surgical resection is feasible in only 10% to 25% of patients with metastatic colorectal cancer. The need for alternative approaches has led to the development of local ablative techniques, such as radiofrequency ablation (RFA), ethanol injection, microwave ablation, photocoagulation, high-intensity focused ultrasound, and cryosurgical ablation. Of these, RFA has become one of the most frequently used modalities to clear liver metastases from colorectal and other cancers.

INDICATIONS AND PREOPERATIVE ASSESSMENT

Patients who are poor candidates for surgical resection of hepatic metastases from colorectal cancer include those with restrictive comorbid conditions or low performance status, surgically inaccessible tumors, large tumor burden, disease recurrence, and inadequate hepatic reserve. These conditions are not necessarily contraindications for RFA because ablation can be performed without general anesthesia and normal hepatic parenchyma can be preserved.

Candidates for surgical resection or ablative techniques should undergo laboratory assessment of hepatic function. They should also undergo computed tomographic (CT) scan, magnetic resonance imaging (MRI), or fluorodeoxyglucose (FDG) positron emission tomography (PET) to evaluate the size, location, distribution, and number of hepatic lesions; to identify any nonhepatic sites; and to estimate hepatic reserve after the tumor is removed or destroyed. Systemic therapy might be the most appropriate option for patients with more aggressive tumor biology or extrahepatic disease. RFA may be an alternative to resection for patients whose postoperative hepatic reserve would be compromised, especially those patients who have hepatotoxicity from prolonged exposure to systemic chemotherapy.

Proper preoperative assessment of hepatic functional reserve usually includes clinical assessment, liver biochemistry, coagulation profile, platelet count, and Child-Pugh classification. The indocyanine green clearance test can be used in patients with chronic liver disease. In addition, computed tomographic scan, volumetry, and laparoscopy are helpful in evaluation of whether the remnant liver is adequate. Adequate volume is usually described as a remnant of at least 25% to 50% depending on the health of the liver. Preoperative techniques to increase liver volume include portal vein embolization (PVE) to induce hypertrophy of the remnant liver. PVE can increase hepatic reserve by 10% to 15% within 6 weeks of treatment.

TECHNICAL CONSIDERATIONS

Unlike cryosurgery, which destroys tumors by freezing, RFA relies on thermal destruction. Heat is generated by radiofrequency energy delivered through a needle electrode (14 to 17.5 G) that is inserted into the tumor. Dispersive electrodes (adhesive grounding pads) are placed on the back or legs. Radiofrequency energy changes the direction of ions around an alternating electrode charge, resulting in high frictional energy, heat conduction, and thermal destruction. Tissue temperatures above 45°C cause apoptosis, and tissue temperatures above 90°C create an irreversible zone of coagulation necrosis.

Radiofrequency Ablation Devices

There are three major U.S. Food and Drug Administration (FDA)–approved devices for RFA (Figure 1). The RITA (AngioDynamics,

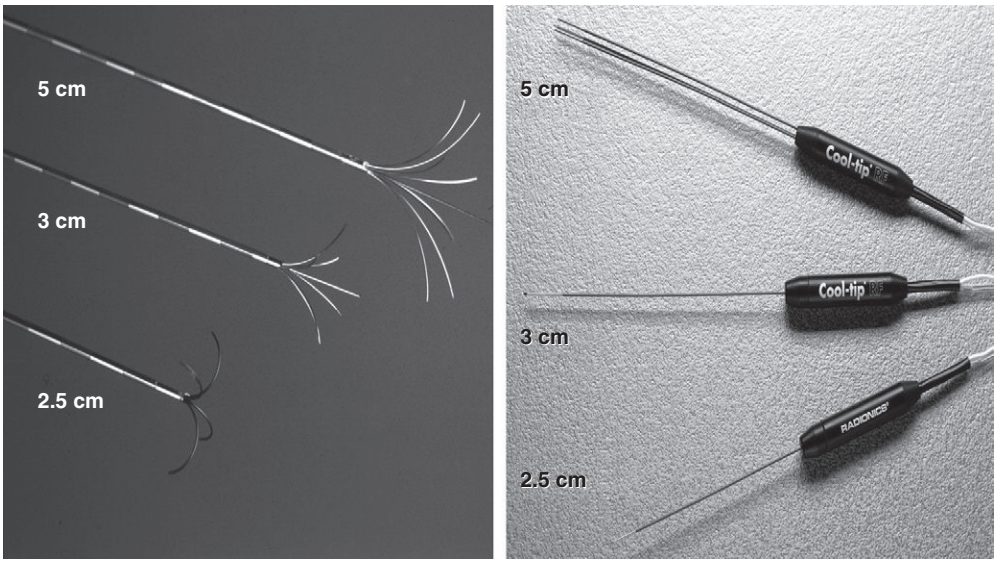

FIGURE 1 RITA *(left;* AngioDynamics, Latham, NY) and Cool-Tip *(right)*; Radionics, Burlington, MA probes used for radiofrequency ablation. *(Bilchik AJ, Krasny RM, Allegra D: Radiofrequency ablation for liver tumors. In Jarnagin WR, Belghiti J, Buchler MW, et al, editors:* Blumgart's surgery of the liver, pancreas and biliary tract, *vol 2, ed 5, Philadelphia, 2012, Saunders, p 1400, Fig. 85C.2.)*

Latham, NY) and Radiotherapeutics (Boston Scientific, Natick, Mass) use multiarray electrodes. The RITA has a single electrode through which multiple tines are deployed. The tines are deployed to varying depths, resulting in circumferential ablation. The tines have thermoprobes that measure temperatures in the ablation zone and maintain a steady temperature during ablation. The RITA system also uses saline solution to reduce impedance and can ablate tumors of up to 7 cm in diameter. The Radiotherapeutics system does not measure temperatures and instead adjusts ablation based on tissue impedance. This system has an ablation diameter of 4 cm. The third system, developed by Covidien (Mansfield, Mass), has a single-pronged or three-pronged electrode that is perfused with cold saline solution and has intermittent pulses that measure impedance and temperature. This system can produce ablation zones that reach 5 cm in diameter.

Radiofrequency Ablation Approaches

Radiofrequency ablation can be performed through percutaneous, laparoscopic, or open approaches. Each approach requires intraoperative imaging to monitor the ablation field during RFA.

Open or Laparoscopic Radiofrequency Ablation

The laparoscopic approach requires two ports in the right upper quadrant; the open approach requires a Chevron or midline incision, depending on previous scars (Figure 2). Both approaches allow visual inspection of the abdominal cavity, which is important because approximately 10% to 20% of patients have undiagnosed extrahepatic disease. If a laparoscopic approach is used, a 30-degree angled laparoscope is inserted to explore the abdomen; if an open approach is used, all parietal and visceral peritoneal surfaces, the lesser sac, omentum, and viscera should be manually palpated. Limited takedown of adhesions is indicated, and the liver should be mobilized with takedown of falciform and triangular ligaments. Adjacent viscera should be protected, and vital structures should be retracted to a distance of 2 cm from the ablation field. Finally, the porta hepatis should be evaluated; if necessary, portal nodes should be biopsied.

Open and laparoscopic approaches rely on ultrasound scan imaging to detect any undiagnosed hepatic disease because preoperative imaging can miss up to 30% of lesions. The liver should be examined with a flexible 7.5-MHz intraoperative ultrasound probe (Figure 3). Ultrasound scan also can identify the location of tumor with respect to major vascular pedicles and bile ducts. If a tumor is too close to large vessels, ablation is not complete because rapid blood flow produces a cooling or "heat sink" effect. Proximity to a central bile duct should be carefully evaluated because of the risk of ablation injury and the potential for fistula and stricture formation. If a tumor is too close to the gallbladder, cholecystectomy should be performed because of the risk of gallbladder perforation.

The RFA electrode is inserted with ultrasound guidance (Figure 4). The electrode should be placed parallel to and within the plane of the ultrasound probe, so that the electrode's tract can be visualized in its entirety. Many electrodes now are multiarray; additional electrodes deploy after placement of the main device into the tumor. During RFA, real-time ultrasonic monitoring shows hyperechogenicity within treated tissue, reflecting the formation of gas bubbles. However, ultrasound scan cannot reliably distinguish between ablated and normal tissue. For this reason, the ablation should start with the most posterior portion of the tumor and then the probe should be systematically withdrawn in 2-cm increments to create sequential overlapping zones of ablation that destroy the tumor and produce a surrounding 1-cm rim. If target temperatures are not reached, then tines can often be withdrawn slightly or rotated to increase the temperature in the region of ablation. Temporary vascular inflow occlusion (Pringle's maneuver) should be considered during laparoscopic or open RFA because it interrupts portal venous flow and decreases the heat sink during ablation, thereby increasing the ablation zone. After ablation, the probe track should be cauterized to minimize bleeding. The laparoscopic approach is associated with a shorter hospital stay, smaller incision, and less postoperative pain than the open approach. Both approaches require general anesthesia.

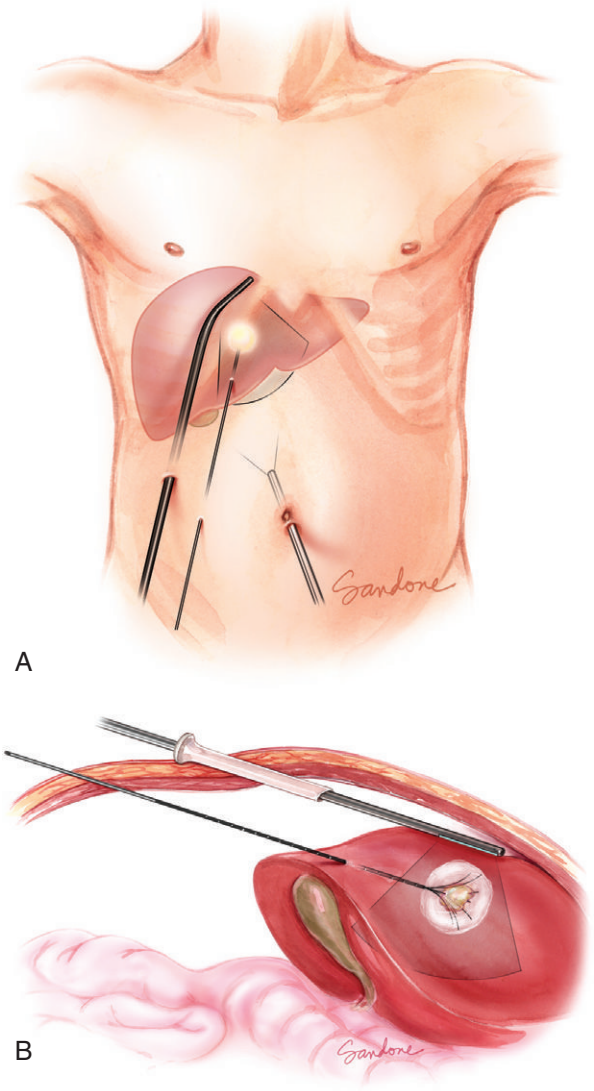

FIGURE 2 Laparoscopic approach in operative radiofrequency ablation (RFA) with intraoperative ultrasound scan guidance. **A,** Placement of ports. **B,** Intraoperative ultrasound scan and RFA probes. *(From Cameron JL, Sandone C:* Atlas of gastrointestinal surgery, *vol 1, ed 2, Hamilton, Ontario, 2008, BC Decker, p 182.)*

Percutaneous Radiofrequency Ablation

Percutaneous ablations are normally performed by interventional radiologists with ultrasound or CT scan guidance. Percutaneous ablation can be performed with a combination of minimal sedation and local anesthetic (Figure 5). CT scan guidance allows precise placement of the electrode and immediate assessment of the adequacy of ablation. On the other hand, the percutaneous approach does not allow visualization of the entire abdominal cavity or intraoperative ultrasound to identify additional lesions. Also, some hepatic lesions cannot be treated percutaneously. For example, ablation of tumors in the

dome of the liver can damage the diaphragm, and ablation of peripheral liver lesions risks thermal injury to small bowel, stomach, or transverse colon. Finally, the percutaneous approach does not allow retraction to protect vital structures. Air, saline solution, or a balloon catheter can be introduced to separate vulnerable structures from the liver to avoid injury, but this can be technically difficult.

COMPLICATIONS

Radiofrequency ablation is relatively safe, with a low mortality rate (0 to 2%). Common complications are thermal, mechanical, septic, or anesthetic. Thermal complications include gastrointestinal perforation, biliary stenosis, and grounding pad burns. Mechanical complications encompass tumor seeding, pneumothorax, and bile duct or vessel injury resulting in hemorrhage or biliary leakage (Figure 6).

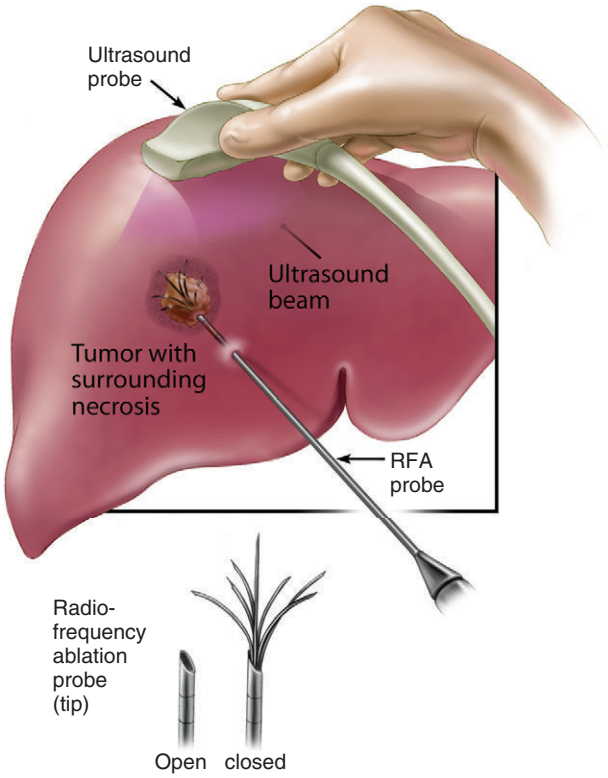

FIGURE 3 Radiofrequency ablation *(RFA)* during open laparotomy with intraoperative ultrasound scan guidance. *(From Johns Hopkins Gastroenterology and Hepatology:* Hepatocellular carcinoma (liver cancer): therapy. www.hopkins-gi.org. *Accessed June 15, 2010.)*

Septic complications are abscesses and wound infection. Finally, anesthetic complications include cardiac arrhythmias, myocardial infarction, and pneumonia. A common complication that occurs in 30% to 40% of patients is postablation syndrome, which likely reflects the release of cytokines from necrotic tissue. It is characterized by low-grade fever, malaise, chills, myalgia, delayed pain, nausea, and vomiting. This diagnosis is one of exclusion and should not be made until sinister complications have been ruled out.

MONITORING AND FOLLOW-UP

Laboratory Follow-up

Because elevated levels of carcinoembryonic antigen (CEA) are associated with local tumor recurrence, CEA levels should be monitored every 3 months after surgery. Although the absolute CEA value may be inconsequential, a rise in CEA level is concerning for recurrence.

Computed Tomographic Scan/Magnetic Resonance Imaging/Positron Emission Tomography

Ablation adequacy is assessed with CT scan or MRI. These scans are most informative with arterial and venous phases, with and without

intravenous contrast material. CT scans with intravenous (IV) contrast are obtained at 1 week (baseline), and then at 3-month intervals during the first year and 6-month intervals thereafter. The baseline image should reveal a hypovascular ablated field with a rim of hypervascular inflammatory tissue. Over the first several months, rim enhancement should disappear as inflammation resolves. Visible residual tumor within or immediately adjacent to the ablation zone within 6 months after ablation is considered a local recurrence or treatment failure. Recurrences usually appear as irregular nonenhancing areas on contrast CT scan. Serial imaging is essential for early detection of recurrence. Ideally, all imaging should be performed at the same institution where the ablation was performed. PET/CT scan is controversial for routine postablation follow-up imaging; however, PET appears to have good sensitivity for early detection of tumor recurrence.

RESULTS AND RESPONSE RATES

The response to RFA depends on the number and size of hepatic tumors. Response rates are higher when tumors are less than 5 cm in diameter and less than 3 in number. As might be expected, the best outcome is associated with RFA of a solitary lesion that is distant from vessels or biliary structures and is less than 3 cm in size. Response rates also are better with the newer generation probes and with increased physician experience. Although there are no randomized controlled trials of different RFA approaches, published results of nonrandomized comparisons suggest that open RFA results in the fewest local recurrences, followed by laparoscopic RFA and percutaneous RFA.

Radiofrequency Ablation Versus Surgical Resection or Systemic Therapy

Median postoperative survival time for patients with resectable colorectal liver metastases is 40 months, with a 10-year survival rate of 20%. Median overall survival time after RFA ranges from 28 to 39 months, with a 5-year survival rate of 17% to 25%. However, published survival endpoints after RFA are difficult to assess because of variations in tumor size, missing data, and multiple treatment options before and after RFA. Comparison of RFA and surgical resection is difficult because candidates for surgical resection usually have a better health status, fewer comorbidities, less liver involvement, and more liver reserve. Even when comparisons of RFA and surgical resection are limited to patients with resectable disease, results are equivocal; some studies show comparable outcomes, whereas other studies show a survival advantage for surgical resection. Unfortunately, many of these studies preceded recent improvements in chemotherapy and catheter technology, and all of these studies were subject to the selection bias inherent in nonrandomized comparisons. Results from these studies are summarized in Table 1.

The first randomized trial to examine the efficacy of RFA was published in 2012. This phase II study randomly assigned patients with nonresectable colorectal liver metastases to systemic treatment alone or to systemic treatment plus RFA. Progression-free survival rate at 3 years was 27.6% for combined treatment versus 10.6% for systemic treatment only ($P = 0.025$). Median progression-free survival rate was 16.8 months (95% confidence interval [CI], 11.7 to 22.1) for combined treatment versus 9.9 months (95% CI, 9.3 to 13.7) for systemic treatment only. Although progression-free survival was significantly longer in the group treated with chemotherapy plus RFA, no difference was seen in overall survival for the two groups (median of 45.3 months for combined treatment vs 40.5 months for systemic treatment alone; $P = 0.22$).

NEWER TECHNOLOGIES

Microwave Ablation

During microwave ablation, electromagnetic waves at microwave frequencies are transmitted along a coaxial cable and through the tip

of an electrode placed in the liver. Microwaves penetrate further into liver tissue than radiofrequency waves, and this ablative technique appears to overcome many of the problems that plague RFA. As compared with RFA, microwave ablation requires less time to achieve tumoricidal temperatures, decreases the heat-sink effect, and allows wider penetration and margins. It also does not require grounding pads or cooling systems, making it simpler to use. A recent study involving 14 Italian centers examined results of microwave ablation in 736 patients with 1037 lesions that included 187 colorectal metastases. The 2.9% major complication rate and 7.3% minor complication rate were equivalent to complication rates for RFA, which suggests that the two ablation techniques are equivalent with respect to safety. As more long-term data accumulate regarding the efficacy of microwave ablation, this modality may replace RFA as a faster and more effective means of destroying liver metastases.

High-Intensity Focused Ultrasound Scan

High-intensity focused ultrasound scan relies on the same principles as conventional ultrasound scan. It propagates harmlessly through living tissue, but if the ultrasound carries sufficient energy and is brought into a tight focus, the energy elevates local temperature and thereby causes necrosis of tumor without damage to the overlying tissue. Currently, little data are available on the safety or efficacy of this treatment.

Computer-Assisted Soft-Tissue Surgery

Computer-assisted soft-tissue surgery, which is performed with the CAS-One system (CAScination AG, Bern, Switzerland), is described by the manufacturer as the GPS for liver surgery. It involves a three-dimensional ultrasound technology planning model that allows interactive navigation of the liver and aligns image data with the patient. This new technology allows for greater precision, efficiency, and safety during placement of the RFA electrode in the tumor and can be used in conjunction with all ablation systems. The Cas-One is currently approved for use in Europe but not in the United States.

CONCLUSION

Ablation was initially used for local control of unresectable metastatic liver lesions, but advances in technology have given it curative potential, particularly when combined with neoadjuvant or adjuvant administration of systemic agents. RFA has been used to destroy hepatic metastases during resection of primary colorectal cancer, and it also has been combined with liver resection to maximize residual liver volume and hepatic reserve and to treat recurrences.

Although hepatic resection is currently the gold standard for resectable liver tumors, some retrospective studies suggest that RFA can confer similar disease-free survival in carefully selected patients who have small tumors. Currently, the only randomized controlled trial assigned unresectable tumors to chemotherapy plus local ablation versus chemotherapy alone. It was sponsored by the European Organization for Research and Treatment of Cancer and was ultimately closed because of nonaccrual. Certainly, the time for a randomized study for resectable tumors is fast approaching.

Radiofrequency ablation can be a powerful tool, but certainly any treatment of colorectal metastasis to the liver should involve a multidisciplinary team to determine the best therapeutic options. This decision should be based on the institution's expertise, the tumor's location, and the patient's characteristics and comorbidities. In each case, the goal is individualized treatment that optimizes outcome.

The Management of Hepatic Abscess

Fady Michael Kaldas, MD, and Johnny C. Hong, MD, FACS

OVERVIEW

Hepatic abscesses are an uncommon disease with an annual incidence rate of approximately 3.6 per 100,000 in the United States. Although hepatic abscesses account for only 8 to 20 cases of every 100,000 hospital admissions, liver abscesses are uniformly fatal if untreated and require prompt recognition and treatment. Hepatic abscesses can be divided into three major categories: pyogenic, amebic, and fungal. Pyogenic abscesses represent the majority of liver abscesses in developed countries and tend to contain polymicrobial aerobic and anaerobic bacteria. Recently, liver abscesses secondary to hepatic tissue and tumor necrosis from ablative therapies for liver tumors have increasingly been seen because of the widespread utilization of these interventions. Amebic abscesses are the result of *Entamoeba histolytica,* which has a high endemic prevalence in Mexico, the Indian subcontinent, Indonesia, and tropical Africa. Most patients with amebic liver abscesses in the United States have a history of recent travel to an endemic area. Fungal abscesses are less common and are typically caused by *Candida* species. Fungal liver abscesses are being recognized with increasing frequency in patients with immunocompromise and those with malignant diseases.

The treatment of liver abscesses has evolved over the past decades from operative drainage as the only treatment modality to a multispecialty approach with nonoperative or operative interventions that have significantly improved the care of patients. Although both interventional radiologists and biliary endoscopists may play a major role in the first-line management of these cases, surgeons need to be knowledgeable and must play an active role in the diagnosis and management of patients with liver abscesses because surgical intervention remains the salvage procedure in many of these cases.

PYOGENIC HEPATIC ABSCESS

Pyogenic abscesses are a rare but often lethal disease. The etiologies of the liver abscesses are multifactorial and associated with different disease processes. During the first three decades of the 20th century, pylephlebitis, from appendicitis, was the most common cause, with an overall mortality rate that approached 75% to 80%. During the 1950s to 1970s, biliary obstruction from both benign and malignant diseases accounted for most of the cases. Recently, the emergence of orthotropic liver transplantation (OLT) as the definitive therapy for end-stage liver disease and a more aggressive approach in the surgical therapy of hepatobiliary malignancies have resulted in yet another shift with regard to the etiology of hepatic abscesses.

Pathophysiology

Pyogenic abscesses can develop from multiple potential sources: (1) the biliary ductal system most commonly from ascending cholangitis, (2) the portal blood flow, from pylephlebitis originating from appendicitis or diverticulitis, (3) direct extension from adjacent disease, such as severe cholecystitis, (4) injury from trauma or liver-directed therapy, (5) the hepatic artery, from septicemia originating from a distant source, and (6) a cryptogenic process. In one of the largest Western series at Johns Hopkins Hospital, 40% of pyogenic liver abscesses were biliary in origin, and an underlying malignant disease was the cause in the majority of these patients in the non-OLT setting.

In liver transplant recipients, additional risk factors for pyogenic abscess include: (1) hepatic infarction from vascular thrombosis or anastomotic stenosis, (2) ischemic cholangiopathy (nonanastomotic biliary stricture) as a consequence of hepatic arterial compromise or the use of deceased-donor liver organs procured after circulatory death (donation after circulatory death [DCD]; Figures 1 and 2), and (3) biliary anastomotic stricture. The utilization of partial liver grafts (from live and deceased donors) carries an increased risk of biliary leak from the cut surface of the liver that may result in perihepatic pyogenic abscess. Although the infectious organisms and initial diagnostic and treatment algorithms are similar to non–OLT-related causes, the definitive treatment is based on patency of the hepatic vessels, viability of the bile ducts, and function of the hepatic allograft. In severe cases, retransplantation of the liver is the only life-saving modality.

The types of bacteria isolated from the blood and the bile in patients with pyogenic hepatic abscesses vary with the underlying pathologic process (Table 1). *Escherichia coli, Klebsiella* spp., and *Enterococcus* are commonly isolated in cases related to choledocholithiasis, whereas *Pseudomonas* spp., other multiple resistant gram-negative aerobes, vancomycin-resistant *Enterococcus* (VRE), and yeast are the more likely pathogens in patients with biliary obstruction from unresectable biliary malignancy who received multiple courses of antibiotics. Although cases with liver abscesses from diverticulitis and appendicitis are attributed to gram-negative aerobes and *Bacteroides fragilis,* patients with severe forms of cholecystitis are likely to harbor anaerobes such as *Clostridium perfringens* and

Bacteroides spp. Other pathogens frequently associated with specific conditions are *Staphylococcus* and methicillin-resistant *Staphylococcus aureus* (MRSA) from subcutaneous abscess, enterococcal and staphylococcal pathogens from endocarditis, and anaerobes in cryptogenic abscesses.

Diagnosis

The classic initial symptom of a pyogenic hepatic abscess is fever, which occurs in more than 90% of patients. Approximately one half of those with an abscess have abdominal or right upper quadrant pain. Other frequent symptoms include malaise, anorexia, and nausea. Occasionally, the diaphragm is involved, resulting in pleuritic chest pain, cough, or dyspnea. The mode of presentation may also include severe sepsis in patients with an underlying biliary malignancy and after liver-directed therapy or hepatic transplantation. On physical examination, the liver may be tender and enlarged, or the patient may appear jaundiced. Pyogenic liver abscesses rarely rupture, and frank peritonitis is unusual.

Over the past 40 years, advances in imaging have dramatically improved the diagnosis of pyogenic hepatic abscesses. Plain films may show an elevated right hemidiaphragm, right pleural effusion, right lower lobe atelectasis, abnormal extraluminal gas in the right upper quadrant, or portal venous gas if pylephlebitis is the source. Ultrasound scan (US) is a useful initial screening study for hepatic abscess because it has a sensitivity of 80% to 95% and is excellent in evaluation of the gallbladder and intrahepatic bile ducts. A computed tomographic (CT) scan is more sensitive (95% to 100%) in the detection of abscesses, and the presence of gas and rim enhancement with intravenous contrast is very suggestive of a hepatic abscess. CT scan also allows for a more thorough evaluation of the abdomen for detection of the underlying cause. Magnetic resonance imaging (MRI) of the liver is an equally sensitive technique in detection of liver abscesses and, in combination with magnetic resonance cholangiopancreatography (MRCP), provides detailed information with regard to the relationship of the hepatic abscess to the biliary system.

Treatment

Pyogenic hepatic abscesses are associated with a significant mortality rate, and prompt diagnosis and treatment of hepatic abscesses is crucial for good outcomes. Management must include treatment of both the liver abscess and the underlying source. Most pyogenic hepatic abscesses are managed with antibiotic administration and drainage.

Antibiotics

When a pyogenic hepatic abscess is suspected, blood cultures are drawn and empiric, broad-spectrum intravenous antimicrobial therapy is initiated. The antibiotic coverage is subsequently modified based on results of bacteriologic studies. A fluid sample obtained from the abscess is equally important in tailoring an antimicrobial regimen. If drainage is not undertaken, aspiration of the liver abscess may be performed to determine the bacteriology. As outlined previously, the bacteria found usually correspond to the source (see Table 1). As such, the choice of the initial antibiotic agents should be based on the presumed source of the hepatic abscess. For example, for a presumed biliary source, gram-negative aerobe and enterococcal coverage might include broad-spectrum single agents such as piperacillin-tazobactam, ticarcillin-clavulanate, or meropenem. However, if the patient has had multiple episodes of cholangitis and has indwelling stents, double coverage for pseudomonal species, and an agent such as linezolid for VRE, might be an appropriate start. For a presumed colonic source, the combination of fluoroquinolone or a third-generation cephalosporin with metronidazole provides appropriate coverage. For severe cholecystitis, a broad-spectrum penicillin should be included to cover *Clostridia,* and the addition of metronidazole for *Bacteroides* is a reasonable starting combination. If a subcutaneous abscess or endocarditis is the presumed source, inclusion of vancomycin for MRSA is appropriate.

Once the actual bacteria are isolated and sensitivities are determined, the antibiotic regimen should be adjusted to more specific, less broad, and less costly agents. Parenteral administration of antibiotics should be continued for 10 to 14 days. Classically, antibiotic treatment has been recommended for 4 to 6 weeks; however, shorter antibiotic duration may be appropriate if adequate drainage has been achieved. Even when prolonged antibiotics are indicated for multiple small abscesses with no abdominal source, oral antibiotics may be substituted for home intravenous antibiotics.

Drainage

Intravenous antibiotics have decreased the mortality rate of patients with pyogenic hepatic abscesses; however, most patients also need abscess drainage, either with percutaneous catheter placement, closed aspiration, or surgery. The surgical therapy of liver abscess has evolved to a multispecialty approach with rapid developments in minimally invasive surgery and ablative therapies, and advances in image-guided interventions.

Once the pyogenic abscess has been confirmed with CT scan and no intra-abdominal source necessitates operative intervention, the initial management should include systemic antibiotics and percutaneous drainage. At Johns Hopkins Hospital from 1973 to 1993, 45% of patients were treated with a percutaneous drain; many of these cases, especially later in the series, involved multiloculated abscesses. Rajak and colleagues (1998) compared catheter placement with percutaneous aspiration and found that the success rate was superior with catheter placement (60% vs 100%). Percutaneous catheter placement involves the insertion of an 8F to 14F pigtail catheter over a guidewire with imaging guidance. The abscess cavity is then studied with the injection of contrast through the catheter. Finally, the catheter is left to gravity or suction, until complete resolution of the

drainage and collapse of the abscess cavity have occurred (Figure 3). Percutaneous drainage is not appropriate for patients with multiple large abscesses, a known intra-abdominal source that requires surgery, or ascites or in whom transpleural drainage is required.

Percutaneous needle aspiration involves imaging-guided drainage of the abscess without placement of the catheter. The benefits of needle aspiration are decreased cost, less invasiveness, and avoidance of drain discomfort. Yu and colleagues (2004) compared the outcomes after aspiration and drainage of liver abscesses and showed equivalent results between the two treatment modalities. Although aspiration resulted in less liver trauma, patient discomfort, and cost, this approach was associated with a higher recurrence rate requiring repeated aspiration procedures compared with catheter drainage.

Although patients with small hepatic abscesses and no biliary obstruction respond to prolonged intravenous antibiotics without drainage, a select group of patients requires surgical intervention.

When an intra-abdominal source for the infection requires an operation, the liver abscess can be drained surgically in concert with management of the primary problem (Figure 4). Surgical treatment is also required in cases of failed nonoperative therapies and remains the salvage procedure.

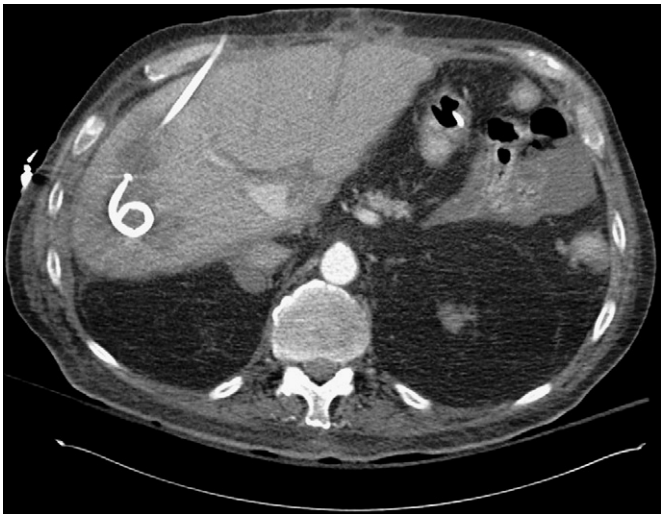

FIGURE 3 Radiograph showing percutaneous drainage of pyogenic abscess.

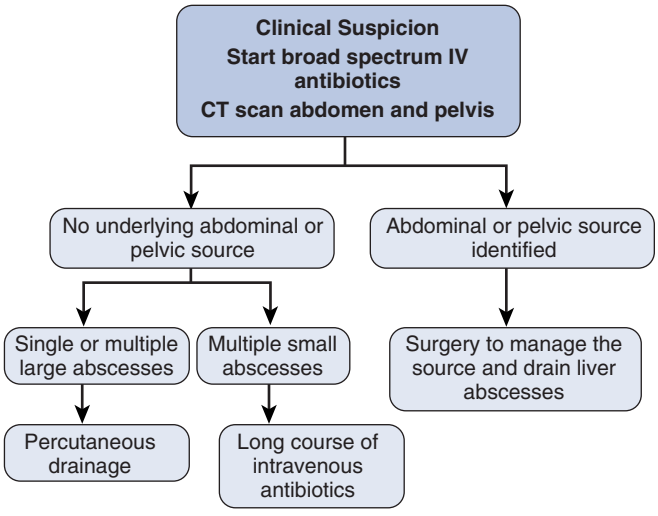

FIGURE 4 Algorithm for management of pyogenic hepatic abscesses. *CT,* Computed tomographic scan; *IV,* intravenous.

Before the availability of systemic antibiotics, an extraperitoneal approach for surgical drainage was performed to avoid contamination of the peritoneum. The availability of modern antibiotics and the current technique of a transperitoneal approach via a midline or right subcostal incision provides direct access to the liver abscess, abdomen, and pelvis. After the underlying pathology in the abdomen is addressed, the liver is evaluated and the hepatic abscess is located with palpation and intraoperative US. The area to be drained is then isolated from the rest of the abdomen with towels, and aspiration of the abscess is performed to obtain fluid for culture (Figure 5). A tract is then created through the hepatic parenchyma toward the cavity, ideally to drain the abscess in a dependent fashion. Next, the cavity is irrigated and suctioned to remove purulence and minimize contamination. The tract should then be enlarged and the abscess débrided to break up any loculated pockets of purulence. A large-caliber drain is placed in the abscess cavity, and the perihepatic area around the abscess may also be drained; however, these drains are brought out through separate incisions. All hepatic abscesses should be biopsied to rule out a tumor and to evaluate for trophozoites of *E. histolytica*.

Although drainage of a liver abscess in combination with systemic antibiotic is successful in most cases, hepatic resection is necessary in unusual circumstances. In patients in whom an inflammatory mass develops as a result of multiple percutaneous drainage procedures or chronic biliary obstruction from multiple biliary drainage procedures that involve one hemiliver, a hemihepatectomy is necessary to remove the diseased portion of the liver. However, these patients are prone to profound sepsis with liver manipulation; therefore, partial hepatectomy should be undertaken cautiously (Box 1).

AMEBIC HEPATIC ABSCESS

Amebiasis is a relatively common global parasitic infection caused by the protozoan *E. histolytica,* with the highest incidence in tropical and subtropical climates. Amebiasis typically affects men between the ages of 20 and 40 years. Although uncommon in the United States, amebic abscesses should be included in the differential diagnosis in patients with a history of travel to or immigration from endemic areas of the world and in the presence of human immunodeficiency virus (HIV).

The liver is the most common extraintestinal location of amebiasis, and amebic liver abscesses occur in 1% of patients with amebiasis. Human infestation occurs with the ingestion of a mature cyst in fecal contaminated food, water, or hands. Excystation occurs in the small intestine, and trophozoites are released and migrate to the large intestine. The trophozoites multiply by binary fission and produce cysts, which are passed in the feces. In many cases, the trophozoites remain confined to the intestinal lumen (noninvasive infection) of individuals who are asymptomatic carriers, passing cysts in their stool. In some patients, the trophozoites invade through the intestinal mucosa (intestinal disease), through the bloodstream, or via extraintestinal sites such as the liver, brain, and lungs (extraintestinal disease), where it forms into an abscess. The most common complication of amebic abscesses is rupture into the surrounding organs, such as direct extension into the pleuropulmonary space or rupture into the pericardium or peritoneum. The diagnosis and management of pyogenic and amebic abscesses differs, and these differences are reviewed.

Diagnosis

The presentation of amebic abscesses may be acute with fever and right upper quadrant pain or less specific with weight loss, fever, and abdominal pain. An amebic liver abscess usually does not present at the same time as colitis but within a year after the initial infection. Unlike a pyogenic abscess, the patient is not jaundiced and does not

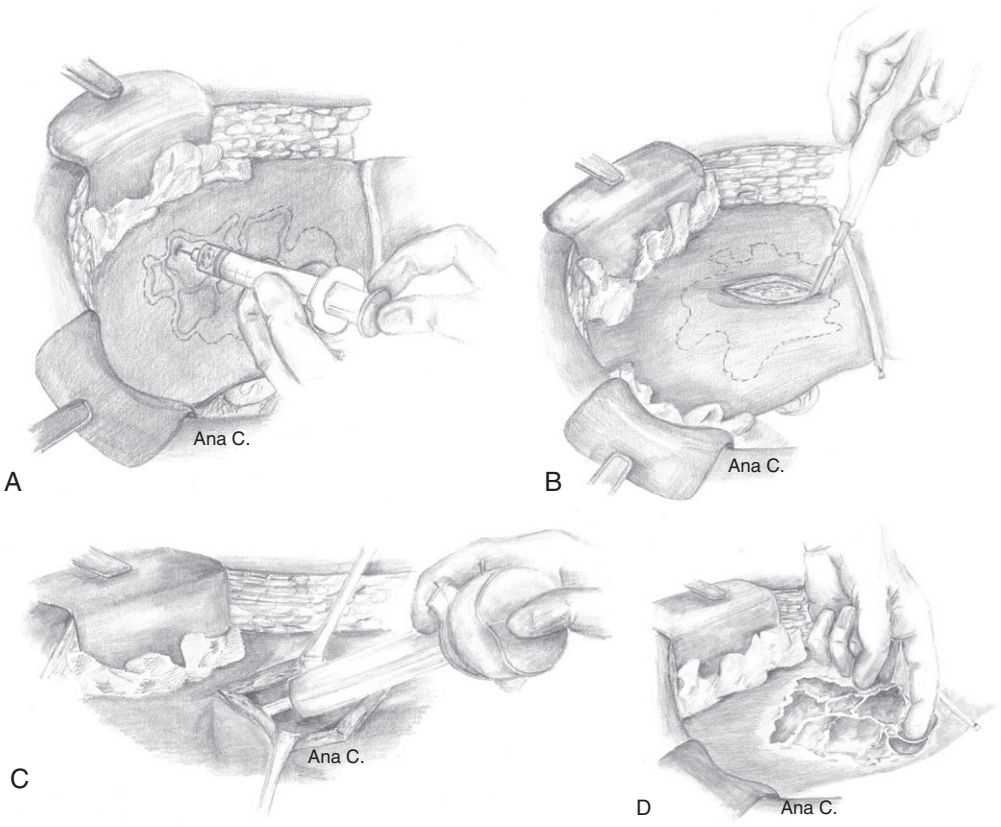

FIGURE 5 **A,** Abscess aspiration for aerobic and anaerobic culture. **B,** Incision of the liver capsule to drain the abscess. **C,** Irrigation of abscess cavity. **D,** Manual disruption of loculations. *(Illustrations by Ana Costache.)*

BOX 1: Pearls for pyogenic hepatic abscesses

- The most common organisms isolated from pyogenic liver abscess are gram negative; however, because of increased use of indwelling biliary stents, infection with other organisms, such as *Pseudomonas, Streptococcus,* and fungal species, has increased.
- Bacteriology and initial antibiotics should be tailored to the presumed underlying source.
- Aspiration of liver abscess should be undertaken in most patients, unless the abscess is small, because it provides rapid relief of symptoms and renders samples for culture.
- Percutaneous drainage is usually required, and open surgery should be reserved for selected patients.

have underlying biliary disease. Also, most patients are younger than 50 years and have a history of travel to an endemic location. The definitive diagnosis of an amebic liver abscess is by identification of *E. histolytica* trophozoites in the pus or serum antibodies to the ameba. The majority of amebic liver abscesses (75% to 80%) show up as a single focus in the right lobe.

Treatment

With the introduction of metronidazole decades ago, drainage procedures (surgical or percutaneous) are only necessary in circumstances in which a questionable diagnosis, bacterial coinfection, or complications from the amebic abscess exist.

Antibiotics

The mainstay for treatment of invasive amebiasis is metronidazole. Tinidazole and ornidazole are other nitroimidazole derivatives that are effective treatments; however, they are not currently available in the United States. Metronidazole is able to reach high concentrations in the liver. Current recommendations for metronidazole are 750 mg 3 times a day for 5 to 10 days. Caution should be taken in pregnant and breastfeeding mothers because metronidazole does cross the placenta and is secreted in breast milk. Ninety-five percent of patients respond after 10 days of therapy; however, 5% to 15% are resistant to metronidazole. Luminal antimicrobials, such as paromomycin and iodoquinol, should also be used to eradicate intestinal colonization because 10% of patients have relapse without luminal amebicidal agents.

A second-line luminal agent, diloxanide furoate, is available from the U.S. Centers for Disease Control for patients who clinically do not respond to paromomycin or iodoquinol. Follow-up stool examination is recommended after completion of therapy to ensure eradication of the infection.

Drainage

Blessmann and colleagues (2003) performed a prospective randomized trial to determine whether any significant benefit was obtained by adding aspiration to antibiotics for the treatment of amebic abscesses. In this study, aspiration did not improve the outcomes; therefore, image-guided percutaneous treatment is used only in the following circumstances: (1) if no clinical response is seen after 5 to 7 days of antibiotics, and (2) if an abscess, especially a large one, is at high risk for rupture. If the complication of rupture or extension does occur, percutaneous drainage is useful in treating pulmonary, peritoneal, and cardiac complications. Although surgical drainage is

rarely required for this disease, surgical intervention is required in unusual situations such as hemorrhage, erosion into surrounding organs, or sepsis from a secondarily infected amebic abscess that has failed percutaneous treatment.

Outcomes

The vast majority of patients with amebic abscesses have defervescence and improvement after 3 days of therapy. However, if not treated in a timely fashion, this condition can be fatal, with mortality rates ranging as high as 15% to 20%. Several patient factors that are independent predictors of mortality include: (1) a bilirubin value greater than 3.5 mg/dL, (2) encephalopathy, (3) an abscess volume greater than 500 mL, (4) an albumin value less than 2 g/dL, and (5) multiple abscesses. In addition, patients with complications of the abscess, rupture, or direct extension as previously described have a worse outcome.

In conclusion, amebic abscesses have an excellent outcome with medical management, and drainage procedures are reserved for patients who do not respond to medical therapy. Patients have clinical improvement with amebicidal therapy more rapidly than radiologic resolution is observed. Complete radiologic resolution may take up to 9 months, and follow-up imaging is advised (Box 2).

FUNGAL HEPATIC ABSCESS

Bacteria and parasites constitute the majority of hepatic abscesses, but the incidence of fungal liver abscesses has been increasing. Most monomicrobial fungal abscesses are seen in patients with immunecompromise, such as with chemotherapy, with HIV infection, or after organ transplantation. Mixed bacterial and fungal abscesses typically occur in patients with biliary malignancies who have had long-term indwelling stents and have been frequently treated with antibiotics.

Treatment

Treatment of fungal abscesses follows the same principles as treatment for pyogenic hepatic abscesses, focusing on antimicrobial agents and drainage. Drainage is, again, with simple aspiration, percutaneous drainage, or surgical drainage. About 80% of fungal abscesses contain *Candida* spp.; the next most common fungal organisms are *Aspergillus* and *Cryptococcus*. Historically, amphotericin B was the first-line therapy, but micafungin and caspofungin are currently the agents of choice. An adequate course must be used; an earlier analysis suggested that inadequate treatment with amphotericin B was associated with a high mortality rate. Oral fluconazole may be used after initial intravenous therapy if *Candida albicans* is the cause. Patients with mixed fungal and bacterial abscesses also should receive appropriate antibiotics for the isolated bacteria.

BOX 2: Pearls for amebic liver abscesses

- Only 10% to 20% of patients with amebic liver abscess have a history of diarrhea.
- Treat the intestinal infection to prevent relapse of amebic liver abscess. Failure to use luminal amebicidal agents after metronidazole in cases of amebic abscess results in a 10% relapse rate.
- Failure to show response to antiamebic medication requires evaluation for polymicrobial infection with bacteria.
- Amebic abscess usually responds clinically to antimicrobial therapy in 3 to 7 days, although imaging takes several months to show resolution.
- Percutaneous drainage is rarely required.

Outcomes

Fungal abscesses of the liver are a significant source of mortality. The series from Johns Hopkins that analyzed fungal infections from 1973 to 1993 reported that all four patients with monomicrobial fungal abscesses with fungemia died. However, those patients who received a complete course of amphotericin B and did not have fungemia survived. In mixed fungal and bacterial abscesses, the overall mortality rate was 50%; however, adequate amphotericin B treatment resulted in a lower mortality rate (20% vs 62%). In conclusion, although fungal hepatic abscesses carry a high mortality rate, early administration of modern antifungal agents for the prevention of fungemia should improve survival.

Transarterial Chemoembolization for Liver Metastases

Nikhil Bhagat, MD, and
Jean Francois H. Geschwind, MD

INTRODUCTION

According to the most recent epidemiologic data, the incidence of hepatocellular carcinoma (HCC) is rising worldwide. A number of therapeutic options exist for patients with liver cancer, whether primary or metastatic. The two definitive therapies are surgical resection and liver transplantation. However, surgical resection is often not possible because of multifocal tumors or poor hepatic reserve, and transplant recipients significantly outnumber donors. Transarterial chemoembolization (TACE) has been shown to improve survival in those patients with unresectable disease.

HISTORY

Yamada and associates first described the delivery of chemotherapy-soaked gel-foam pledgets within the hepatic arteries of those patients with HCC in the 1970s. The rationale for chemoembolization is as follows: normal liver tissue receives most of its blood supply (75% to 83%) from the portal vein, and liver tumors receive most of their blood supply (90% to 100%) from the hepatic artery.

Lipiodol, an iodine ester derived from poppy seed oil, began to be used in the 1980s as part of the chemoembolization cocktail. Lipiodol (or ethiodol) is taken up by the liver (normal hepatocytes and tumor cells), but it not metabolized by the tumors because of their lack of Kupffer's cells. As a result, lipiodol can be seen in tumors months after treatment and can be used to monitor treatment areas after TACE. In addition, lipiodol has been shown to have an embolic effect, which serves to decrease blood flow and retain chemotherapeutic agents in the tumor.

Although no data show increased efficacy of one chemotherapeutic agent over another, the most common cocktail used in the procedure is cisplatin, doxorubicin, and mitomycin. These agents have all been shown to have good liver extraction and low systemic drug concentrations when administered into the hepatic artery. In addition, the intratumoral concentration of chemotherapeutic drug is reported to be 10 times higher than if it was delivered through the hepatic artery as compared with the portal vein. The most common dosages of the medications are as follows: 50 mg doxorubicin (Adriamycin; Pharmacia-Upjohn, Kalamazoo, Mich), 100 mg cisplatin (Bristol Meyers Squibb, Princeton, NJ), and 10 mg of mitomycin C (Bedford Laboratories, Bedford, Ohio). This mixture is usually mixed in a 1:1 ratio with lipiodol.

Embolic agents are also usually used during the chemoembolization procedure, whether temporary agents (gel-foam slurry or pledgets) or more permanent agents (polyvinyl alcohol [PVA] or other particulates). The administration method for the embolic agent is not standard; some prefer to mix it with the chemotherapy, and others prefer to give the embolic agent at the end. Some data have suggested that postchemotherapy embolic agents help improve long-term arterial patency. Long-term arterial patency is necessary for repeated chemoembolization because its efficacy is related to the number of times it can be repeated.

As stated previously, the standard chemotherapy cocktail contains Adriamycin, cisplatin, and mitomycin. This cocktail is mixed with lipiodol (see previous mention for details) and administered through the microcatheter in a relatively superselective position. Although the lipiodol is embolic, further stasis is achieved after the administration of chemotherapy with another embolic agent; this agent is gel-foam slurry, PVA particles, or gelatin microspheres. The most commonly used agents include gel foam and PVA. The primary reason for the additional embolic agents is to help retain the chemotherapeutic agents within the tumor and to induce ischemic necrosis.

TECHNIQUE

A thorough preprocedure workup is necessary before chemoembolization. The diagnosis of HCC is made through either tissue diagnosis or imaging characteristics and elevated alpha-fetoprotein levels. A multiphasic cross-sectional imaging study, either magnetic resonance imaging (MRI) or computed tomographic (CT) scan, should be obtained to determine: (1) size of tumor; (2) extrahepatic tumor spread; (3) possible variant arterial anatomy supplying the tumor; (4) biliary ductal dilation; and (5) portal vein infiltration. Serum chemistry and hematology values also need to be ordered, including prothrombin time, international normalized ratio (INR), liver function tests, creatinine value, and alpha-fetoprotein level. Before the start of the procedure, intravenous fluids, prophylactic antibiotics (broad-spectrum to cover gram-negative and enteric), and antiemetics are administered.

Vascular access is typically obtained from one of the common femoral arteries in the groin. A vascular sheath is placed, and angiography of the superior mesenteric artery (SMA) is performed with delayed portal venous imaging. The purpose of visualization of this vessel is identification of any anomalous arterial supply to the liver parenchyma (originating from the SMA) and verification of the patency of the portal vein. Next, the celiac artery is catheterized and arteriography is performed to identify any anomalous vessels and primary supply to the tumor. Potentially dangerous locations for chemotherapy administration are identified on this angiogram (including left gastric artery, right gastric artery, cystic artery, and falciform artery). Many catheters can then be used for selective catheterization of the hepatic artery; usually, this is accomplished with a 5F reverse curve catheter, such as a Cobra, Simmons, or Sos. Superselection of the specific hepatic lobe (based on tumor burden) is performed with a microcatheter and microwire. On occasion, fluoroscopy is not sufficient to delineate the proper location of the microcather for embolization; in these cases, a CT scan can be obtained immediately after injection to verify optimal positioning (XperCT, Philips, Netherlands; DynaCT, Siemens Medical, Germany). Details are included in Figure 1.

PALLIATION FOR OTHER LIVER TUMORS

TACE is not only used in the setting of HCC; it has been used for palliation of cholangiocarcinoma. In addition, TACE has also been used for the palliation of numerous metastatic lesions to the liver, including ocular melanoma, neuroendocrine, colorectal carcinoma, renal cell carcinoma, some sarcomas, and breast cancer.

Cholangiocarcinoma

Cholangiocarcinoma is a rare hepatic malignancy with a typically poor prognosis. The only curative option for cholangiocarcinoma is

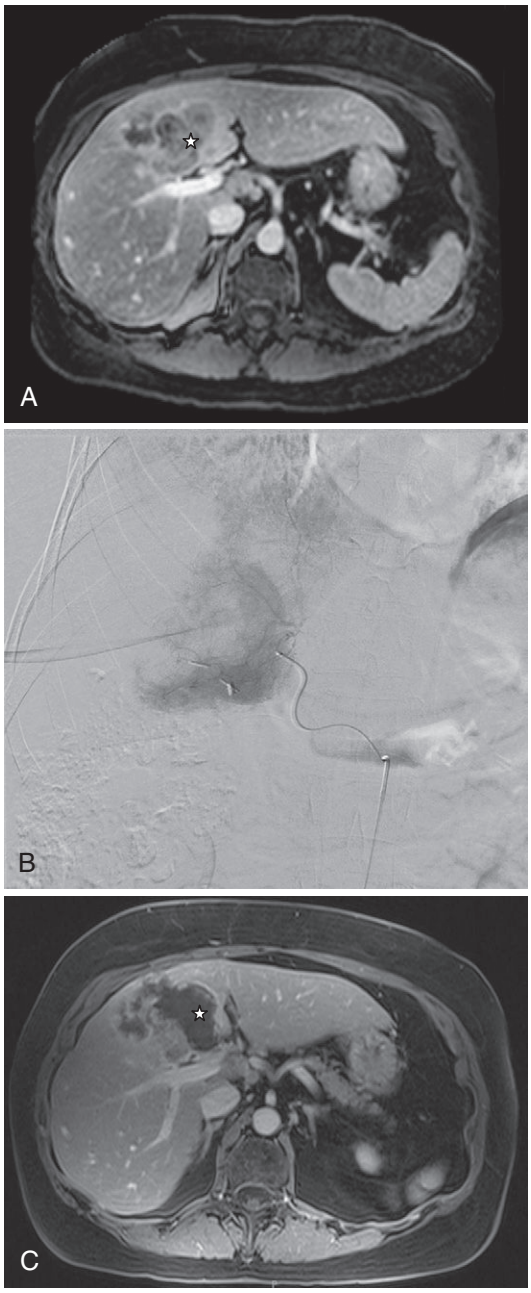

FIGURE 1 **A,** Magnetic resonance imaging (MRI) after contrast of 62-year-old woman showing segment IV cholangiocarcinoma with significant contrast enhancement *(star)*. **B,** Angiogram before chemoembolization showing hypervascularity of lesion shown in **A. C,** MRI after contrast showing central necrosis in same lesion after chemoembolization *(star)*.

surgical resection (see Figure 1). The prognosis is especially poor in those patients with unresectable disease (survival, 5 to 8 months), which usually comprises more than 70% of patients. Systemic chemotherapy has shown no impact on survival as compared with supportive care. Just like HCC, most of the blood supply to intrahepatic cholangiocarcinoma (ICC) is derived from the hepatic artery, making intraarterial therapy attractive. However, given the rarity of the disease, significant data have been difficult to accrue. In the study by Burger and colleagues, 17 consecutive patients were treated with conventional TACE (doxorubicin, cisplatin, mitomycin C, ethiodol, and Embosphere particles [Biopsphere Medical, Rockland, Mass]). These patients were relatively healthy (15 of 17 patients had Child-Pugh A; 14 of 17 had Eastern Cooperation Oncology Group (ECOG) 1-2). The median survival time in this group was 23 months. Two patients with unresectable disease went on to resection after TACE. In another retrospectively analyzed study of 15 patients treated for intrahepatic cholangiocarcinoma with TACE (single agent mitomycin C), Herber and associates found that the median survival time was 16.3 months and that 1-year, 2-year, and 3-year survival rates were 51%, 27%, and 27%, respectively. In this study, the patients were generally healthy with good liver function (14 of 15 had Child-Pugh A). Both of these studies have shown improved survival in those patients with intrahepatic cholangiocarcinoma after TACE therapy.

Ocular Melanoma

Ocular melanoma is the most common intraocular malignant tumor in adults. Up to 50% of those patients diagnosed with ocular melanoma have subsequent development of systemic metastases within 2 to 5 years. The metastatic disease tends to involve the liver; greater than 70% of cases of metastatic ocular melanoma involve the liver, and the liver is generally the first site of metastases. Once the melanoma metastasizes to the liver, the prognosis worsens, and survival is typically between 2 and 9 months. In a study by Sharma and colleagues in 2008, 20 patients with ocular melanoma were treated with cisplatin, doxorubicin, mitomycin C, and gel foam. After TACE, 13 of 20 patients had stable disease, with an overall survival time of 9 months. In another study by Vogl in 2007, 12 patients were treated with mitomycin C, ethiodol, and microspheres. Three of 12 had a partial response, and 5 of 12 had stable disease. The overall survival time in these patients was 21 months.

Colorectal Cancer

Colorectal cancer most commonly metastasizes to the liver and is the leading cause of death in these patients. At the time of initial diagnosis, 20% to 50% of patients already have liver metastases. Patients who only receive supportive therapy with colorectal metastases to the liver typically have a 7-month to 8-month survival time. The only curative option for these patients is surgical resection; surgical resection has a median survival time of 28 to 46 months, with 5-year survival rates from 24% to 40%. In a study by Vogl and associates in 2009, 463 patients with unresectable colorectal hepatic metastases that were refractory to systemic chemotherapy were treated with TACE. By imaging characteristics, 68 patients (14.7%) had partial response, 223 patients (48.2%) had stable disease, and 172 patients (37.1%) had progressive disease. The 1-year and 2-year survival rates after chemoembolization were 62% and 28%, respectively. Median survival times from date of diagnosis of liver metastases and date of first chemoembolization were 38 months and 14 months, respectively. In a study performed by Hong and associates, 36 patients were divided into two groups, those who received TACE therapy (n = 21) and those who received Y-90 therapy (n = 15). In these patients, the median survival times for the TACE and Y-90 groups were 7.7 months and 6.9 months, respectively (from the start of therapy). The 1-year, 2-year, and 5-year survival rates for the chemoembolization group were 43%, 10%, and 0, respectively. There were no significant survival benefits of TACE versus radioembolization.

Metastatic Neuroendocrine Tumors

Metastatic neuroendocrine tumors represent approximately 10% of metastatic disease of the liver. Carcinoid and pancreatic islet cell have a predilection to metastasize to the liver, and those patients with liver

metastases have a poorer prognosis and quality of life. Surgical resection is curative but is only possible in less than 10% of patients. In a study performed by Gupta and colleagues in 2005, 69 patients with carcinoid metastases to the liver and 54 patients with pancreatic islet cell metastases to the liver underwent treatments with either hepatic arterial embolization (HAE) or chemoembolization (TACE). They found that carcinoid tumors had better outcomes than those with islet cell carcinomas in terms of response rate (66.7% vs 35.2%; $P = 0.001$), progression-free survival time (22.7 months vs 16.1 months; $P = 0.046$), and overall survival time (33.8 months vs 23.2 months; $P = 0.012$). Patients treated with TACE had a trend towards higher overall survival and improved response in islet cell tumors but not carcinoid tumors, but this difference was not statistically significant. Touzios and colleagues performed TACE with cisplatin, doxorubicin, and mitomycin C. The median survival time and 5-year survival rate were 50 months and 50%, respectively. Ruutiainen and associates performed TACE with cisplatin, doxorubicin, mitomycin, iodized oil, and PVA. The 1-year, 3-year, and 5-year survival rates were 86%, 67%, and 50%, respectively. Most recently, Vogl and associates (n = 15) compared two separate chemoembolization protocols, one with mitomycin C alone and the other with mitomycin C and gemcitabine. Their results showed that the combined mitomycin C and gemcitabine had significantly better 5-year and overall survival rates as compared with the mitomycin C alone (5-year survival rate, 46.67% vs 11.11%; overall survival time, 57.1 months vs 38.67 months).

Renal Cell Carcinoma

Renal cell carcinoma rarely is metastatic to the liver. However, its metastases are extremely vascular, making it an ideal candidate for intraarterial locoregional therapy. In a study performed by Nabil and colleagues in 2008, 22 patients were treated with TACE (either mitomycin C alone or mitomycin C with gemcitabine). Imaging showed a partial response in 13.7%, stable disease in 59%, and progression in 27.3%. Median survival times from diagnosis and from TACE were 68.6 months and 8.2 months, respectively. One-year and 2-year survival rates were 31% and 6%, respectively. Although these survival results are less than those achieved with surgery, those patients treated in this study had significantly more advanced disease as compared with those with surgical resection.

Breast Carcinoma

Distant metastases occur in approximately 6% to 7 % of all patients with breast carcinoma. The 5-year survival rate in these patients with stage IV disease is 10% to 18%. Of these patients (stage IV), 3% to 12% have metastases limited to the liver. In a study performed by Giroux and colleagues, eight patients with metastatic breast cancer were treated with TACE. On imaging, five patients had a partial response, one had stable disease, and two had disease progression. All patients died within 13 months after receiving the treatment, with a mean of 49 months from primary diagnosis.

Abdominal Sarcomas

Approximately 64% to 70% of abdominal sarcomas metastasize to the liver. Once the sarcoma metastasizes to the liver, there is a median survival time of 14 months in those patients who receive supportive care only. In a study published by Rajan and associates, 16 patients with a variety of gastrointestinal sarcomas were treated. Postprocedure imaging showed 2 patients had a partial response, 11 patients had stable disease, and 3 had progression. Survival rate from diagnosis was 81% at 1 year, 54% at 2 years, and 40% at 3 years. Median survival time was 20 months.

CONTRAINDICATIONS TO TRANSARTERIAL CHEMOEMBOLIZATION

Although there are no absolute contraindications to the TACE procedure, relative contraindications can be identified based on the exclusion criteria in most clinical trials: advanced liver disease (Child-Pugh classification C or above), active gastrointestinal bleeding, biliary obstruction, encephalopathy, refractory ascites, vascular invasion or portal vein invasion from tumor, extrahepatic metastases, portosystemic shunts, contraindication to arterial intervention (INR >1.8, platelets <50,000, creatinine >1.5), and poor performance status (ECOG >2).

In the case of biliary obstruction, care must be taken to avoid biliary necrosis of the obstructed segments, which could result in abscess formation. In a study by Kim and colleagues, the authors recommend a reduction in the amounts of oil/gelatin sponge particles to reduce the amounts of biliary complications after TACE (bilomas and focal biliary strictures). If a reversible cause is found for the biliary obstruction, a percutaneous biliary tube should be inserted before TACE. In addition, prior biliary reconstructive surgery has been identified as an independent risk factor for the formation of abscesses after TACE.

In regards to portal vein thrombosis, numerous studies have shown that TACE is safe in these patients. In a study by Pentecost and associates, nine patients with portal vein thrombosis underwent transarterial chemoembolization. In these patients, eight patients responded to treatment. No patient had development of hepatic infarction or insufficiency as a consequence of the procedure. A larger study was performed by Georgiades and colleagues in which 32 consecutive patients with portal vein thrombosis were treated with TACE. In these patients, the median overall survival time was 9.5 months. The 30-day mortality rate was 0, and there was no TACE-related hepatic infarction or acute liver failure. The 6-month, 9-month, 12-month, and 18-month survival rates were 60%, 47%, 25%, and 12.5%, respectively. The authors concluded that portal venous thrombosis should not be considered a contraindication to TACE.

Kothary and associates performed a study in which 52 patients underwent high-risk procedures. All patients had an elevated serum bilirubin values, 76.9% of patients had serum albumin levels less than 3.5 mg/dL, and 25% of the patients had portal vein invasion. Greater than 50% had a Child-Pugh score of 9 or greater. Although patients with multifocal disease and lobar invasion had significantly higher mortality rates, the 1-year and 2 year survival rates were 67.9% and 37.7%, respectively. The authors concluded that patients at high risk did not have a higher rate of mortality as a consequence of the procedure.

COMPLICATIONS

The most common complication after TACE is the postembolization syndrome (PES). It happens in approximately 2% to 7% of patients after the procedure. Symptoms of PES include abdominal pain, nausea, vomiting, and mild fevers. In a study performed by Leung and associates, the two factors associated with an increased risk of PES were gallbladder embolization and total chemoembolization dose administered. They also found that previous embolization was associated with a decreased risk of PES. Patel and colleagues performed a study where they showed that no patient factors (age, laboratory values) or bland versus chemoembolization were associated with a higher risk of PES. The treatment of PES is supportive care only.

The most important and serious consequence of TACE is hepatic insufficiency or failure. Chan and associates found that acute hepatic decompensation occurred in 20% of all patients treated with TACE,

with 3% of cases irreversible. Patient factors associated with a higher rate of hepatic decompensation included: dose of cisplatin used, baseline bilirubin level, baseline prothrombin time, baseline aminotransferase (AST) level, and stage of cirrhosis.

Rarer (but equally as serious) complications of TACE include cerebral lipiodol embolism and pulmonary embolism or infarction. The former (cerebral lipiodol embolism) is caused by an arteriovenous shunt in the liver with either an intracardiac shunt or pulmonary shunt. Five total cases of cerebral lipiodol embolism have been reported in the literature. Pulmonary embolisms or infarctions can occur from an arteriovenous shunt occurring in the liver. A study by Chung and colleagues showed the incidence of pulmonary complications increase as the dose of lipiodol increases.

DRUG-ELUTING BEADS

The use of drug-eluting beads (DEBs) or microspheres signaled a new frontier in interventional oncology. This agent, which incorporates the chemotherapeutic agent on a microsphere, has a dual function: the capability to slowly release chemotherapy in a controlled fashion over time and embolization of the treated artery. The two types of drug-eluting microspheres are DC bead microspheres (Biocompatibles, Farnham, Surrey, United Kingdom) and Quadrasphere microspheres (Biosphere Medical Inc, Rockland, Mass). Much more data have been gathered regarding DC beads as compared with Quadrasphere; as a result, only DC beads are discussed here. The DC beads are derivatives of polyvinyl hydrogel and received European Conformity (CE) mark approval in 2003 for malignant hypervascular tumors. The DC beads are most commonly loaded with doxorubicin and are typically used for the treatment of HCC, cholangiocarcinoma, and neuroendocrine metastases. The beads can also be loaded with irinotecan; this agent is used for treatment of colorectal metastases to the liver.

CURRENT EVIDENCE

The pharmacokinetics of the profile of DEB-TACE is significantly different as compared with that of conventional TACE. The peak drug concentration occurs in both treatments within 5 minutes after injection, but it is significantly lower in the DEB-TACE group (78.97 ± 38.4 ng/mL vs 895.66 ± 653.1 ng/mL; $P = 0.001$). In addition, the variability of the maximal concentration of doxorubicin is considerably higher in the conventional TACE group as compared with the DEB-TACE group. In addition, the total systemic dose of doxorubicin of TACE is also significantly higher as compared with DEB-TACE. This improved pharmacokinetic profile of DEB-TACE allows more selective dose delivery to the tumor and a reduction of systemic toxicity.

One of the first studies to ascertain the effectiveness and safety of DC beads for unresectable HCC was performed by Malagari and associates. In this open-label study of 62 patients with unresectable HCC, mean tumor diameter was 5.6 cm and all patients were either at Okuda stage I or II. On the basis of imaging, after 9 months of treatment, a complete response was seen in 12.2% of patients, a partial response in 80.7%, progression of disease in 6.8%, and stable disease in 12.2%. Alpha-fetoprotein levels showed a mean decrease of 1123 ng/mL after the first session. Severe postprocedure complications were seen in two patients: one had cholecystitis, and one had a liver abscess. Similar results were obtained in a study performed by Reyes and colleagues. In this study, 20 patients had doxorubicin-eluting beads TACE (DEB-TACE). On 1-month imaging, according to European Association for the Study of Liver Criteria (EASL), 12 patients had objective tumor response and 8 had stable disease. No patients had a progression of disease during treatment. Overall survival rates at 1 year and 2 years were 65% and 55%, respectively. Median overall survival time was 26 months.

In a prospective randomized trial comparing DEB-TACE with bland embolization, 41 patients were assigned to the DEB-TACE group, and 43 patients were assigned to the bland embolization group. Tumor response was evaluated with the EASL criteria and alpha-fetoprotein levels. The results showed that the recurrence rate was higher at 9 months with the bland embolization group as compared with the DEB-TACE group. There was also a longer time to progression (TTP) for the DEB-TACE group (42.4 ± 9.5 vs 36.2 ± 9.0 weeks; $P = 0.008$).

The Precision V trial is the only prospective randomized trial comparing the doxorubicin-eluting bead embolization (DEB-TACE) and conventional chemoembolization (administration of doxorubicin-oil emulsion followed by conventional TACE). In this study, there were 212 total patients, 102 in the DC-bead group and 110 in the conventional TACE (cTACE) group. All cases were Child-Pugh A/B and unresectable; the patients were randomized according to Child-Pugh status, performance status, extent of disease, and prior treatment. The primary endpoint was EASL (MRI criteria) 6 months after treatment. A trend towards improved EASL criteria was found in the DEB-TACE group, although this was not significant (DEB-TACE vs cTACE, respectively: complete response, 27% vs 22%; objective response, 52% vs 44%; disease control, 63% vs 52%; $P = 0.11$). A more sick subgroup analysis (Child-Pugh B, ECOG 1, bilobar disease) showed a significant increase in objective response in the DEB-TACE group versus cTACE ($P = 0.038$). Equally as important, the DEB-TACE group had reduced amounts of serious liver toxicity ($P < 0.001$) and significantly lower rate of doxorubicin-related side effects ($P = 0.0001$). The authors concluded that DEB-TACE is a safe procedure, with a better side-effect profile compared with conventional TACE, and is beneficial to patients with more advanced disease.

Many smaller trials have described the use of drug-eluting beads for metastatic liver disease, including primaries from colorectal cancer, neuroendocrine, and cholangiocarcinoma. A few promising trials have described the use of irinotecan-eluting beads for metastatic colorectal carcinoma.

In one study, 55 patients underwent 99 treatments with irinotecan drug-eluting beads. The median disease-free and overall survival time from the time of first treatment was 247 days and 343 days, respectively. A small trial with 11 patients performed by Aliberti and associates described preliminary results from treatment of intrahepatic cholangiocarcinoma with DEB-TACE. They reported a median survival of 13 months and 100% Response Evaluation Criteria in Solid Tumors (RECIST) response from DC-bead treatment.

Drug-eluting beads do carry the risk of complications, however. A recent study by Bhagat and colleagues showed that 7 of 13 patients had bilomas develop after DEB-TACE for neuroendocrine metastases (Figure 2). This rate of biloma formation was higher than previously reported. In the case of metastatic disease, there is a higher chance of biliary necrosis and biloma formation because of a less resilient biliary plexus as compared with those patients with cirrhosis (and HCC).

Portal Hypertension: The Role of Shunting Procedures

Elaine Y. Cheng, MD, Jonathan R. Hiatt, MD, and Ronald W. Busuttil, MD, PhD

Portal hypertension is a clinical syndrome defined by portal venous pressure that exceeds 5 to 10 mm Hg. The various etiologies of portal hypertension can be classified as prehepatic, intrahepatic, or posthepatic (Table 1). Of these, cirrhosis is the most common cause of portal hypertension in the United States, accounting for about 90% of cases.

Variceal hemorrhage is one of the most clinically significant manifestations of portal hypertension, with substantial morbidity and mortality. Varices are low-resistance venous collaterals formed from preexisting vascular channels dilated by portal hypertension. These collateral portosystemic channels arise at sites where portal and systemic veins normally meet (Table 2).

Gastroesophageal varices are present in approximately 50% of patients with cirrhosis; the incidence rate increases with the severity of liver disease. Variceal hemorrhage occurs at an annual rate of 5% to 15%, with size of the varices as the most important predictor of hemorrhage. The mortality rate for each episode of variceal bleeding approaches 20%, which underscores the importance of rapid and aggressive initial management and prevention of recurrent bleeding.

MANAGEMENT OF ACUTE VARICEAL HEMORRHAGE

An algorithm for management of patients with acute variceal bleeding is shown in Figure 1. These patients should be admitted to an intensive care unit for monitoring, resuscitation, and definitive treatment. Endotracheal intubation is often needed for airway protection, particularly during endoscopy and other procedures. Large-bore venous access should be secured, with rapid initiation of blood volume replacement. Packed red blood cells are transfused to a target hematocrit level of 25% to 30%; overtransfusion exacerbates portal hypertension and can increase the severity of bleeding. Coagulopathy is corrected with transfusion of fresh frozen plasma and platelets.

Patients with cirrhosis are at increased risk for infection as a result of impaired host defenses, particularly during or immediately after a major episode of gastrointestinal hemorrhage. Spontaneous bacterial peritonitis represents approximately half of these infections, with urinary tract infections and pneumonia comprising the remainder. Short-term antibiotic prophylaxis, usually with a third-generation cephalosporin, should be used routinely. The use of prophylactic antibiotics has been shown to reduce the risk both for rebleeding and for mortality in patients with acute variceal bleeding.
